Handbook of Systematic Musicology

Bader
Editor

Springer

Springer Handbook of Systematic Musicology

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook

Preface

Systematic Musicology is a field that grew tremendously over the last decades to such an extent and into so many topics, that for quite some time researchers as well as students in the field have been demanding a comprehensive overview of the different parts of the discipline. As the field of Systematic Musicology is so wide, there is a need for introductions, reviews, teaching materials, and the display of recent trends for researchers in related fields who want to connect and interact within this highly interdisciplinary area. Therefore, the *International Working Group of Systematic and Comparative Musicology* decided to compile such a volume, covering the major areas of research in Systematic Musicology, and making them easily accessible to the community. This volume tries to present the state-of-the-art in the field while also giving an overview of basic and fundamental methodologies and terminologies. It also discusses recent trends and topics and therefore hopefully is also inspiring in terms of an interchange of ideas and subjects.

Systematic Musicology is a highly interdisciplinary field, which it has been ever since its ancient origins with philosophers like Pythagoras, Archytas of Tarrent, or Aristoxenos. Here the connection between music, mathematics, geometry, astronomy, well-being, politics, and other fields were discussed. Much attention was given to music theory, especially tonal systems or rhythm theory. Ancient writings of music theory, like the Indian *Natyashastra* on music and the arts, or the music theory embedded in the ancient Tamil epic *Cilappatikāram* of today's Sri Lanka show complex tonal system theories. The Chinese *Yueji* from 1st and 2nd century BC is not only a music theory, but also discusses aspects of nature and the social role of music. In all these traditions musicology, concerned with all aspects of music, continued to the present day in many forms.

In modern times the roots of Systematic Musicology lie in Comparative Musicology, which tries to determine laws and universals by comparing the musical traditions of the world. This was only possible from around 1900 after the invention of the Edison phonograph, which made it possible for the first time to record and playback music on wax cylinders. Following the systematic approach, right from the start the Hornbostel/Sachs classification of musical instruments used a taxonomy based on the acoustical and mechanical driving mechanisms of musical instruments, i. e., plucked, bowed, blown, etc. The Berlin phonogram archive, recording music from around the world on wax cylinders, started with a recording of a Thai *phi pha* orchestra in the Berlin *Tiergarten* in 1900. Jaap Kunst was among the first to collect recordings in today's Indonesia in the 1920s and 1930s developing Ethnomusicology on his many fieldtrips. In the US, Charles Seeger was co-founder of the Society of Comparative Musicology and Frances Desmond was collecting the music mainly of native Dakota Indians.

Carl Stumpf was among the first to introduce music psychology in modern terms, by discussing how a pitch sensation can appear from a multisensory input of many frequencies entering the ear. A distinct influence on these early findings came from Gestalt psychologists, who indeed first used musical melodies to derive their Gestalt laws. Early experiments on musical timbre were performed again by Stumpf and others, especially focusing on music and speech as well as on musical transients and tone color.

Many problems of music psychology, like the problem of tonal fusion addressed by Stumpf, were based on the experimental evidence that sounds consists of overtones, which was published by Hermann von Helmholtz in 1863. The growing field of electronic music enhanced research in these fields in the Bell labs in the US or in the Heinrich-Hertz Institute for vibration of Karl Willy Wagner in Berlin, where also Barkhausen was working on tubes and on the light bow for building a loudspeaker and microphone in one device. Research on musical instruments was prominently performed by Felix Savart around 1800, especially on violins, building a trapezoid-shaped violin body or an *octobass* ranging over two floors. Also around this time Friedrich Chladni was discovering longitudinal waves and building musical instruments with this invention, the *clavicylinder* and the *euphonium*, and wrote the first comprehensive work on vibrating musical systems.

All these and many more early works building up the field of Systematic Musicology were followed by a tremendous increase in the number of works after WWII. Today, the topics discussed in Systematic Musicology range from Musical Acoustics and Musical Signal Processing, Music Psychology and Neuromusicology, Music Ethnology and Comparative Musicology, Musical Syntax and Philosophy to Musical Applications in modern music production and distribution,

alongside many related topics. The aim of the discipline is still to understand music, its production and perception, its cultural, historical and philosophical background in a systematic way. This cannot be done by discussing one aspect alone. So, for example, the development of musical instruments is shaped not only by tradition, but by acoustical, physiological and psychological constraints, the needs of different compositional styles, to be technically state-of-the-art, or by political and economic demands. Therefore, Systematic Musicology needs to consider all aspects of music so as to aim for a system of music, the *Kunst* (art) in the Renaissance or Baroque sense of a system of rules, as J.S. Bach used the term in his *Die Kunst der Fuge* (The art of the fugue). This late work by Bach concerned displaying the rules and possibilities that lie within the polyphonic system of fugue composition.

So Systematic Musicology believes that understanding music can only truly be achieved by considering all aspects of music. The Handbook tries to reflect this interdisciplinary nature of Systematic Musicology in seven sections. These sections follow the main topics in the field, Musical Acoustics, Music Psychology, and Music Ethnology while also taking recent research trends into consideration, such as Embodied Music Cognition and Media Applications. Other topics, like Music Theory or Philosophy of Music are also discussed. Of course, they could also have been presented as sections in their own right, taking their salience into account. These topics are incorporated within one of the main sections under recent developments in the field. This may, however, be subject to respective developments over the next decades.

Part A, edited by Rolf Bader, presents an overview of the state-of-the-art of research in *Musical Acoustics*. After an introduction to basic models, mathematical frameworks and formulas, the section discusses materials for musical instruments as well as modern measurement techniques used in the field. Then, the main instrument families are discussed, string and wind instruments, organs and percussion instruments, in terms of their basic properties as well as special features. A discussion on nonlinearities and synchronization in musical instruments tries to give a global framework for instrument families. Finally, modern Room Acoustics is discussed, both in terms of general findings as well as modeling techniques.

In Part B, edited by Jonas Braasch, modern *Musical Signal Processing* is discussed. Again the section starts with the fundamentals of modern music recording studio equipment and methods, digital audio processing using delay lines and waveguides, and an introduction to Fourier and convolution methods. It then turns to sound source separation and state-of-the-art automatic musical score extraction and adaptive music control. Modern synthesis methods are discussed in terms of multichannel audio reproduction systems using wavefield synthesis, physical modeling using Finite-Difference methods (FDM), as well as hardware implementation of FDM with highly parallel processing Field-Programmable Gate Array (FPGA) hardware.

Part C, edited by Stefan Koelsch, turns to *Music Psychology*, addressing many aspects of music perception and associated musical parameters. It starts with a review of music time perception, which is a basic issue of an art form developing in time. This leads to the topic of the dependency of sensual information stored in memory, both short- and long-term memory processing and auditory working memory. Here many findings from brain research using EEG, fMRI, MEG, or related techniques are reported and discussed. On a higher level musical syntax needs to be understood, both in terms of music theory often based on syntax rules found in speech and its relations to music, as well as in terms of experimental findings again using brain research techniques. Following on from brain research findings, rhythm and beat perception are discussed, as well as the relation between music perception and active music production. Finally, music and emotion are discussed in terms of their relation to sensory data.

Part D, edited by Albrecht Schneider, is devoted to *Psychoacoustics*, its fundamentals, history, methods, and findings. The philosophical background of sensation as found in ancient as well as Renaissance and Baroque times is discussed and basic models of perception and psychophysics are presented. Thereafter, pitch and pitch perception is addressed, with basic parameters like virtual or residue pitch, tonal fusion, scales, or intonation. The auditory pathway is presented from the cochlea up to the auditory cortex. Then timbre and sound color are discussed in terms of their notion as well as their use in musical instrument organology, both of acoustic as well as electronic music, together with the relatedness of pitch and timbre and its use for audio segregation. Finally, loudness is treated as a psychological sensation related to physical sound pressure level, and different loudness models are presented and discussed in modern disco and club performance scenarios.

Part E, edited by Marc Leman, presents the emerging field of *Embodied Music Cognition*. After an introduction presenting ontological and epistemological foundations, the method is applied to musical parameters like timing, expressiveness, or expectation. The role of musical gestures are discussed and new trends and questions are addressed. The ideas are then transferred to compositional ideas using sonic objects as basic compositional units of timbre in terms of analysis

and synthesis. Music therapy is also subject to embodiment applications, where the relation between rhythm perception and body coordination is shown to improve well-being and the health of patients. Finally, the interaction of musicians and listeners using sensors and other techniques is treated, both in terms of basic frameworks as well as technical issues concerning sensors and their applications.

Part F, edited by Isabel Barbancho, concentrates on the application side within the *Modern Media Application* domain of music production and reproduction in terms of Music Information Retrieval (MIR). One aim is to extract musical features from audio files and use them for content analysis, song suggestions, or further analysis. Problems of data mining, automatic analysis, or visualizations are discussed on a technical level. Advanced hearing aids are also a subject of music applications, especially as normal hearing aids only have poor abilities to reproduce music. Modern tools and ideas help to enhance music perception through hearing aids. Applications of MRI also improve music education and education as a whole, and this is discussed in general as well as in a case study. Embedding music in a media structure is another recent challenge, as users expect highly automatic guidance and help tools, as well as many additional features besides the auditory stream. Changes in music production and perception due to modern media are a recent issue discussed along with their development over the last decades. Applications to music ethnology are treated in the domain of Computational Ethnomusicology, detecting high-level features of non-Western music styles through MIR. Also composition is due to automatization, especially voice but also for other instruments. Modern instrument building uses sensors or additional components to enhance musical instrument features, also addressing a world music approach.

The final Part G, edited by Rolf Bader, discusses problems in modern *Ethnomusicology* along with some examples of musical styles from around the world. It begins with two papers introducing the history of the discipline focusing on the relation between Systematic Musicology and Ethnomusicology, as well as discussing modern Analytical Ethnomusicology, focusing on musical features, instruments, and compositions rather than extramusical features like social or economic issues. Displaying relations between a wide range of musical styles, a systematic overview of the music of Africa is presented. As an example of the relationship between musical diversity and relatedness, the music of Southeast Asian minorities are addressed. Many musical features, like the origin of music or its historical development are often discussed in analogy with the music of the stone age, therefore an overview of music archaeology is given. As improvisation is a common feature of many musical styles around the world, a framework, as well as problems and discussions on free improvisation are also present. Finally, music and its relation to politics is presented with the history of protest songs in the postwar US.

We hope that the Handbook is not only of use to students in the discipline but also to advanced scholars and people working outside the field that are interested in an overview of Systematic Musicology, its recent developments, findings, and problems. Of course not all issues, problems, and topics of modern Systematic Musicology may be addressed in a single Handbook, especially not for a field that is in its own right so interdisciplinary. Still, it is our hope that researchers from other fields may be inspired by the topics and problems found in this Handbook and may enlarge their views in a truly interdisciplinary way.

Hamburg, January 2018
Rolf Bader

About the Editor

Rolf Bader is Professor for Systematic Musicology at the Institute of Systematic Musicology, University of Hamburg, Germany. He studied Systematic Musicology, Physics, Ethnology, and Historic Musicology at the University of Hamburg where he obtained his PhD and Habilitation on topics of Musical Acoustics, Music Psychology, and Musical Signal Processing. He was a visiting scholar at the Center for Computer Music and Research (CCRMA) at Stanford University (2005-2006). His major fields of research are musical acoustics and musical signal processing, musical hardware and software development, music psychology and neurocognition, music ethnology, and philosophy of music.

He is co-editor of the Springer series *Current Research in Systematic Musicology* and published several books here as an author, like *Nonlinearities and Synchronization in Musical Acoustics and Music Psychology* or *Computational Mechanics of the Classical Guitar*, or as an editor like *Sound – Perception – Performance* or *Concepts, Experiments, and Fieldwork: Studies in Systematic Musicology*, alongside many contributing book chapters or peer-reviewed papers.

He has conducted fieldwork as an Ethnomusicologist in Bali, Nepal, Thailand, Cambodia, Myanmar, Sri Lanka, China, and India since 1999. He has also worked as a professional musician, composer, artist, running recording studios, as a music journalist, leading exhibitions, and running a cinema.

Part D Psychophysics/Psychoacoustics

Part E Music Embodiment

Part F Music and Media

List of Abbreviations

k-NN	*k*-nearest-neighbor
1-D	one-dimensional
1C	one's complement
2-D	two-dimensional
2C	two's complement
3-D	three-dimensional

A

A/D	analog-to-digital
A1	primary auditory cortex
AAF	anterior auditory field
AAF	advanced authoring format
ABR	auditory brainstem response
AC	autocorrelation
ACC	anterior cingulate cortex
ACE	acoustic conversion efficiency
ACF	autocorrelation function
AD	Alzheimer disease
ADC	analog-to-digital converter
ADM	adaptive delta modulation
ADPCM	adaptive differential pulse code modulation
ADSR	attack, decay, sustain, release
ADU	analog-to-digital unit
AEP	auditory evoked potential
AF	auditory filter
AI	active intensity
AI	artificial intelligence
AIFF	audio interchange file format
aKE	affected KE family (FOXP2 mutation)
ALM	adaptive logic module
AM	amplitude modulation
AN	auditory nerve
ANN	artificial neural network
AoIP	audio over IP
AoM	area of motion
AP	absolute pitch
APS	artifact-related perceptual score
AR	autoregressive
ARMA	autoregressive moving average
ARQ	automatic repeat request
ASBF	structured audio sample bank format
ASCII	American standard code for information interchange
ASIC	application-specific integrated circuit
ASSP	application-specific standard part
ASW	apparent source width
ATN	augmented transition network
AuP	auditory pathway
AVI	audio video interleaved
AWB	audio workbench

B

BA44	Brodmann area 44
BBS	Baseler Befindlichkeits-Skala
BC	boundary condition
BD	book-dependent
BEM	boundary element method
BER	bit error rate
BF	best frequency
BHAD	blind harmonic adaptive decomposition
BI	book-independent
BIAS	brass instrument analysis system
BLAS	basic linear algebra subprograms
BM	basilar membrane
BMF	best modulation frequency
BOLD	blood-oxygen-level-dependent
BPM	beats per minute
BRAM	block RAM
BRECVEMA	brain stem reflex, rhythmic entrainment, evaluative conditioning, contagion, visual imagery, episodic memory, musical expectancy, and aesthetic judgment
BS	beam splitter
BWF	broadcast wave format

C

CAD	computer-aided design
CAM	common amplitude modulation
CAP	central auditory processing
CB	critical band
CC	corpus callosum
CCD	charge-coupled device
CCF	cross-correlation function
CD	compact disc
CE	computational ethnomusicology
CF	characteristic frequency
CFL	Courant–Friedrichs–Levy
CGM	corpus geniculatum mediale/medial geniculate body
CI	cochlear implant
CLB	configurable logic block
CM	comparative musicology
CMR	comodulation masking release
CN	cochlear nucleus
CNS	central nervous system
codec	coder-decoder
CoM	centroid of motion
CP	cochlear partition
CPS	closure positive shift
cps	cycles per second
CPU	central processing unit
CR	critical ratio
CT	corpus trapezoideum

CT	center time
CTF	cochlear transfer function
CV	computer vision
CWMN	common Western music notation

D

DA	distribution amplifier
DAC	digital-to-analog converter
DARMS	digital alternative representation of music scores
DASH	digital audio stationary head
DAT	digital audio tape
DAW	digital audio workstation
DBN	dynamic Bayesian network
DCC	digital compact casette
DCN	nucleus cochlearis dorsalis
DCT	discrete cosine transformation
DDR	double data rate
DE	differential evolution
DES	differential emotions scale
DESPI	decorrelated electronic speckle pattern interferometry
DFT	discrete Fourier transformation
DirAC	directional audio coding
DIY	do-it-yourself
DL	difference limen
DM	delta modulation
DMIF	delivery multimedia integration framework
DML	distributed-mode loudspeakers
DOP	data-oriented parsing
DPCM	differential pulse code modulation
DPOAE	distortion product otoacoustic emission
DRM	digital rights management
DSP	digital signal processing
DTS	digital theatre system
DTT	distorted tunes test
DTW	dynamic time warping
DVB	digital video broadcast

E

EAN	early anterior negativity
ECG	electrocardiogram
EDT	early decay time
EEG	electroencephalogram/ electroencephalography
EEPROM	electrically erasable programmable read-only memory
EKF	extended Kalman filter
ELAN	early left anterior negativity
EMG	electromyogram
EMI	electromagnetic interference
EMI	experiments in musical intelligence
EPROM	erasable programmable read-only memory
ERAN	early right anterior negativity
ERB	equivalent rectangular bandwidth
ERF	event-related field
ERN	error-related negativity
EROSS	easily removable, wireless optical sensor system
ERP	event-related potential
EsAC	Essen associative code
ESM	experience sampling method
ESPI	electronic speckle pattern interferometry
ET	equal temperament

F

FA	factor analysis
FD	finite difference
FDDI	fiber-distributed digital interface
FDM	finite-difference method
FDTD	finite-difference time domain
FEC	forward-error correction
FEM	finite element method
FFR	frequency-following response
FFT	fast Fourier transform
FFTW	fastest Fourier transform in the West
FHT	fast Hadamard transformation
FIFO	first in/first out
FIR	finite impulse response
FLAC	free lossless audio codec
FM	frequency modulation
FMC	FPGA mezzanine card
fMRI	functional magnetic resonance imaging
FPGA	field programmable gate array
FRF	frequency response function
FSM	finite-state machine
FSR	force-sensing resistor
FT	Fourier transform
FTC	frequency-threshold curve
FTD	frontotemporal degeneration
FTP	file transfer protocol
FTT	Fourier time transformation
FWHM	full width at half maximum

G

GDIF	gesture description interchange file format
GEMS	Geneva emotional music scale
GKSO	Gustafsson Kreiss Sundstrom Osher
GME	middle-ear pressure gain
GMS	gesture motion signal
GOFAI	good, old-fashioned artificial intelligence
GPGPU	general purpose graphics processing unit
GPL	general public license
GSR	galvanic skin response
GTTM	generative theory of tonal music
GUI	graphical user interface

H

HCI	human–computer interaction
HDL	hardware description language

HDMI	high-definition multimedia interface
HLS	high-level synthesis
HMM	hidden Markov model
HMN	human mirror neuron
HNR	harmonic-to-noise ratio
HOA	higher-order ambisonics
HPC	high-performance computing
HRIR	head-related impulse response
HRTF	head-related transfer function
HRV	heart rate variability
HT	half tone
HTML	hyper-text markup language

I

I/O	input/output
I2S	inter-IC sound
IC	inferior colliculus
IC	information content
ICA	independent component analysis
ICC	central nucleus of the inferior colliculus
IF	instantaneous frequency
IFF	interchange file format
IHC	inner hair cell
IID	interaural intensity difference
IIR	infinite impulse response
IL	interface layer
ILD	interaural level difference
IM AF	interactive music application format
IMUTUS	interactive music tuition system
INA	Ideale Nierenanordnung
IOI	interonset interval
IP	intellectual property
IP	internet protocol
IPF	impulse pattern formulation
IPL	inferior parietal lobule
IPS	intraparietal sulcus
IPS	interference-related perceptual score
ISA	independent subspace analysis
ISI	interstimulus interval
ISIH	interspike interval histogram
ISO-BMFF	ISO based media file format
ISRC	international standard recording code
ISS	informed source separation
ITD	interaural time difference

J

JI	just intonation
JND	just-noticeable difference

K

K–H	Kirchhoff–Helmholtz
KdRV	Critique of Pure Reason
KF	Kalman filter
KL	Kullback–Leiber divergence
KOPRA-M	Entwicklung und empirische Validierung eines Modells musikpraktischer Kompetenzen

L

LA	line array
LAN	left anterior negativity
LDV	laser Doppler vibrometry
LEV	listener envelopment
LF	lateral energy fraction
LFE	low-frequency effect
LHA	latent harmonic allocation
LMA	Laban movement analysis
LP	linear prediction
LPC	late positive component
LTAS	long-term average spectrum
LTI	linear time-invariant
LTM	long-term memory
LUT	look-up table

M

MAC	medium access frames
MAC	multiply-and-accumulate
MADI	multichannel audio digital interface
MAP	multiactuator panel
MAP	maximum a posteriori
MCML	motion capture markup language
MDL	minimum description length
MDS	multidimensional scaling
MEG	magnetoencephalography
MEMS	micro-electric mechanical system
MEP	motor evoked potential
MF	missing fundamental
MFCC	Mel-frequency cepstral coefficient
mid-DLPFC	mid-dorsolateral prefrontal cortex
MIDI	musical instrument digital interface
MIR	music information retrieval
MIS	University of Iowa musical instrument samples
MKSA	meter, kilogramm, second, ampere
MLP	multilayer perceptron
MLS	maximum length sequence
MMN	mismatch negativity
MMNm	magnetic mismatch negativity
MMSE	mini-mental state examination
MMSE	minimum mean square error
MOP	maximal outerplanar graph
MoR	model routing layer
MPE	multipitch estimation
MPM	music paint machine
MPML	multimodal presentation markup language
MPO	maximum power output
MPT	music perception test
MRI	magnetic resonance imaging
MSD	mass-spring-damper
MTL	medial temporal lobe

MusicXML	music extensible markup language
MXF	material exchange format

N

NAH	near-field acoustic holography
NB	naive Bayes
NCD	normalized compression distance
NFS	network file system
NICA	nonnegative independent component analysis
NIFF	notation interchange file format
NIME	new interfaces for musical expression
NLL	N. Lemniscus lateralis
NMF	nonnegative matrix factorization
NN	neural network
NONCE	novel, optionally novel, nondeterministic process, constraint, existing element
NTF	nonnegative tensor factorization
NTT	number theoretic transform

O

OAE	otoacoustic emission
OCB	olivocochlear bundle
OCR	optical character recognition
OCT	optimized cardioid triangle
ODD	one document does it all
ODS	operating deflection shape
OHC	outer hair cell
OHCI	open host controller interface
OI	optical imaging
OMF	open media framework interchange
OMR	optical music recognition
OPS	overall perceptual score
OPSI	optimized phantom source imaging
OSC	open sound control
OSI	open standard interconnection
OSPL90	output sound pressure level with 90 dB SPL input
OW	oval window

P

PA	public address
PAF	posterior auditory field
PANAS	positive and negative affect scale
PC	personal computer
PCA	principal component analysis
PCAP	peristimulus compound action potential
PCIe	peripheral component interconnect express
PCM	pulse code modulation
PCP	pitch class profile
PD	Parkinson's disease
PDE	partial differential equation
PDF	probability density function
PEASS	perceptual evaluation methods for audio source separation
PET	positron emission tomography
pFMC	posterior frontomedial cortex
PLCA	probabilistic latent component analysis
PLD	programmable logic device
PM	phase modulated
PMC	premotor cortex
PML	performance markup language
POF	polymer optical fiber
POMS	profile of mood states
PP	planum polare
PPM	peak program meter
PROMS	programmable read-only memory
PSA	prior subspace analysis
PST	poststimulus time
PT	planum temporale
PTC	psychophysical tuning curve

Q

QEF	quasi-error-free
QoL	quality of life
QoM	quantity of motion
QoS	quality of service

R

R	referent
RA	radiatio acustica
RAAM	recursive auto-associative memory
RAM	random access memory
RANN	recurrent artificial neural network
RBM	restricted Boltzmann machine
RCD	radial convergence diagram
REPET	repeating pattern extraction technique
RESTFT	recursive exponential short-time Fourier transform
RI	reactive intensity
RIFF	resource interchange file format
RMS	root mean square
RP	relative pitch
RPCA	robust principal component analysis
RSSM	rhythm self-similarity matrix
RSV	reserved
RTCP	real-time transport control protocol
RTL	register transfer level
RTP	real-time protocol

S

SACD	super audio CD
SAM	self-assessment manikin
SAM	speckle-averaging mechanism
SAOL	structured audio orchestra language
SATA	serial advanced technology attachment
SBR	spectral band replication
SCR	skin conductance response
SD	standard deviation
SD	semantic dementia
SDI	serial digital interface

SDIF	sound description interchange format
SDM	sigma-delta modulation
SDS	sample dump standard
SF	spectral flux
SFS	sound field synthesis
SHS	subharmonic pitch summation
SI-PLCA	shift-invariant probabilistic latent component analysis
SM	systematic musicology
SMA	supplementary motor area
SMG	supramarginal gyrus
SMO	sequential minimal optimization
SMS	sensorimotor synchronization
SMS	spectral modeling synthesis
SMTP	simple mail transfer protocol
SOC	superior olivary complex
SOM	self organizing map
SPI	serial peripheral interface
SPINET	spatial pitch network
SPL	sound pressure level
SPOAE	spontaneous otoacoustic emission
Spt	Sylvian-parietal-temporal
SR	spontaneous rate
SSEP	steady-state-evoked potential
SSM	self-similarity matrix
SSR	state-space representation
SSSPV	stochastic state-space phase vocoder
STFT	short-term Fourier transform/short-time Fourier transform
STG	superior temporal gyrus
STM	short-term memory
SV	Sonic Visualiser
SVM	support vector machine
SVTF	stapes footplate velocity

T

TC	tonal center
TCP	transmission control protocol
TEN	threshold equalizing noise
TEN (HL)	threshold equalizing noise test in dB HL
TEOAE	transient evoked otoacoustic emission
TFLOPS	tera floating point operations per second
THD	total harmonic distortion
TIE	total intonation error
TMACS	tera multiply-and-accumulates per second
TMS	transcranial magnetic stimulation
TOJ	temporal order judgment
TPS	target-related perceptual score
TU	transmission unit

U

ucf	user constraint file
UCL	uncomfortable loudness level
UDC	uniform discrete cepstrum
UDP	user data protocol
UHF	ultra high frequency
USB	universal serial bus

V

VAME	verbal attribute magnitude estimation
VCN	nucleus cochlearis ventralis
VCO	voltage-controlled oscillator
VHDL	very high speed integrated circuit hardware description language
VLPFC	ventrolateral prefrontal cortex
VoIP	voice over IP
VU	volume unit meter

W

WAN	wide-area network
WAV	waveform audio file format
WCLK	word clock
WDF	wave digital filter
WDRC	wide dynamic range compression
WFA	wave field analysis
WFS	wave field synthesis
WM	working memory
WMA	Windows media audio

X

XMF	extensible music format
XML	extensible markup language

1. Systematic Musicology: A Historical Interdisciplinary Perspective

Albrecht Schneider

A brief account of the historical development of systematic musicology as a field of interdisciplinary research is given that spans from Greek antiquity to the present. Selected topics cover the rise of music theory from the Renaissance to modern times, the issue of *harmonic dualism* from Zarlino and Rameau to the 20th century and the controversy about *physicalism* versus *musical logic* in music theory. Sections of this chapter further relate to the notion of a *system* and the concept of *systematic* research (which is exemplified with respect to the work of Chladni, Helmholtz, Stumpf, and Riemann), and to the concept of Gestalt quality that spawned contributions to music perception from Gestalt psychology. In addition, some developments in music psychology outside the Gestalt movement as well as in the sociology of music are sketched, followed by a paragraph on modern research trends, which include semiotic, computational, and linguistic approaches to music perception and cognition as well as contributions from the neurosciences. A final paragraph provides some of the background that led to establishing systematic musicology as an academic discipline around 1870–1910, from where further disciplinary and scientific developments defined the field in the 20th century.

1.1 Systematic Musicology: Discipline and Field of Research

The term systematic musicology denotes a scientific discipline as well as a large and interdisciplinary area of research. While the academic discipline of systematic musicology was established only in the 20th century in universities, research in this field dates back far into history. In this chapter, a brief account of several stages in the historical development of research pertaining to systematic musicology will be given. It goes without saying that, within the frame of a chapter, this account cannot even attempt to cover every relevant fact and person. The focus here is on selected areas where certain problems have either been approached for the first time, or where a theoretical and methodological framework has gained the role of a *paradigm* for some period (as, for example, Gestalt theory or musical semiotics; see below). Moreover, there are problems that tend to resist a *final* solution (which seems a condition typical for science at large [1.1]).

Historical developments for some subfields of systematic musicology have been covered in comprehensive works (such as music theory in the ten vols of the *Geschichte der Musiktheorie* [1.2] and in a concise volume edited by *Christensen* [1.3]). However, there is a host of new concepts and methodologies issued in research related to sound and music production as

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_1

well as to music perception, cognition, and social reception due to developments in electronics, computer and media technology, and also in areas such as the neurosciences. Publications resulting from research efforts in various fields need to be evaluated in regard to theoretical foundations, methodology, and factual outcome (as in this Handbook). *Elschek* [1.4] provides a systematic overview that covers much of the research in musicology and neighboring disciplines from the 19th century to about 1970–80.

1.2 Beginnings of Music Theory in Greek Antiquity

Scholars of Greek antiquity conducted a huge amount of research on the fundamentals of tone systems and scales using an approach that combined mathematical reasoning with observation and measurement (see [1.5] and the collection of sources and commentaries in [1.6, 7]). This scientific effort, which probably had antecedents in Mesopotamia and Egypt (as well as possibly some parallels in early China), usually is traced back to Pythagoras of Samos and his pupils. The so-called Pythagoreans (as Platon addressed them) pursued studies in arithmetic, geometry, astronomy, and music theory (besides, they were interested in philosophical, religious and political issues). Though the works of Philolaus (6th century BCE) and of Archytas of Tarentum (who lived from around 420–355 BCE, see [1.8]) survived only in fragments, their central ideas apparently were known to the music theorist Aristoxenus of Tarentum (4th century BCE, see [1.6]) and were still referred to by scholars of the Hellenistic era like Ptolemy (Klaudios Ptolemaeus) and Nicomachus of Gerasa (as to their works, see [1.6, 7]). Essentials of Pythagorean mathematics and music theory are also found in the writings of Euclid. Of particular interest is Euclid's *Sectio canonis* in which he, among other issues, explains that (pairs of) consonant tones form a *mixture* while dissonant tones lack this quality [1.9]. Also of major interest is that Euclid treats intervals like line segments (several of which can be added up or, conversely, subtracted from each other). While Archytas probably explored pitches with a pan pipe-like instrument, a kanon or monochord apparently was in use as a device for measurements around 300 BCE [1.10].

Greek mathematics and music theory rested on numbers representing both ideal magnitudes and measurable quantities. Ratios of whole numbers in general were used to establish intervals and scales. Pairs of ratios form proportions like $6:8=9:12$ known as a Pythagorean Tetraktys, which contains the intervals of the octave $1/2$, the fifth $2/3$, the fourth $3/4$, and the whole tone $8/9$. Ratios considered as fundamental for harmony could either contain multiples of a basic number like $(2/1, 3/1, 4/1)$, or be formed according to $m+1/m$ (the class of superparticular intervals $3/2, 4/3, 5/4, 6/5, 7/6, 8/7, 9/8, \ldots$). In addition, there were so-called superpartientes (ratios of the form $(n+1+m)/n$ like $5/3$ considered in particular by a range of medieval scholars [1.11, pp. 64–87]). Besides such arithmetic there was also a geometrical approach based on the division of a line or string (or of several such strings arranged in parallel, as Ptolemy confirms) into sections. In this respect, considerations based on ratios of numbers could always be tested empirically by dividing strings so as to sound the basic musical intervals and scales. Plato (Pol. 530 C–531 C, ed. by *Burnet* [1.12]), who opposed empiricism, in fact let Socrates refer to the Pythagoreans as people who torture strings by working on their tension with tuning pegs. Archytas it seems already distinguished between the arithmetic, the geometric and the harmonic division (that can be applied either to an interval defined by numbers or to sectioning a line or string of given length). Though observation was used as a method for scientific investigations, mathematical reasoning among the Pythagoreans was regarded superior for its logical coherence and general applicability.

Since there evidently was music performed in various contexts in Greek societies (as many paintings and engravings demonstrate), the question of course is to what extent fundamental structures described by theorists (such as different divisions of the tetrachords, see Sect. 31.8 of this handbook) were actually found in musical practice. On the one hand, there are indications that theorists like Archytas were familiar also with musical practice [1.8]; on the other, a comprehensive treatise on music theory like the *Elementa harmonica* provided by Aristoxenus of Tarentum (4th century BCE [1.6]) gives many hints that musical practice at his time did not (or perhaps no longer) conform in every respect to norms and models that had been set up mainly by the Pythagorean school. One of the fundamental objections Aristoxenus made is that musical experience based on performance and listening may differ from, or may even contradict, certain models and propositions developed from arithmetic.

Much of classical Greek music theory survived in writings of the Hellenistic period, in particular in the works of Claudius Ptolemaeus and Nicomachus of

Gerasa (both lived in the 2nd century [1.6]). Boethius (around 480–528), who was familiar with a broad range of Greek and Hellenistic writers, condensed their works in his own treatise *De institutione musica* [1.13], which became the most important source for medieval music theory that, for the most part, was still close to Pythagorean tradition [1.11]. In the realm of musica speculativa, scholars throughout the Middle Ages and up to about the 15th century were contemplating correspondences between ratios and proportions of numbers and musical intervals; in addition, various divisions of the monochord were discussed (not just from a theoretical but sometimes from a clearly empirical point of view). An impressive survey of speculative music theory (where speculative has to be taken in the medieval sense) was provided by Jacob of Liège (*Jacobus Leodiensis*, around 1330; see the critical edition [1.14]). Phenomena of polyphonic music such as the organum were treated in writings on music theory as early as the *musica enchiriadis* (9th century).

1.3 From the Middle Ages to the Renaissance and Beyond: Developments in Music Theory and Growth of Empiricism

While much of medieval music theory reflects its Pythagorean origin and background, issues relevant to musical practice and organology gained increasing importance. One area where a transition from basically mathematical to empirically validated approaches can be shown is the mensuration of organ pipes [1.15, 16]; another is music theory itself where more *practical* views on musical syntax were included along with the time-honored considerations of consonance based on small integer ratios [1.17]. By the end of the 15th century, treatises on musica practica appear besides musica theorica. Within the domain of theory, where traditionally tone systems, scales and modes had been elaborated, an expansion of topics as well as a discussion adapted to developments in contemporary musical practice is observed (for a detailed account [1.18]). For example, expansion of the hexachord system as well as of the traditional modes (as in Glarean's *Dodecachordon* of 1547) should be mentioned. At about the same time, one had to provide tunings for keyboards and fretted instruments suited to performing music in acceptable temperaments (such as 1/4-comma meantone or similar tunings [1.19–21]). *Schlick* [1.22, Chap. 8] discusses how to tune an organ where the fifths have to be narrowed a little bit so as to get rid of the comma. Tempering the fifths is already controlled by audible beats. Also, composers and theorists in the 16th century (and well into the 17th) experimented with tone systems that covered the chromatic and the enharmonic genus. They had special instruments designed that offered 17, 19 or even 31 keys per octave [1.21, 23]. The intervals thus available were assessed not only in regard to their musical use but also with respect to sensory qualities such as consonance and dissonance. Zarlino's comprehensive works on music theory (including aspects of organology, tunings, etc.) must be regarded as milestones in the history of systematic musicology. *Zarlino* [1.24, Part III, Chap. 31] states that the arithmetic and the harmonic division of the fifth yield the (just) major and the (just) minor third respectively, from which he concludes that this distinction is the ultimate cause of harmony. Though *Zarlino* discusses intervals such as $2/1, 3/2, 5/4, 6/5$ [1.24, Part III, Chap. 32], one in fact can derive the major and the minor chord from the operations Zarlino proposes for the two divisions of the fifth, and later theorists like Rameau and Riemann therefore saw Zarlino's ideas as decisive steps on the way to modern tonality. As a matter of fact, Zarlino elaborated vertical harmony in his own polyphonic works (*Modulationes sex vocum*, 1566).

In the 16th century, progress was also made in musical acoustics when Fracastoro (1546) correctly explained the nature of resonance in strings (while the phenomenon as such, i. e., sympathetic vibration, was known long before [1.25]). Instrument building had reached a high level of invention and craftsmanship by about 1600, and many types were in use, for example of reed instruments (as is obvious from the account *Praetorius* [1.26, T. II] gives). As *Praetorius* [1.26, T. III, pp. 126f.] reports, in Italy organization of a range of string, woodwind and brass instruments into a Chorus instrumentalis alternating or playing together with the Chorus vocalis (in concert-like form) was part of musical practice.

With the rise of mechanics, the theory of vibration and the concept of frequency became areas of research based on empirical observation and mathematical scrutiny (for detailed accounts covering the period from around 1580–1750 see [1.27, 28]). *Mersenne* [1.29] found a formula for the calculation of frequencies of vibration and worked on absolute frequencies; he was familiar with a host of musical instruments including the enharmonic experiments Giambattista Doni and others were conducting in Italy. In the 17th century, logarithms for calculating musical intervals and temperaments were developed [1.30]. An early attempt to

expand the theory of consonance from ratios of numbers or string sections to actual sound was based on the coincidence of pulses assumed to be emitted into the air from vibrating strings (or air columns in pipes), and received in our ears as series of small *strokes* hitting the tympanum. This approach was taken, in about 1620, by Isaac Beeckman, who had formal training in medicine and understood the basic function of the tympanum and the middle ear ossicles. He apparently even knew the oval window that he, however, took as the entrance to the auditory nerve (the microanatomy of the cochlea was studied, by Alfonso Corti who in 1850 discovered the spiral structure of the receptor organ for hearing inside the bony part of the cochlea known since as Corti's organ). Though Beeckman's *atomistic* approach to sound was flawed (he opted for a corpuscular concept instead of a wave theory; for a detailed account of Beeckman see [1.27]), and his ideas, which he noted in his diaries, were not published before the 1940s (but had been shared with fellow scientists Descartes and Mersenne), the coincidence theory offered a physical explanation of consonance that could be tested as well as modified along with new observations. From this theory, Beeckman also understood the nature of roughness and beats. While it was known for a long time that each musical tone contained at least two components (in modern terminology, the fundamental and its octave, the second harmonic), Mersenne it seems could hear out several harmonics, which he identified as fundamental, octave, tenth and twelfth. *Mersenne* [1.29, L. VII, prop. XVIII] believed he could hear these partials also in the sound of bells, however, he recognized there were possibly some deviations from this scheme. Jacob van Eyck, an outstanding musician and musical scholar working at Utrecht, according to a note contained in the diary of Isaac Beeckman (24th of Sept. 1633) had been able to hear out some of the prominent partials in bells without touching the bell [1.31, pp. 310–11]. Apparently, van Eyck used to sing or whistle tones in order to excite a resonance in a vibrating body like a bell.

Once acoustics was introduced into musical science by Beeckman, Mersenne and also by Christiaan Huygens (who had more of a musical background than the aforenamed scholars), it was clear that sound as actually produced in performance and perceived by listeners was as important for music as were rules of counterpoint and harmony. However, one has to take developments in musical composition as well as in music theory into account. For example, intervals regarded as imperfect consonances in medieval treatises (the two thirds and the two sixths) were actually employed in composition already before 1500, and massively so in the 16th century when settings in four voices had become customary. Madrigals composed by Cipriano de Rore and, by the end of the 16th century, Luca Marenzio (in particular his fifth and sixth book of madrigals) demonstrate ample use of chords as vertical sonorities, and Monteverdi, in his fifth book of madrigals (1605), finally offered a major chord including the *dominant seventh* dissolving into the major third of the tonic (*Cruda amarilli*, m. 41–42). Soon, both works for keyboards (as, for example, the *Toccata quinta per il cimbalo cromatico* of Ascanio Mayone, published in his Secondo libro di diversi capricci per sonare, Napoli 1609) and the bold textures of sonorities Gesualdo created in his fifth book of madrigals (1611) became truly adventurous in exploring harmony. These explorations went along with experiments in tunings and temperaments as well as in building enharmonic instruments [1.20, 21, 32] designed by Mersenne (1636) and many other music scholars.

Though it is beyond the scope of this chapter to discuss developments in music and music theory in any detail, it seems safe to say that music theory from the 15th century onward comprised several large areas whereby the medieval division of *musica speculativa* and *musica practica* was maintained, in some respects (which can be traced in works such as Gaffori's and Zarlino's, and still around 1700 in, for example, Werckmeister's publications). While the theoretical and speculative approach was continued by scientists like Kepler and Mersenne [1.27], composition, performance practice and also teaching demanded works with a more *practical* orientation (for overviews covering developments in France, Italy, England, Germany and neighboring countries, see vols. 6, 7, 8/1, 8/2 and 9 of the *Geschichte der Musiktheorie*, 1986–2003 [1.2]). It was also from practical considerations that organ building had introduced pipe ranks an octave or two apart (like 16′ and 4′, see [1.22] and [1.16, pp. 89ff.]). Doubling of voices at the octave appears to have been in use not only in organ music but also in other musical genres (as testified by *Praetorius* [1.26, Vol. III, pp. 132ff.], see [1.33, pp. 445ff.]). Equivalence of octaves as tones and pitches thus was a common experience. Another such experience must have been that of harmonic triads (termed *trias harmonica* by *Lippius* [1.34]) especially when, not long after around 1600, musical genres with a basically homophonic structure were propagated and sequences of chords were arranged according to basso continuo rules. Inversion of chords is one of the topics elaborated in a number of 17th-century books on *practical theory*.

1.4 Sauveur, Rameau and the Issue of *Physicalism* in Music Theory

In 1687, Newton's *Philosophiae naturalis principia mathematica* appeared, which offered a coherent rational basis for mechanics. In 1677, John Wallis had published a paper on harmonic vibration and resonance in strings [1.28, pp. 44ff.]. By about 1700, *Sauveur* investigated harmonics in vibrating strings [1.35] and also discussed harmonics in organ pipes as well as the effect of superposition of several complex harmonic sounds [1.36]. He came to the conclusion that the use of several pipes from different organ stops gave the same basic harmony one could observe in vibrating bodies (*L'orgue ne fait qu'imiter par le mêlange des ses jeux, l'harmonie que la nature observe dans les corps sonores, qu'on appelle harmonieux*). Years after Sauveur had postulated that the harmonic series was the principle governing complex sounds, his findings were reported to *Rameau* (see [1.37, p. 3], [1.38, pp. 87f.], and [1.39, Chap. 6]). To be sure, *Rameau* had already stressed the unique role of the octave in regard to production and perception of pitches in his *Traité* [1.40, art. 3] where he points to overblowing a flute into the higher octave simply by increasing the blowing pressure. He also mentions a statement of Descartes (found in his *Musicae compendium*, written in 1618, and published in 1653 and 1656) according to which a (complex harmonic) tone is somehow always contained in his octave. Later, *Rameau* [1.41, p. 16] said:

> *je sçavois par experience que l'octave n'est qu'une replique, combien il y a d'identité entre les sons & leurs répliques, & combien il est facile de prendre l'un pour l'autre, ces sons même se confondant à l'oreille* [...]

Again, in a letter to Leonard Euler, which was published in part [1.42, pp. 167ff.], Rameau argued that tones one or several octaves apart blend perfectly since *la représentation d'un son dans ses octaves* gives a sensation of identity (*Identité*). This concept of functional and perceptual octave equivalence permitted Rameau to take the octave as a frame within which intervals can be inverted. Hinting at the commutative law (*Rameau* [1.40, p. 7] speaks of *raison ou comparaison renversée*), he pointed to a principle of *renversement* that became a major issue in his theoretical works since it could be used for deriving basic intervals as well as chords (e.g., [1.40, p. 10], [1.43, pp. 20f.]) from a given interval or triad. Octave equivalence and chord inversions played a distinctive role in functional harmony, and Rameau has been lauded to have made significant contributions to this field with his concepts of *son fundamental*, *basse fondamentale*, *dominante* and *sous-dominante*, *note sensible* (leading note) and other considerations [1.33, 38]. Moreover, he has been viewed as a proponent of so-called harmonic dualism for his derivation of both the major and the minor tonality from a set of basic principles.

Since harmonic dualism (a concept to be explained in brief below) was, and to some extent still is, a major issue in music theory [1.33, 44, 45], it seems apt to review at least some of the background. When *Zarlino* [1.24, Part III, Chap. 31] discussed the harmonic and the arithmetic division of the fifth, it was clear to him that the two thirds he obtained could be combined in two different ways, which, by implication, yielded a major and a minor triad, i. e., the basic building blocks of harmony *(...& da questa varietà dipende tutta la diversità, et la perfettione delle Harmonie*). The harmonic and the arithmetic division hence serve as generators of either a major or a minor triad. Apart from calculation (which shows that the two means between 2 and 3 are either $12/5 = 2.4$ or $5/2 = 2.5$), one may find the major and minor third intervals from division of an actual string.

The concept of harmonic dualism claims, in the first place, that major and minor are two distinct types of tonal organization for which principles for the generation of intervals and chords must be stated. One method suited to derive relevant intervals in fact could be arithmetic and harmonic division of a string. Arithmetic division proceeds from sectioning a string into n equal parts ($n = 1, 2, 3, \ldots$). For example, division of a string into five equal parts gives the fundamental ($5/5$ of the string) and the major third (at $4/5$ of the string) as well as the major sixth ($3/5$); division into six equal parts yields the fundamental note (at $6/6$), the minor third above this tone ($5/6$), the fifth ($4/6$), and so on [1.44, pp. 16ff.]. The tones from a division into five parts relative to C_4 ($5/5$), are E_4 ($4/5$), A_4 ($3/5$), E_5 ($2/5$), E_6 ($1/5$). One may regard this series as representing a chord in terms of *undertones* in particular if the series is centered at E_6, from which the other tones viewed downwards are in the intervals of an octave, fifth, fourth, and major third (it is easy to continue this series to the minor third A_3 etc.). What can be demonstrated is that a series of *undertones* derived from operations of equidistant sections of a string and a series of *overtones* found from sounding the fractional length $1/n$ of a string (where $n = 1, 2, 3, 4, 5, \ldots$) yields two series that are complementary and symmetric [1.44]. Since tones/notes representing the major chord are contained in the series of *overtones* $4 : 5 : 6$, and the tones/notes representing the minor chord in the series of *undertones* respectively, one might be inclined

to take both as equivalent in structure. In a formal approach, this is correct because of the symmetry of both series (Fig. 1.1).

The problem, however, is that *overtones* in fact are contained in each complex tone produced from a vibrating string or air column (as in an organ pipe or trumpet), while *undertones* (under normal conditions) are not (electronic instruments such as the Trautonium finally offered sounds comprising subharmonics which, as fractions of a fundamental frequency f_1, are representing series of *undertones* like $1/2f_1$, $1/3f_1$, $1/4f_1$, etc.). At the time of Sauveur and Rameau, *overtones* were of interest since it was understood (since Mersenne, Beeckman, van Eyck, see above) such tones are contained in single sounds produced from a *corps sonore*. As these partials were in harmonic ratios (like 2 : 4 : 5 : 6 as pronounced by Mersenne), a general idea emerged of harmonic superposition relevant not just for single sounds, but also for combinations thereof. For instance, *Rameau* [1.37, pp. 13, 16] reports small experiments where he experienced tones from several organ pipe ranks (activated one after another or simultaneously) blending and fusing while the single tones could still be distinguished (it was from quite similar experiments involving organ mixture stops that Carl Stumpf explored his concept of *Verschmelzung* around 1880–90; see below). To be sure, an instrument well known at the time of *Sauveur* and Rameau was the trompette marine [1.35, pp. 300f., 356] which, in particular in versions developed and played by the virtuoso Jean-Baptiste Prin around 1700–1720 [1.25, pp. 313ff.], employed sympathetic strings (as did the Baryton and the viola d'amore also in use at that time). *Sauveur* [1.35, p. 356] understood that the *trompette marine*, due to the peculiar regime of vibration in its long string *ne produit que les sons harmoniques*, and that, in long strings, there were knots (*nœuds*) where no motion was observed while motion was maximal at the antinodes (*ventres d'ondulations*). Since a long string vibrates in total as well as in parts, there is a *son fondamental* as well as *sons harmoniques*. *Sauveur* [1.35, pp. 300f.] said that during the night (when it was quiet) one could hear, besides the *son principal* (the main pitch of a long string) some small tones (*d'autres petits sons qui étoient à la douzième & à la dix-septième de ce son).* What is meant, from the table *Sauveur* [1.35, p. 350] includes in his essay, is partials no. 1, 3, 5 of a harmonic series.

In his system of tones and intervals, *Sauveur* [1.35, pp. 302ff.] offers a symmetric arrangement of tones relative to a son fondamental into upper *octaves ou octaves aigues* as well as lower ones (*sous-octaves ou octaves graves*). It may well be that this symmetric arrangement became known to Rameau. After *Rameau*

Fig. 1.1 Symmetry of *overtones* and *undertones*

had been informed about Sauveur's findings, he ([1.43, pp. 20ff.] and throughout [1.37]) set out his concept of harmony as a combination of elements known from Zarlino (the harmonic and arithmetic division of the fifth as a basis for the major and minor triad respectively) and Sauveur. Consequently, one finds the two proportions 1 : 3 : 5 and 1 : 1/3 : 1/5 as well as the concept of *son fondamental* and harmonic partials, and there are operations such as *renversement* and contraction of partials into one octave in order to establish symmetry needed for the juxtaposition of harmonic major and minor. Summing up his views, Rameau argued there are some fundamental intervals (unison, octave, fifth, major third) whose prominence is due to natural laws (namely, harmonic vibration), and that both harmonic major and minor can be grounded on proportions reflecting such laws. The harmonic proportion that *Rameau* [1.37, p. 29] states, in whole numbers, as 15 : 5 : 3 gives the *accord parfait* (put into one octave, the tones ut–mi–sol), but also the minor triad (viewed as the arithmetic proportion 6 : 5 : 4 . . . : 3; [1.37, p. 37], and examples I and II annexed to the book, also [1.41, pp. 20ff.]), though admittedly not just as perfect and *natural* than major [1.37, p. 32], because of its reciprocal relation to major is a construct backed at least by logical argument [1.37, Chap. IV]. As is well known (see [1.38], [1.39, Chap. 6]), Rameau's attempt at finding also an acoustical explanation for the minor triad in the pattern of sympathetic vibrations of strings tuned to harmonic ratios below a string actually set to motion, was flawed as far as sympathetic vibration of the lower strings in their full length (i. e., in their fundamental mode) is concerned. However, *Rameau* [1.37, p. 36f.] was cautious enough to suggest his reciprocal scheme of the major and minor triad seemed plausible for certain reasons; he did not claim it was verified by experimental observation. He later [1.41, pp. 21f. 63ff.] made it clear that strings tuned lower than that string actually played can only go into aliquot sympathetic vibration (a point underpinned also by [1.46] who had been supporting Rameau for a long time). *Rameau* [1.41, 47] maintained, though, that the major and minor mode should be conceptualized as forming

reciprocal relations (modeled after harmonic proportions).

Rameau offers a number of concepts that became essentials of music theory in the later 18th century and throughout the 19th century. One of course was his *basse fondamentale*; another the relation of a central tone (*le principe ut* [1.41]) to the major third and fifth above and below as well as the reciprocity of major and minor proportions. Further, there are tonal functions for certain tones such as the *dominante*, the *note tonique*, and the *note sensible* [1.40, p. 56]. The reciprocal construction of harmonic minor includes *la sousdominante* [1.37, pp. 132ff.] and another concept, termed by Rameau the double use (*double emploi*), affords that a chord f–a–c'–d' (played after c–e–g–c' as tonic), may be conceived, by inversion (*renversement*) also as d–f–a–c'. Hence, the chord of the *sousdominante* can appear in two different forms, and thereby can represent two different modes [1.41, 46]. However, taking f–a–c'–d' (relative to the initial C-major chord this is a major chord with sixte ajoutée) as equivalent to d–f–a–c' (which thus would be conceived as a minor chord with a minor seventh added on top) clearly is a reinterpretation (notwithstanding both resolve easily into a G-major chord, which in turn may be followed by the initial C-major to complete the cadence). Both *renversement* and reinterpretation of chords in regard to their tonal function played an important role in the theory of harmony ever since (the more so as equal temperament, proposed by Rameau in his later writings as well as by other music scholars around 1760–1800, became the standard tuning for pianos in the 19th century; see Sect. 31.7). Rameau's dualistic concept of major and minor was taken up by music theorists such as Moritz Hauptmann (who also adopted the concept of the octave, the fifth and the major third taken as *directly comprehensible* intervals) and Hugo Riemann. *Arthur von Oettingen* [1.48, 49] made a serious attempt to provide the acoustical and psychoacoustical foundations for harmonic dualism that Rameau could not offer [1.50, 51]. In order to give their approach to harmony foundations a base in natural laws, many theorists (like [1.52]) pointed to the harmonic series as a model for the major chord (e.g., c–e–g corresponds to the harmonics 4 : 5 : 6, while the first inversion e–g–c' would be equivalent to harmonics 5 : 6 : 8, and the second inversion G–c–e to harmonics 3 : 4 : 5) and also the minor triad (as represented by harmonic partials no. 10 : 12 : 15). A musicologist familiar with scientific methods [1.53] was critical of the adherents of *overtones* (he addressed them as *Obertönler*) and of *physicalism* in music theory in general since, as Hauptmann and Riemann had underpinned, harmony in music should be conceptualized in logical form (as an analogue to *well-formed* sentences or *propositions* [1.54, 55]) rather than as derived from sound structure. Though the logical and *propositional* approach to music theory is certainly relevant for the analysis of musical works (in particular as manifest in a symbolic notation but also as sound textures that are perceived by listeners more or less familiar with a musical syntax [1.56]), the disregard for actual sound properties of, for example, harmonic cadences and chord progressions was unfortunate. A new interest in psychoacoustic aspects of harmony [1.57–59] was spawned by empirical research in pitch perception including virtual pitch (Chap. 31) as well as by approaches to music cognition based on actual sound patterns. As far as the difference between major and minor is concerned, signal processing methods permit researchers to show that a significant difference in major and minor chords formed on the same fundamental (in just intonation) can be found in the subharmonic virtual pitches they give rise to [1.51]. Also, differences in the degree of spectral harmonicity can be found for major and minor chords from piano tones in ET12 (Fig. 1.2) when the periodicity of the signal is measured in the time domain.

1.5 Concepts of Systems and Systematic Research

It is obvious that the work of Greek and Hellenistic philosophers and scientists such as Aristotle, Euclid, and Ptolemy covered several if not many areas, and that they had both outstanding theoretical and factual knowledge. In certain respects, their knowledge gained what one may call systematicity since it was ordered according to first principles, integrated across individual observations, coherent and complete (as much as possible at a given time in the process of research). Aristotle discusses these criteria in regard to nature (physis) as well as science (theoria) directed toward the study of nature in the first place (see his lectures on Physics, in particular book II, and book X and XI of his Metaphysics). To understand the world (containing all of nature) as a whole, science also must be comprehensive. If nature in total is viewed as a system (or as a system of systems, as it is still in modern science) the research effort pursued by science will reveal more and more of the laws and categories governing nature. Thereby, a correspondence between nature (viewed as a large and

complex system) and science (viewed likewise as an increasingly complex and differentiated system) can be established. The science of nature by Aristotle *is seen as a systematic whole because it presents an account of the world that is similarly systematic* [1.60, p. 31].

The notion of a *system* and the principle of *systematicity* became constitutive for philosophy and the sciences to this day in a number of ways (for at least some of the background, see [1.50]). For example, if individuals are to acquire coherent and reliable knowledge, they proceed by integrating new information into a framework of (innate or learned) categories, and do so according to certain rules (as has been stressed, for language acquisition, by *Chomsky* [1.61]). One can draw a parallel between the process of cognitive systematization individuals effectively carry out over most of their lives in order to build up coherent knowledge of the *world* (as well as of themselves; the process is reflexive), and the collective endeavor of many scientists building up coherent knowledge of the *world* [1.1, 62]. Kant's epistemology (as set out in his Critique of Pure Reason (KdRV) and other writings, see *Rescher* [1.63]) permits such a parallel perspective since categories and principles fundamental to acquisition of coherent individual (ontogenetic) experience are fundamental also to structuring collective scientific knowledge. Kant himself, however, did not elaborate this approach for specific areas or disciplines of science. One of his few remarks on *system* (at the very end of KdRV) is that reason (Vernunft) is not additive yet integrative and rule-based so as to provide unity and coherence within the manifold of knowledge (KdRV B 860). Therefore, reason must rest on principles, and the scientific method must always be *systematic* (KdRV B 884) to achieve coherence.

It is of course outside the scope of this introductory chapter to delineate the concepts of *system* and *systematization* as they were developed in philosophy and in various areas of science within the 19th and 20th centuries. It is known that some philosophers, in particular in the 19th century, elaborated comprehensive *systems* of inquiry and reasoning (comprising logic, epistemology, philosophy of nature and other areas), and that Hegel's philosophy perhaps was the most advanced in regard to establishing a coherent yet in part speculative system derived from basic notions and principles. However, even in the 20th century, an approach from quite a different angle (that of so-called neopositivism [1.64], combined with elements from pragmatism and operationalism) explicitly called for a *Unified Science*. The movement, originating in Vienna in the 1920s and later centered in the United States, launched an encyclopedia as well as journals such as *Erkenntnis* and *Philosophy of Science*. Its members – for the most part philosophers, mathematicians, physicists, linguists and psychologists – published many works on theory and methodology of science. The idea still was to provide a framework suited to guide research in many areas so that coherent knowledge would be gathered and presented in an orderly fashion along the same basic principles. Another notable contribution to offering an integrative perspective was that of general system theory [1.65], which became influential in many fields (from the life sciences to economics).

Concepts of *system* and *systematization* played an increasingly important role in empirical science since, in the 18th and 19th centuries, factual and theoretical knowledge was expanding fast while a large number of fundamental principles governing both organic and inorganic nature were discovered (from mechanics and astronomy to organic chemistry and genetics). In addition, *evolution*, acknowledged first as a teleological principle [1.66] and then as biological fact [1.67], became accepted as perhaps the most fundamental *law* governing nature (including humans, their ways of living, as well as their arts and even their morals [1.68, Chaps. 4–7]). Growth of factual knowledge had led to ordering and classification of phenomena (e.g., the taxonomy of plants as worked out by Carl von Linné). A dynamic approach to systematization was established when, in the course of the 19th century, methods of classification and typology were combined with the principle of evolution. From this perspective, a number of *evolutionist* models were established not only in biology and physical anthropology, but also in prehistoric archeology and cultural anthropology. Humanities in general and musicology as an academic discipline, reestablished in Austrian and German universities around 1870, were to follow soon with concepts of so-called *Entwicklungsgeschichte* (developmental history) which, in most cases, offer Hegelian thoughts on progressive development mixed with ideas on *natural evolution* and with typological ordering of phenomena from simple to complex. Such series of types then are interpreted as representing *stages of evolution* (from *primitive* to *developed* and, historically, from *ancient* to *modern*). One has to remember, further, that in the 19th century the comparative method gained prominence in various areas of research (from anatomy of vertebrates to Indo-European linguistics) including, from about 1890 onward, comparative musicology [1.69].

1.6 Systematic Approaches: Chladni, Helmholtz, Stumpf, and Riemann

As outlined in the preceding paragraph, a systematic approach in scientific disciplines is one striving for coherent knowledge based on principles, categories, and empirical evidence needed for causal explanations. A serious attempt at presenting scientific as well as cultural knowledge that had been accumulated up to a certain time, in a concise format, was the *Encyclopédie* (1751–1772) edited by Diderot and d'Alembert with the support of famous collaborators. The *Encylopédie, ou dictionnaire raisonné des sciences, des arts et des métiers* includes an article on *system* (système, T. XV, Paris 1765, 777–781, written by d'Alembert, Le Blond, de Jaucourt and Rousseau) as well as an article on music (musique, T. X, 1751, 898–909, provided by Rousseau, de Jaucourt and Menuret), which stems from the established distinction between musique spéculative and musique pratique, and which is historical (with a focus on Greek antiquity) in its main orientation. The article on *system* covers areas from philosophy to astronomy and science in general as well as music (the musical part refers to structures of the Greek tonal system and later developments in a more precise and detailed manner than the article on music). While the authors maintain that the criteria of reasoning from principles and coherence are essential to a *system*, the article is clearly antispeculative while it underpins the need for experience and factual evidence *(Les experiences & les observations sont les matériaux des systems*). A system, in this sense, is an ordered presentation of facts along with principles suited to explaining their relationships as well as possible effects.

In 1802, Ernst Florens Chladni was the scholar that presented facts and principles for the field of acoustics in a truly *systematic* account. *Chladni*'s classic work [1.70] discusses generation of sound in vibrating bodies (such as rods and plates) as well as sound propagation in solids and in air. His book includes quite many chapters on auditory sensation (part 4) as well as on musical intervals, scales and temperaments (in part 1). He also invented a number of musical instruments suited to exploring sound properties in regard to pitch and timbre [1.71]. In 1852, Opelt issued a three-dimensional model of pitch (Chap. 31, Fig. 31.31), and at the same time *Marchese Corti* had made seminal discoveries of the anatomical structure of the cochlea and the auditory nerve [1.72]. Also, by about 1850 mathematical psychology [1.73] and psychophysics became an area of research that soon led to *Fechner*'s famous treatise [1.74].

Hermann (von) Helmholtz, a physician and physicist who, in 1855, was appointed professor of anatomy and physiology at the University of Bonn, picked up the findings of Corti in a public lecture where he elaborated on their implications for the theory of hearing and even for harmony in music [1.75]. This lecture discusses in a nutshell what a few years later would find extensive treatment in *Helmholtz*'s comprehensive book [1.76]: namely the interrelationship between fundamentals of vibration and sound, hearing as a sensory and perceptual process, and music as an art based on patterns of sound suited to communicate pitch structures, *sound colors* (German: *Klangfarben*, see Chap. 32 of this book) as well as temporal and dynamic parameters to subjects performing and/or listening to music (for an evaluation of Helmholtz's work in auditory theory and psychoacoustics see [1.77], [1.78, Part 1]). The impact of Helmholtz's *Tonempfindungen*, which saw six German editions and an English translation by Alexander John Ellis (*On the Sensations of Tone*) in two editions (the first, published in 1875, was based on the third German edition; the second, published in 1885, on the fourth German edition) as well as a number of reprints, can hardly be overstated. A decisive factor for the general acceptance and even popularity of the *Tonempfindungen* as well as of other works Helmholtz had published (e.g., his equally comprehensive books on physiological optics) was that Helmholtz reported a wealth of observations he had made himself, in experiments for which he even designed instruments for measurement. Moreover, his extensive research in central areas of physics, mathematics, and physiology allowed him to pursue an integrative approach to the sciences (as well as in related areas like musical acoustics and psychoacoustics). In addition, Helmholtz had a thorough understanding of epistemology and methodology, from which he developed his own theoretical framework in regard to sensation, perception, and cognition [1.79]. His reasoning combined fundamental categories of Kantian epistemology with realism and empiricism rooted in experiment and observation. Finally, like many scientists (from Huygens to Planck, Einstein, Fokker or Van der Pol) he had a musical background that let him study musical problems from his own experience and judgment. For experimental observations of pitch and interval perception and exploration of musical scales, he had a 53-keyed instrument (see [1.80] and the picture in [1.81, p. 76]) at his disposal. Taken together, all these factors made the *Tonempfindungen* a paradigm of music-related science as the book offered a coherent and systematic treatment progressing from fundamentals of vibration and properties of sound to auditory sensation and, in the final sections, to an assessment of concepts established in music theory (like tonality, harmony, voice leading) in

the light of empirical facts and explanations. Of course, later research has shown that some of Helmholtz's hypotheses were not confirmed by fact; this holds true in particular for the basilar membrane (BM) conceived as a chain of resonators tuned to certain *best frequencies*. (Later concepts still view the BM in regard to a tonotopic organization; the concept of *best frequency* also plays an important role in auditory theory; see Chap. 31.)

Carl Stumpf was a philosopher and psychologist with a thorough musical background (he learned to play a number of instruments and used to sing; he even pondered a musical career in his youth [1.82]). He studied philosophy with Brentano and then with Lotze (for his Ph.D. degree), the former known for his contributions to logic and studies on perception and cognition, the latter (with formal training also as a physician) likewise for books on logic and epistemology yet with a deep interest in psychology and aesthetics (for historical background, see *Boring* [1.83], *Pongratz* [1.84]). Combining theoretical analysis with empirical observation, Stumpf elaborated on the sensation and perception of tones (single tones as well as series of tones and intervals) in his *Tonpsychologie*, originally conceived in four volumes of which two appeared, in 1883 and 1890, under this title, and most of what was planned for vol. 3, separately as *Konsonanz und Dissonanz* [1.85]. It was with this latter monograph that Stumpf opened a series, *Beiträge zur Akustik und Musikwissenschaft* (H. 1–9, 1898–1924), which offered many articles on sensation and perception of musical sound as well as on topics from comparative musicology.

Stumpf acknowledged some of Helmholtz's achievements in psychoacoustics but was critical of his concept of consonance and dissonance as it lacked, as Stumpf saw it, a psychological explanation. Taking Helmholtz's criteria (beats, roughness, coincidence of partials) as objective features inherent in the sound structure, *Stumpf* [1.86, 87] argued these are in fact antecedent conditions relevant for acoustics and sensory physiology, whereas a psychological explanation must look for the effects sound structures have in the perception of listeners. Perception, for Stumpf as well as for his teacher, *Franz Brentano* [1.88], includes cognitive acts and functions such as noticing certain objects and features, identification and comparison of such features, judgment, and apprehension of chords and melodies in music as configurations of elements. Stumpf therefore offered a different concept he believed was fundamental to the experience of consonance in both complex harmonic tones as well as in multiplicities of sound. This concept he addressed as *Verschmelzung* ([1.89] and Chap. 31 of this handbook).

With his background ranging from sensory physiology and acoustics to foundations of psychology as related to theory of knowledge [1.82, 90], Stumpf pursued research that integrated systematic and comparative musicology [1.50, pp. 29ff.] since he was of the opinion that perceptual and musical phenomena, such as formation of tone systems and scale types, consonance and dissonance, cannot be studied appropriately if confined to observations from European art music (similar concerns had been expressed also by *Helmholtz* [1.76]). Stumpf's Psychological Institute (founded in 1894 as a seminar, expanded in 1900) soon included a collection of non-Western music recorded in the field or in Berlin from ensembles visiting the capital. One such recording session took place in September 1900 with a *Siamese* (Thai) ensemble [1.91]. From the recordings as well as from additional information *Stumpf* had gathered in interviews and small experiments he took with the musicians, he prepared an in-depth study of the tone system and music of this culture [1.92]. This study can be called exemplary in that it offers a description of the instruments played by the Thai ensemble along with data from measurements of their tuning, followed by a discussion of how the seemingly equiheptatonic scale of the Thai and a similarly equipentatonic scale assumed for the Javanese *gamelan slendro* might be explained in regard to perception. To be sure, sectioning an octave (2 : 1) into two equal parts involves calculating the geometric mean, which is $\sqrt{2} = 1.41421$, the frequency ratio of the tritone in modern ET12. Sectioning an octave into five, seven, or twelve equal parts (as in ET12) is even more demanding (one has to calculate the basic step as $\sqrt[5]{2}$, $\sqrt[7]{2}$, or $\sqrt[12]{2}$ respectively, and then take their multiples). *Stumpf* [1.92, p. 89], therefore, asked: How could one establish such scales like the *Siamese* and slendró without calculating roots and logarithms? Stumpf drew on *Fechner's law* (which relates stimulus magnitudes to sensation, see Chap. 30 of this book) and considered also distance estimates for a tentative explanation. As a trained musician, he was able to transcribe and analyze a substantial portion of the music as well [1.92].

A device that facilitated Stumpf's investigation of Thai (and other non-Western) music was Edison's *perfected* phonograph that became available in 1888. *Stumpf* [1.92, p. 136] also used a brand-new *Telephonograph* (also *Telegraphon*, invented by the Danish physicist, Valdemar Poulsen), the first machine to offer magnetic recording on a steel wire, in a much improved sound quality. Recording of actual sound for analysis and transcription was a fundamental requirement for systematic and comparative musicology as well as for phonetics [1.93]. For a period of more than two decades, Stumpf engaged himself (as well as his

coworkers) in analysis and synthesis of sound as well as in experiments on perception. He condensed his many observations into a monograph addressing speech sound but also phenomena relevant for music such as *sound color* and intonation [1.87].

Hugo Riemann, like Stumpf, took his doctorate with Lotze. He submitted a thesis [1.94] on music perception, which he relates to cognitive foundations of functional harmony. In his thesis and some other early writings, Riemann tried to integrate concepts from *Rameau* [1.37, 41], *Hauptmann* (1853) [1.95], *Helmholtz* (1870) [1.96], and *von Oettingen* (1866) [1.48]. At the core of his considerations is harmonic dualism, which brings up the problem of symmetry between *overtones* and *undertones* tackled by Rameau (see above). *Riemann* [1.94, pp. 12ff.], referring to Helmholtz's BM resonance theory, made some rather speculative remarks where he asserts that *undertones* could be evoked in auditory sensations since fibers in the BM corresponding to subharmonics of the frequency of a tone actually presented to the ear could be set to partial sympathetic vibration. From such a pattern of partial BM fiber responses he concluded we would have *an implicit perception of undertones*. Riemann did not, as has been erroneously presumed at times, assert that *undertones* were part of the sound wave reaching our ear, and hence an acoustic phenomenon (see [1.94, pp. 12f.], [1.51]). His argument by and large follows *Rameau* [1.41] yet is beefed up with a hypothesis of sympathetic resonance in BM fibers in the light of Corti's discovery and Helmholtz's resonance theory (strange enough, *Rameau* [1.37, p. 7] made reference to *Fibres qui tapissent de fond de la Conque de l'Oreille*, which he believed would resonate like *corps sonores*).

Riemann, like Rameau before him, needed *undertones* (even if only perceived indirectly) for a symmetric model of major and minor. He had one remark on harmonic minor, evaluated as *blurred major* even by Helmholtz, saying that, in a minor chord, the harmonic partials contained in each complex tone (e.g., of a piano) would interfere with the intervals between the tones of the minor chord while they would fit well to a major triad. This is indeed a point that can be proven empirically, for if a minor chord on a grand piano tuned to ET12 is played (in *root* position with the bass note doubled in the lower octave) by simply moving one finger one key down from the major to the minor third, the degree of harmonicity (measured as harmonic-to-noise (HNR) ratio from cross-correlation and expressed in dB) drops significantly (Fig. 1.2). This is why minor chords in *root* position with tones condensed into one octave in fact are *less perfect* (as Rameau had it) than major chords. Composers aware of this fact often have

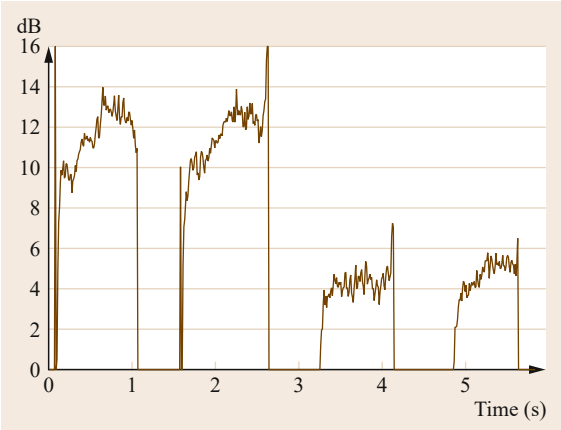

Fig. 1.2 C-major (*left*) and c-minor (*right*) played in *root* position, grand piano (ET12), HNR (dB) over time

set minor chords so that their tones are distributed over more than one octave.

Riemann apparently had hoped for some cooperation with scholars experienced in acoustics and sensation (like Helmholtz, Oettingen, Stumpf) that unfortunately never materialized [1.50]. At the same time, his aim was to continue the *logical* approach to tonality outlined by *Hauptmann* [1.54] who viewed tonal and chord functions in terms close to Hegelian dialectics. Hauptmann argued that the chord of the tonic is the basic unit (equivalent to a thesis) and that harmonic tension is generated from the fifth above and below a tonic that *disunites* with the tonic. However, the dominant and subdominant lead back to the tonic, and the three chords thereby are considered as an *organic unit*. The scheme *Hauptmann* [1.54, p. 26] gives for this unit (the elementary cadence) is symmetric (he also was a dualist)

F a C e G C e G h D

Since Hauptmann conceived his tonal relations in just intonation pitches (like Helmholtz, von Oettingen, and also Riemann in his early years), one may write the scheme as follows

−1 a e h
0 f c g d
(−1 = 1 syntonic comma flat relative to 0)

It is plain to see that there are four pure fifths at the bottom, three of which have a pure major third above. The tones a, e, h again are in relations of just fifths among each other, however, the interval d–a is not a pure fifth but is narrowed by one comma to 680 cents. One may use the seven notes as a just major scale [1.44] for

melodic intervals. Like Rameau before him, *Hauptmann* struggled with harmonic minor [1.54, 32ff.] and modeled the minor triad as the inverse (6 : 5 : 4) of major. Applying his logical arguments, he considered minor a *negation* of major.

Riemann took up Hauptmann's idea of a *musical logic* in a range of writings, of which his *Musikalische Syntaxis* (1877) sketched the conceptual framework while his books on harmony [1.97], on rhythm and metrics [1.98] as well as on other musical subjects expanded and detailed his ideas. The broad spectrum of his publications (from instruments and musical acoustics to performance practice, composition, analysis, and aesthetics) established him as perhaps the most versatile music scholar of his time. He played a key role in the development of musicology as an academic discipline around 1880–1910 in that he alone covered almost every field of historic and systematic musicology in a large number of publications, and moreover was acknowledged as a musician and teacher.

1.7 Gestalt Quality and Gestalt Psychology

In much of 19th century psychology [1.83], association served as a fundamental principle. It basically suggests an *additive* mode of experience, in that it assumes subjects combine elements such as elementary sensations into a complex perceptual object, in a sequence of associations. In a quite different approach, one of the problems tackled by *Brentano* [1.88] was if, and perhaps how, several complex objects may be perceived in one act of cognition. The dispute whether sequential association or integrative acts might offer appropriate models for perception was still under way when, in 1890, Ehrenfels published his famous article in which he argued that a melody is not the sum of tones sensed in a row yet probably a new entity, perceived as such. *Mach* had already pointed to the fact that subjects identify two melodies as representing the same *Tongestalt* if they share the same consecutive intervals [1.99, Chap. XIII]. As a parallel, he mentions geometric figures that we can recognize as similar in shape if their parts have identical relations. Mach ascribed the experience of convergence to sensations as well as to memory. *Ehrenfels* took another approach since, in a melody transposed by a certain interval up or down, all tones in the transposed version differ from the original in their pitch, which implies tone sensations must be different while transposition does not affect the profile of intervals making up this melody [1.100]. He suggested hearing a melody would produce a chain of tonal images or *impressions* (*Eindrücke*), which are integrated into one complex conception in the listener's consciousness (the German term he uses is *Bewusstsein*). The elements integrated into the complex can still be identified as such in perceptual analysis, however, the specific quality of the complex (which makes a melody or a geometrical shape identifiable against others) cannot be derived from the row of elements (e.g., tones) in a temporal Gestalt, or from the sum of elements (such as points, lines, angles) in a spatial Gestalt. While the elements (tones, lines, etc.) are real in terms of sensory data, the complex conception (in modern terminology: the perceptual object) is constituted in cognitive acts. Gestalt qualities according to Ehrenfels' definition are *positive conceptual contents* (*positive Vorstellungsinhalte*) that require perception of ordered complexes of elements. These complexes are fundaments (*Grundlagen*) for Gestalt qualities. Hence, the scheme Ehrenfels suggests contains three stages: first, sensation of elements; second, integration of elements into one complex conception; and third, apperception of a Gestalt quality. Though the process is sequential in regard to the first two steps, Ehrenfels argued the Gestalt quality would be *given* as a psychic fact immediately and concurrently with its *Grundlage* (the conceptual complex derived from temporal and structural integration of elements).

A few decades later, when Gestalt psychology became a paradigm [1.83, Chap. 23], this aspect of immediacy at times has been emphasized to the point that Gestalten should be *given* as wholes, and that these *complex wholes* (as Kurt Koffka called them) would be perceived as such, not as an additive sum of sensations and not even as a perceptual structure integrated over time and/or space. In a radical way, this view claims primacy of a Gestalt over its constituents, in regard to their occurrence in perception as well as their hierarchy. A more moderate view was that temporal structures such as melodies or rhythmic patterns give rise to perception of a Gestalt quality in that listeners recognize a well-formed, stable configuration of elements (and may mentally *complete* a temporal configuration after perceiving just the first few elements ordered into a structure). A Gestalt thereby is an emergent quality assigned to a perceptual object. To be sure, *Stumpf* [1.90, § 15] was quite critical of some tenets of the Gestalt school (spearheaded by his former students Wertheimer, Koffka, and Köhler), and in particular of Gestalten as immediately given, complex wholes.

He maintained that, for most Gestalt-like configurations (such as chords in music) perception includes an evaluation of relations between structural elements (otherwise, at least a musically trained listener may hear a complex, but may not perceive a Gestalt). Stumpf's approach was that of a cognitivist who would not expel an analytical stance for perceiving Gestalten. He [1.87, 90] admitted, though, that there were complexes in musical sound that, in certain respects, were Gestalt-like in quality yet indeed difficult to analyze perceptually into their constituents. Musical timbres (or sound colors) were among such complexes. *Robert Lach* [1.101], in a scholarly paper on indeterminacy and ambiguity of Gestalten in music, argued there were four basic parameters of tone sensation (pitch, intensity, sound color, duration) and three Gestalt qualities in tonal music (sound color, harmony, melody). Though sound color could be explained in physical terms (according to the Ohm–Helmholtz concept of additive Fourier synthesis) it would not be perceived (different from melody and harmony) as elementary, coherent and unambiguous. Notwithstanding such ambivalence, sound color would be perceived as a complex that in itself has a primary Gestalt quality in terms of aesthetic appreciation.

The Gestalt concept, which had been developed first in regard to temporal and spatial structures (melody, geometric figures) derived from perception of ordered complexes, was soon extended to various *wholes* (including, for example, emotions). Also, from Ehrenfels' concept of Gestalt quality an expansion was made (by Meinong) toward *higher order* Gestalten. The configuration that is perceived as a Gestalt by itself of course can be used as an element in a complex of Gestalten (such as a melodic theme in a polyphonic setting). *Hornbostel* [1.102], from his background in phenomenology and Gestalt psychology, surveyed auditory phenomena where he, among other topics, discussed consonance in terms of Gestalt criteria such as unity, simplicity, stability, and closedness. In a contribution to the Festschrift for Guido Adler (known for his book on the concept of *style* in music), *Hornbostel* [1.103] suggested musical works might be apprehended as representing a certain *style* from the perceptions a number of musically trained subjects have in common by *centering* on the same structural features contained in particular works.

Since the experience of a subject performing music or listening to music is perception of a multitude of Gestalt-like formations, the concept lends itself to music analysis as well as to music psychology and aesthetics. For example, *Wellek* [1.104], who had academic training both as musicologist and psychologist, employed Gestalt concepts in his studies and gave criteria (like closedness, stableness, degree of inner structuredness) for the evaluation of Gestalt-like formations in music. In the United States, *Leonard Meyer* [1.105] discussed pattern perception in music in regard to well-known Gestalt *laws* (of which *Helson* [1.106] provided a list that contained more than one hundred items) like good continuation, completion and closure.

From the side of experimental psychology, rhythm was one area investigated with respect to perception already before 1900 (in studies by Bolton and by Meumann). *Koffka* [1.107] took up rhythm in his dissertation (at Berlin under Stumpf) and found subjects tend to structure isochronous pulse sequences into perceptual patterns. One may regard subjective groupings of (sonic or optical) pulses that have the same intensity, quality, and duration in a sequence the result of cognitive activity (that is, grouping is viewed as a *psychic function* in line with Stumpf's concept). However, such grouping processes often take place almost involuntarily if a stimulus (in this case, an isochronous pulse sequence) is presented for some time. A similar observation is that subjects tend to instantly complete ensembles of graphic elements so as to make up a geometric figure. As to rhythm perception, *Schmidt* [1.108] found that subjects structure the elements within a rhythmic pattern from a larger unit containing a number of beats (a period, which can be taken as a temporal Gestalt), that is, the Gestalt as a whole governs the arrangement of the parts. In addition, a range of experiments conducted in France confirmed that rhythm is a temporal Gestalt phenomenon that, however, involves motor behavior [1.109, 110].

Another experiment from Gestalt psychology relevant for music perception was to offer the initial part of a melody to subjects (with some musical background) who were asked to *continue* as well as to *complete* the fragment [1.111]. Such experiments explored the actual range of melodic patterns that subjects regarded as a *good continuation* of a given melodic shape. In discussing temporal organization of tones in melodic patterns, *Koffka* [1.112, p. 434] had the following example (Fig. 1.3) for which he argued that, in the two scales (played staccato, one ascending from C_4 to C_5, the other descending from C_5) the common tone A_4 *will not be heard as one long note, but as two notes of normal length*. Koffka concludes that *the factor of uni-*

Fig. 1.3 Ascending and descending scales, *uniformity* versus *good continuation*

formity or homogeneity (as realized in the two scales) *has been overcome by the factor of good continuation*.

A quite advanced research project was conducted, by *Truslit* [1.113], on gestural motion in and along with music (where musical Gestalten induce a number of *typical* gestural movements condensed in trajectories that can be shown as curves). One may regard such gestural movements as spatiotemporal Gestalten (see articles in [1.114]).

1.8 Music Psychology: Individual and Sociocultural Factors

Gestalt psychology addressed, for the most part, perception as observed in individuals. However, there were also issues such as musical ability and aptitude as well as actual musical performance that became topics in psychology of music. *Carl Seashore* developed a test for musical talent and published a monograph on the same subject [1.115]. His lab in Iowa became a center of music psychology, a field covered in one of his textbooks [1.116]. Seashore's seminal work on musical *talent* spawned revised versions of his test (from his own lab) as well as some tests (Bentley, Wing, Gordon) more or less similar in design (but expanding from elementary to more *musical* items). He also edited collections of experimental studies on topics in music psychology, for example intonation in singing and violin playing (see contributions by *Harold Seashore*, Ray Miller, Arnold Small, and Paul Greene in [1.117]). As to intonation practice, this had been investigated earlier by *Stumpf* and *Max Meyer* [1.118]; the latter then went to the United States to continue his work at Iowa [1.83]. *Seashore* [1.119] also devoted himself to empirical aesthetics of music. Musical enjoyment had been studied experimentally by *Weld* [1.120] who employed psychological as well as psychophysiological methods. *Hevner* [1.121–123] employed her well-known cycle of adjectives to investigate how musical parameters such as the major and minor mode as well as pitch and tempo can influence the perceived expressiveness and the affective value of music. *Gundlach* [1.124], in a study noteworthy for its statistical techniques including factor analysis, presented 40 short musical phrases to more than 100 subjects who were asked to mark those of 17 preselected *categories* (adjectives such as exalted, mournful, glad, melancholy) or add some of their own choice that would characterize each phrase (and the presumed attitude of its composer) best.

In the studies published by Gundlach and by Hevner, the effect of music on subjects listening to music was investigated. Since their subjects typically were college students, reasonable homogeneity of subjects in their samples can be assumed in regard to mental capacity and other parameters. However, responses of subjects of course depend on their musical training and background as well as on preferences. To study a possible dependence of aesthetic judgments on intelligence, age, and musical training, *Rubin-Rabson* [1.125] presented 24 examples of music covering the period of around 1750–1925 from phonograph recordings to 70 adult men and women who could express their liking or dislike for each item on a rating scale. From the intercorrelation matrices she interpreted three parameters (age, intelligence, training) as positively or negatively related to groups of musical examples regarded as representing three historical and stylistic periods (classic, transition, modern).

One has to remember that in the 1930s the issue of *like* and *dislike* as well as factors relevant for listening preferences of audiences had become of interest to the industry behind the media (radio, phonogram records, publishing) as well as for social scientists. In the years 1938–1941, Th. W. Adorno was involved in the Princeton Radio Project (led by Paul Lazarsfeld), for which he wrote several critical papers that include proposals for empirical research focusing on individual listeners of radio programs. The essence of his criticism in regard to *popular* music as presented in radio and other media is condensed in the chapter on *culture industry* in the book he wrote jointly with *Horkheimer* [1.126]. *Adorno*'s contributions to social psychology and sociology of music [1.127] are based on his observations and critical judgment but do not attempt to provide empirical data or similar factual evidence in support of arguments. However, a more formal approach to the social psychology of music including *musical taste* was soon established by, in particular, *Farnsworth* [1.128] who had measured, among other issues, the interest school children had in either *serious* or in *popular* music. Empirical studies on the reception of music among school children and adolescents [1.129, 130] confirmed the dominant role pop and rock music play in the life of young people. Empirical and theoretical studies were also carried out in music sociology with the aim of studying uses and functions of various types of music in societal groups [1.131]. The *International Review of the Aesthetics and Sociology of Music* (founded in 1971) publishes scholarly papers from both areas including aspects of media. Journals such as *Popular Music* are devoted to various musical, technical, and sociocultural aspects of the field.

1.9 Some Modern Developments

Summing up developments briefly sketched in the preceding paragraphs, one can say that, by about 1960, areas such as musical acoustics, music theory, and music psychology were established and productive areas of research that yielded many articles in specialized journals as well as a number of monographs and textbooks. For example, the *Journal of Music Theory* was issued in 1957, and a comprehensive book on music perception by Robert Francès appeared in 1958 (for an English translation, see *Francès* [1.132]). While experimental research on perception of musical intervals [1.133] and rhythmic structures [1.110] was continued (largely from a Gestalt psychological perspective), several new areas gained interest, among them sound as a medium for creative work in primarily electronic music, and timbre as a *dimension* relevant for both musical production and perception (see [1.134] and Chap. 32 of this handbook). Further, with the rise of communication and information theory, computers were employed for *experimental music* [1.135] beginning in the 1950s, and information theory soon reached sound and music research [1.136–139]. Since about 1970, computers were widely employed for sound generation as well as composition and analyses of music, often in combination with signal processing methodology (for an overview, see articles in [1.140–143]). The *Computer Music Journal* (founded in 1977) and the *Journal of New Music Research* (formerly *Interface*, founded in 1972) serve an international community of scientists and musicians studying sound and music with computers. Signal processing of course became central in musical acoustics and sound research [1.144], and in particular in physical modeling and design of virtual instruments (there is a large body of relevant publications, many of which are referenced in [1.145, 146]). Further, computers along with special codes have been employed in modeling perception and production of music with artificial intelligence (AI) methodology (e.g., contributions in [1.147, 148]) and by means of artificial neural networks (ANNs) [1.149–151]. In addition, parameters of musical performance, such as tempo and dynamic changes adapted to musical textures and relevant for artistic expression, have been modeled with special software [1.152, 153]. More recently, areas of machine learning, automated music transcription as well as music retrieval and data mining have become large fields of research, partly with practical applications (see chapters in *Klapuri* and *Davy* [1.154] and *Ystad* et al. [1.155] and articles in a special issue edited by *Conklin* et al. [1.156]).

Around 1970, concepts from structural linguistics and semiotics were adapted more frequently to music research, which implies some parallels between natural languages and music. Of course, there are certain analogies that have been stressed long ago (as in concepts of *musical rhetoric* in Renaissance and Baroque music theory and practice [1.157]). Quite many books on *practical* music theory provide rules for creating *well-formed* musical textures (see, for example, [1.158]). Well-formedness of sentences in regard to grammar and syntax of course is a criterion for accurate speech as much as well-formed musical settings should follow the rules of harmony and counterpoint. The analogical relation between speech and musical textures gained a more formal status when *Hauptmann* [1.54] and in particular *Riemann* [1.55, 97] conceived of harmony and musical structure in terms of syntax and grammar, implying musical *sentences* or *propositions* have to conform to *musical logic*. However, the parallel between language and music gained new ground when music was indeed viewed, beginning in about 1950, as a *communication system* and as a *sign phenomenon* that would lend itself to an adaptation of categories developed in linguistics and semiotics. Adaptation of course means one has to establish correspondences in a plausible way between structures in language and music in regard to syntactic, semantic, and pragmatic categories, and it calls also for a definition of sign categories. The discussion of obvious parallels as well as of distinctive differences between language and music was intensive in the 1970s and 1980s (of the many publications, see [1.159–164]). Though it is possible to demonstrate, in a plausible way, how (indexical and other) signs are used to *make sense* in certain genres and pieces of music [1.165], it was found rather difficult to establish semiotics for music in general. One of the reasons probably is that music in most of its forms and contexts in essence seems gestural rather than propositional (see [1.161] and articles in [1.114]). Quite a different matter is that musical analysis cannot avoid language to conceptualize music and to communicate its findings (since it could be a problem to sing or whistle such results to colleagues in music and musicology), a circumstance that *Charles Seeger* [1.166] has called the *linguocentric predicament*.

The linguistic paradigm of generative-transformational grammar [1.167] clearly has been the inspiration for the generative theory of tonal music (GTTM) worked out by *Lerdahl* and *Jackendoff* [1.56]. Their endeavor has been lauded for the vigor with which rules have been set up for an analysis of music into segments pertaining to hierarchical structures, but there has been criticism arguing, for example, that listeners would rather perceive music as a sequence of mean-

ingful units arranged to temporal order than mentally *represent* musical structures like hierarchical tree diagrams. However, GTTM in fact attempts to formulate rules that reflect perceptual and cognitive strategies of the *experienced listener* (in a similar vein, *Riemann*'s musical logic, with a mental representation of music as tonal conceptions (*Tonvorstellungen*, see [1.168]), aimed at subjects with a thorough musical background).

Another problem that became apparent in cognitive music research during the 1980s was that the distinction of *symbolic* and *subsymbolic* in regard to music production and perception may be misleading. The notion of *symbol* and concepts of *symbolic* processing of course have played a major role in semiotics and computer science, from where they were transferred into cognitive sciences including areas of *cognitive musicology* (for a detailed account of concepts, see *Seifert* [1.148]). To be sure, there are definitions of cognition in terms of computation such as: *cognition is symbolic computation* or *cognition is massively parallel numerical computation* [1.169, p. 46], which express a metaphor according to which the *mind* and/or the brain functions in ways equivalent to a computer. Though the *mind-as-computer* idea has been questioned as a suitable model for cognition [1.170], and other metaphors (e.g., *cognition as intuitive inferential statistics* [1.171]) have been shown to reflect methodological tools available to scientists at a certain time turned into explanatory models, this does not necessarily impair their heuristic value. The point of interest here rather is that, in cognitive musicology of the 1980s, descriptions and analyses often refer to scores viewed as a *symbolic* representation of music. By comparison, music as organized sound has been approached as *subsymbolic* so as if it were the mere fundament for a *higher* level of processing: that of cognition directed to analyzing musical structures from scores. This in fact is the time-honored approach of the musical expert who, according to *Riemann* [1.55, 168], apprehends music from carefully *reading* scores. While this might in fact be enough to understand syntactic and formal structures, it is obvious that the score of a work falls short of representing timbral and dynamic parameters in sufficient detail, and that one needs *ears* to perceive and apprehend music in full (in addition, musical sound is suited to eliciting emotional qualities, on a psychophysiological basis). Thus, if music reduced to a score can be called a *symbolic* representation, a live or studio performance including a range of timbral and dynamic shadings as well as subtleties of intonation, phrasing, etc. should be taken as *suprasymbolic* rather than *subsymbolic* (for it yields more than just reading symbols). The signification process in music in fact relates to sound, in the first place [1.172].

With the upswing of the *cognitive sciences* (including a range of computational, psychological, neurological, etc. approaches [1.173]) in the decades beginning by around 1960, a fresh interest in music perception including conceptualizations of music, musical memory, and musical imagery has led to an impressive range of empirical plus theoretical studies. Topics of research included basic structures and schemata of tonal organization, pitch perception and scale formation, melodic contours, memory for pitch and melodic shapes, perception of timbre, rhythm and meter, the role of time and *timing* in the production, performance and perception of music, music as related to bodily movement and gestures, musical form, musical imagery, musical creativity, improvisation (also in jazz and in non-Western music), learning of music (with a focus on cognitive development as well as actual musical training), performance practice (in particular, parameters relevant for expression), emotion and *mood* as related to music, etc. In addition to a large number of articles published in journals such as *Psychology of Music* (founded 1977), *Psychomusicology* (founded 1981), *Music Perception* (founded 1983), and *Musicae Scientiae* (founded 1997), there have been many monographs and anthologies covering specific areas of music perception and cognition or providing an overview of relevant research close to a textbook format. The following list is but a small selection (given the space available for this chapter) from a much broader range of relevant publications. In chronological order, the selection includes [1.174–184], [1.150], [1.185–193], and [1.114].

Among the many developments in experimental and cognitive music psychology, a revival of Gestalt psychology principles (in a modern and expanded approach termed auditory scene analysis [1.194]) seems noteworthy. Also of interest is the more recent rediscovery of the body as part not only of music perception but also cognition [1.193]. As a matter of fact, people tend to synchronize bodily functions such as heart and pulse rate or breathing as well as their movements in walking or dancing to periodic stimuli, and there is entrainment on various levels (see [1.195] and a range of peer commentaries, also [1.196]).

This brings us to a final point in this section, a research area sometimes labeled neuromusicology. It was clear to Helmholtz, Stumpf and other scholars that brain structures were the ultimate stage where sound and music perception as well as cognition (*apperception*) takes place. It was not possible, though, to investigate brain functions in a noninvasive technique before the invention of the electroencephalogram (EEG) (around 1930). Anatomical, neurophysiological and functional studies in regard to sound and music were intensified

in the 1960s and 1970s when handedness and hemispheric dominance as well as music-related disorders and clinical applications of music in therapy became major issues for research (some of which was summarized in [1.197]; see also articles in [1.198, 199]). In the course of the 1980s, measurement of auditory evoked potentials (AEP) was a standard technique, and brain imagery by means of positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) had become available also for research related to sound and music perception [1.200]. Since the 1980s, an enormous amount of research has been done in experimental neuroscience and neuropsychology including studies on music perception and cognition (see articles in [1.201–203], and Part C as well as Chap. 31 of this handbook).

1.10 Systematic Musicology as a Musicological Discipline

Though musicology as an area of research and as a body of knowledge has been established in antiquity, to be continued in modern times (see above), it was only in the 19th century that a discipline under this name became part of European universities. In Germany and Austria, the movement known as *Historismus* (historicism) led to incorporating subjects such as prehistoric archeology, art history and musicology into the philosophical faculties. Musicology had a strong historical and philological orientation (with a focus on European music history, biographies of composers, and scholarly edition of works from various epochs and musical genres according to philological principles), which is obvious from the first professorships that were installed at Prague, Vienna, and Berlin (all in the 1870s). However, by that time a somewhat broader view of musicology had already been pursued by the Belgian composer and musicologist, François-Joseph Fétis (who published also on music theory, and who, in addition to studying European art music, had an interest in genres of folk and even non-Western music traditions). Also, as outlined above (Section 1.6), areas such as musical acoustics and psychoacoustics had been firmly established by about 1860–70, so that the philological and historical approach to music history and performance was paralleled by the scientific study of sound and fundamentals of music including perception and appreciation (Fechner was one of the scholars who had propagated empirical foundations not only for psychology but also for aesthetics [1.204]). So, by about 1880 two different orientations existed side by side, and research in a third area, namely folk and vernacular music traditions in Europe as well as the study of so-called *primitive* music in areas of Africa, Asia, the Americas, and Oceania, was also underway.

When *Guido Adler*, in 1885, opened a new journal devoted to musicology with his programmatic article [1.205], he included already comparative musicology into his synopsis of musicological research fields and subdisciplines. Adler's bipartite scheme of *historic* and *systematic* (the latter including comparative musicology) entailed conceptual decisions [1.50] that relate to ideas of music history viewed in terms of development and *evolution*. In short, the historical branch of research should furnish factual evidence for a *progressive* development of music from modest beginnings to full art as evident in European genres, while the task of finding *governing laws* (as contained in fundamental structures of sound and music) for that *evolution* was assigned to the systematic branch. To complete the picture in regard to geographical and ethnic diversity as well as developmental stratification, comparative musicology would have to provide specimens of music from all around the world, and to put them into some order in regard to musical structures and functions as well as tentative musical development ([1.206] and [1.207] are synopses written from this point of view; see also [1.69]). From Adler's scheme, a tripartite organization of musicology into historic, systematic, and comparative resulted, which in fact had practical consequences far into the 20th century, if not to the present (the unifying ideas behind Adler's scheme were abandoned when, in the 20th century, the all-embracing evolutionary perspective was given up for, first, historical indifference and cultural relativism, and then for various trends of *postmodernism* and emphatic *multiculturalism*).

A significant difference between historic and systematic orientations in musicology in fact was and is that the former worked (and continues to work) predominantly with music as *text* (conventional notations or similar *symbolic* representation), while the latter from the very beginning had a focus on sound and perception [1.93, 150, 172]. Further, systematic musicology, like acoustics, psychoacoustics, and psychology, made use of experimental methodology including statistics. Even *Stumpf*, who argued that it is unreasonable to believe that dozens of unmusical laymen could judge musical items more reliably than any single expert musician or musically experienced researcher, included statistics in his studies [1.118]. In the 20th century, experiments and statistics became an integral part

of music psychology [1.208, 209]. Controlled observation, field work and statistics of course are fundamental also to sociocultural studies conducted by researchers in comparative musicology and ethnomusicology as well as in the field of popular music and jazz.

The division of musicology into historic and systematic subdisciplines, consequent to conceptual and methodological differences [1.50, 210], was put into practice early when, at the University of Vienna, a professorship in musicology was established that, in essence, combined areas of music psychology and comparative musicology. Vienna has maintained a combination of *scientific* and *cultural* research efforts in a specific concept of *Vergleichend-Systematische Musikwissenschaft* [1.211, 212] for a long time, and at Berlin, Stumpf's associate Erich M. von Hornbostel also covered systematic and comparative musicology in his teaching and in his publications. With the decline of comparative musicology due to political and other factors [1.69], and the rise of ethnomusicology as a discipline with a descriptive and *culturalist* rather than a systematic orientation (see [1.213]), a tripartite division into historic, systematic, and ethnomusicology was carried out at a number of universities (e.g., Cologne, UCLA). In academic institutions of the US, music theory also gained relative independence as a musicological subdiscipline (that typically includes analysis of works from European art music, and may include also genres such as electronic and computer music).

The idea of systematic musicology as *fundamental science of music* stems from a combination of several factors. One (that relates to basic concepts of numbers, *counting* and *measurement* as well as directed observation) certainly is of antique heritage; another relates to developments in music theory from around 1400–1750 (as outlined above) that gradually introduced empirical observation and, in particular with Rameau, musical acoustics and perception into music theory. Musical acoustics and psychoacoustics expanded greatly in the 19th century, and with their groundbreaking results demonstrated theoretic and methodological independence of *systematic* areas of research from historic-philological orientations. In a wider sense, musicology thus was one particular field marking the general split of disciplines into sciences and *humanities* (that took place, roughly, between 1800 and 1860). In regard to music research, this split was perhaps unavoidable, though not total since of course music theory and also studies in music psychology often combine aspects from both areas (the *integrative* approach is still evident in Helmholtz's seminal book, where its author offers chapters on music theoretical topics in the main body and – not to embarrass a more general readership – puts the differential equations into appendices to his work).

Notwithstanding trends of professional specialization that led to establishing new disciplines (such as psychology in about 1870–80 and sociology also in the second half of the 19th century), systematic musicology as an area of interdisciplinary research benefited from the many contributions offered by scholars who were located in departments other than music or musicology. Perhaps the closest connections were with acoustics and psychology (but also with experimental phonetics, linguistics, anthropology as well as with medical subjects). A common denominator (which prevails to this day) was that many scientists had training and even thorough experience also as musicians, which often led them into research projects on various aspects of sound and music (e.g., [1.214]).

The division of musicology into subdisciplines and fields of research (as envisaged already by Adler, see above) gained new impetus in the years after WWII, for methodological and practical reasons. First, the differences in perspective (e.g., music as *text* versus music as *sound*, historical versus synchronous [1.215, 216]) as well as in research topics and methodology were too obvious to be overlooked. Second, in order to integrate somehow theoretical and factual knowledge accumulated in the large number of studies on musical sound, music perception and performance as well as on sociocultural contexts that had been published during the past decades, one needed scholars capable of dealing with this matter (and qualified to continue research on a professional level). Therefore, establishment of *systematic musicology* as *fundamental and integrative music science* was proposed [1.217]. While the scientific status of systematic musicology as *fundamental science* was acknowledged by many if not most of the scholars working in musicology, there were opinions that stressed the interdisciplinary relation of historic, systematic and comparative research [1.218], which implied a common disciplinary and institutional umbrella. Third, even if one wanted to maintain a single academic discipline of *musicology*, it was clear that professorships for systematic and comparative musicology/ethnomusicology had to be set up at least in a number of universities, as in fact was done in Germany and in the US (plus the chair that had been established at Vienna decades earlier).

With ongoing specialization in areas such as musical acoustics and music psychology and new areas of research coming up with the advance of electronics and studio technology (and when, not much later, also computers became available to musicologists), historic and systematic musicology had been drifting far apart (with ethnomusicology becoming a largely independent subject that, in many institutions in particular in the US, was closer to anthropology and ethnology than

to the somewhat old-fashioned historic musicology). In view of factual and methodological developments reached in the 1970s, it was only natural to give former musicological *branches* independent disciplinary and organizational status.

At Hamburg, comparative musicology had been installed by about 1930, and systematic musicology was part of regular teaching and research since 1948. In 1975, the University of Hamburg decided to make systematic musicology a *sovereign* discipline and subject that can be studied, with a special curriculum (the introductory textbook in 1976 was from *Vladimir Karbusicky* [1.219]) for a *major*. In addition, students can choose *minor* subjects ranging from the sciences to law and economics as well as to humanities. There are some more universities now that offer systematic musicology as a *major* to be studied in a combination with other subjects, and there are also quite many institutions that offer ethnomusicology in some form. It should be noted that major parts of systematic musicology in some institutions are incorporated into programs with more *modern* designations (referring to *computer*, *sound* or *cognition* in their respective titles). As one may expect, with the development of scientific investigations in areas including sound and music, new designations for special segments have been proposed, for example *psychomusicology* (see journal of same title) or *cognitive musicology* [1.220], in order to delimit a certain approach and field of research (see articles in [1.184] and [1.150]). Others have simply opted for a broad label called *empirical musicology*, which may cover many things (given the range of different meanings *empirical* had in psychology alone since the 19th century [1.83]). Systematic musicology in fact almost always included *empirical* observation and experimental research, however, it also includes theoretical reasoning on natural and cultural foundations of music [1.221, 222] and certainly mathematics and modeling [1.223–225] as part of an interdisciplinary tradition that spans from Archytas to the present.

Part A Musical Acoustics and Signal Processing

Ed. by Rolf Bader

In the Hornbostel/Sachs classification of musical instruments first published in 1914, the instrument families were ordered according to their physical driving mechanism, such as bowed, plucked, or struck instruments. This scheme reflects the nature of systematic musicology, which aims to search for universals in music that govern all musical genres around the world.

Still, musical acoustics itself is much older. Joseph Sauveur (1653–1716), who coined the term acoustics in the sense we use it today, was already sorting vibrating systems in terms of strings, membranes or plates at this time, well in accordance with musical instruments. This also reflects the close correspondence between music, physics, geometry and arithmetic, which was present in ancient times with the Pythagoreans or in the music theory of Archytas of Tarrent (428–347). Music was part of the Quadrivium in Renaissance times, for example in the music theory of Johannes Kepler in his *Harmonices Mundi* from 1619. Music was also often close to mathematics and geometry in the work of mathematicians like Mersenne, Zarlino, Euler or Gauss, philosophers like Rene Descartes or physicians like Hermann von Helmholtz, who in his *On the sensations of tone as a physiological basis for the theory of music* from 1863, was able to derive the Western tonal system from acoustical, physiological and psychological findings.

However, investigations of musical instruments in detail were only prominently carried out first by Felix Savart (1791–1841) on the violin. Savart, known to physicists due to the Biot–Savart law of magnetostatics, also invented an octobass: a huge double bass so high that it needed two floors and two players, one bowing on the first floor and one pressing down the strings on the second. Later, Helmholtz was the first to visualize the sawtooth motion of a violin string by stroboscopy. He and Lord Rayleigh were also among the first to investigate the organ theoretically as well as experimentally.

After World War II research on musical instruments intensified, as is reflected in the work of the *Cutgut Acoustical Society* in England, *the Physikalisch-Technische Bundesanstalt* in Braunschweig or the *Institut de Recherche et Coordination Acoustique/Musique* (*IRCAM*) in Paris and by many individuals mainly in the US, Canada, Europe, Australia and Japan. Other parts of the world where musicological research is performed were concentrating not so much on musical acoustics but more on music ethnology, such as in China or India, although an Indian researcher, Chandrasekhara Venkata Raman (1888-1970) was the first to develop a theory on the bowed string.

Today musical acoustics, which has been growing tremendously over the last decades, is a very active and lively scene with increasing numbers of researchers. The instrument industry, which has always been working in this field in very close contact with researchers, is profiting from the results in musical acoustics, which is also reflected in patents and applications improving instrument quality and design. Indeed many myths about musical instruments are around among instrument builders, and musical acoustics may help here too. Related industries like the software-developing market, which has been building synthesizers and virtual musical instruments in recent years, have increasingly profited from models of musical instruments developed in musical acoustics to realize more realistic-sounding plugins or synthesizers, mainly in the domain of physical modeling.

After about two hundred years of research in musical acoustics, many open questions are still present in the field. The present models, although often sounding very realistic, are still quite restricted to certain instrument types or articulations. A basic understanding of the role of turbulence in wind instruments is an ongoing debate since many researchers, starting from Helmholtz and Rayleigh, found the organ to be a linear system that does not correspond to our understanding of turbulence. The role of forced oscillations in musical instruments and the difference between the eigenmodes of guitar and violin bodies and the forced oscillation patterns found empirically when driving the instrument with strings are also an ongoing debate. Furthermore the radiation of a musical instrument, its dependency on the driving point, or its transient nature are not fully understood yet. The role of material, its stiffness and, maybe even more importantly, its damping, is not yet understood at all. This list could be continued. So not only are details of musical instruments still under debate, but often the basic process of tone production is still discussed.

The reason for these ongoing debates may be seen in the extreme sensitivity of the human ear. We judge the quality of an instrument not by just producing sound at all; we are interested and fascinated by the details of the sound, the range of articulatory possibilities of an instrument, its character and *musicality*. Therefore musical acoustics is a discipline with many open questions and hopefully many fascinating new results in the future.

The present section gives a systematic overview on basics in the field as well as addressing open questions and providing insight into ongoing debates. The choice of topics is also related to the position of musical acoustics in the field of systematic musicology: opening links to signal processing and applications via mathematical

modeling of instruments, music ethnology through discussion of wood properties, basic driving mechanisms or non-Western instruments, or music psychology by discussing timbre- or articulation-related aspects of the instruments. In the end, musical instruments are the source of a musical performance and provide the possibilities a musician might use to express themself. Very often tools become music and improvements to the instruments only triggered new musical styles, sounds and extended techniques.

In Chap. 2 *Wilfried Kausel* gives a comprehensive and systematic mathematical introduction to musical acoustics starting with one-dimensional vibrating systems. After introducing a mass-spring system and deriving complex numbers he considers the wave equation on strings and in ducts including reflections, forced oscillations and impedance. He also discusses stiffness in one-dimensional media and longitudinal vibrations in bars, explaining many mathematical functions in detail as used in musical acoustics on an everyday basis.

Wilfried Kausel then enlarges the one-dimensional picture of Chap. 2 into a two- and three-dimensional one in Chap. 3. He derives and discusses the mathematics of membranes as used in drums or string instruments like the banjo and turns over to stiff two-dimensional geometries like rectangular and circular plates as basic components of stringed instruments. He then gives the basic equations for three-dimensional geometries as cavities or rooms and discusses modes and resonances.

Switching from abstract mathematical models to basic material, in Chap. 4 *Chris Waltham* and *Shigeru Yoshikawa* discuss wood used for musical instruments, mainly for stringed, wind and percussion instruments. After a summary of common tonewoods they discuss many aspects of the relation between wood and the sound of the instrument. They conclude that even if knowledge about wood does not guarantee a high quality sound from the instrument, it still helps to avoid many mistakes and errors in instrument building.

Measuring musical instrument vibrations is nontrivial and *Thomas Moore* in Chap. 5 discusses the techniques used in the field. He discusses the use of microphone arrays in terms of acoustic holography, where the vibrations of radiating musical instrument surfaces are measured using multiple microphones recording the radiated sound, which is then back-propagated to the instrument surface. Another powerful tool introduced is laser Doppler interferometry, where deflections of the instrument surface are measured as phase shifts in a split laser beam. Finally, accelerometer measurements are discussed using piezoelectric crystals attached to the instruments.

Turning then to stringed instruments, *Nicholas Giordano* in Chap. 6 gives a brief overview of pianos, guitars and violins. He introduces the basic differential equations of the instruments while discussing the driving mechanisms, the energy transfer and the modes of vibrations. The paper is rich with many complex and interesting phenomena associated with the instruments, which cannot always be discussed in detail but where the appropriate literature is referenced.

Turning to wind instruments, *Benoit Fabre*, *Avraham Hirschberg* and *Joël Gilbert* in Chap. 7 give an overview of the clarinet, the oboe, the harmonica, the trombone, and the modern transverse flute. The instruments are classified along a general model system consisting of a nonlinear generator and a linear resonator holding as a general principle for the very diverse systems of single and double reed and wind jet instruments. The paper presents models that can easily be implemented as physical models, which can end in sound-producing software tools.

In Chap. 8, *András Miklós* and *Judit Angster* present measurements and a model of the organ pipe. They emphasize the role of the attack transient, the very first beginning of the sound, which perceptually is the most salient part of musical tones in general. The instrument is discussed as a coupled system of a hydrodynamically oscillating air jet and a resonating pipe with wall losses. The measurements of the attack show a complex transient phase known to organ builders as *chiff*, which is known to be a quality criterion for organ pipes.

In Chap. 9, *Andrew Morrison* and *Thomas Rossing* give an introduction to percussion instruments with many examples, as well as theoretical and experimental findings. The drums of a rock or jazz drum set with snare, bass drum and tom-toms are discussed as well as instruments from other parts of the world like Caribbean steelpans, Indian tablas, Chinese stone chimes, Indonesian gongs or Japanese drums. Many laser interferometry measurements of the instruments' eigenmodes are shown and systematic investigations in terms of tuning systems and strike notes are discussed.

Discussing the role of nonlinearities in musical instruments in Chap. 10, *Rolf Bader* distinguishes between nonlinearities that lead to an enhancement of the brightness of musical instrument timbres and those nonlinearities that are crucial for musical tone production. He finds synchronization in harmonic overtone structures in wind instruments as a result of synchronization

within these instruments driven by turbulent damping. Applying this finding to other instrument families, a general understanding of musical instruments as self-organized systems is possible.

The section closes in Chap. 11 with *Michael Vorländer* presenting room acoustics as the link between musical instruments and the audience in a concert hall. He discusses basic aspects of room acoustics while introducing ray-tracing algorithms for modeling concert spaces. Using the resulting impulse response as a filter function for a dry musical signal in a fast convolution algorithm, he shows that the acoustic space can be reproduced in silico, making it possible for architects to estimate the room acoustics during the process of designing a space.

2. Vibrations and Waves

Wilfried Kausel

This chapter deals with vibration and wave propagation under the general assumption that amplitudes are sufficiently small in order to neglect nonlinear effects when vibrations or waves are superimposed. It will be shown how wave equations can be derived for strings, bars and air columns and how analytic results can be obtained for some boundary conditions. This chapter will also review techniques for the calculation of resonance frequencies. Finally an introduction into the analysis of real musical instruments in the frequency domain will be given.

2.1 Vibrations

Musical instruments are built to create sound. The musician typically sets some part of it into vibration and this vibration is coupled to other parts radiating sound waves perceived by a listener. For example, a violinist uses his bow to set a string into vibration. This vibration is coupled to the bridge and from there to the body of the violin. The vibrating plates are large enough to initiate a sound wave propagating in the surrounding air towards the ears of listeners.

The terms *vibration* and *wave* are often not used in a consistent way. Vibration obviously describes an oscillating state, a physical quantity like displacement, velocity, air pressure, or a spatial profile or a deformation, varying periodically around an equilibrium state, which will be reached when no stimulating force is present and after any existing vibration has decayed completely.

The most simple vibrating system is hypothetical. It consists of a point mass and an ideal spring. The vibrating characteristics are displacement, velocity and acceleration of the mass as well as force and displacement of the spring, the latter two being perfectly proportional in an ideal spring. The vibration itself is characterized by the period, which is the time duration of one complete cycle, and its reciprocal value, the frequency, which is the number of cycles per second. Each oscillating quantity has its amplitude, which can be indicated as a peak value or as an RMS value (root mean square integrated over an integer number of periods), which is related to the average power of that quantity.

Waves are characterized by the fact that they propagate at a certain speed. They occur if a medium (or space itself in the case of electromagnetic waves) provides a continuum of infinitesimal small oscillatory systems, which are locally coupled in a way to pass on their own vibrational state to adjacent systems. Waves are characterized by their propagation speed, their amplitude and their wavelength.

In reality vibrations and waves are strongly connected. Looking at a wavy water surface one can ob-

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_2

serve numerous floating particles or froth oscillating up and down. Observing carefully one will recognize that a vibrating string is actually a nearly one-dimensional continuum where perturbances propagate as a wave in both directions until they are reflected at the ends. Vibrating reeds and lips of brass players consist of spatially distributed mass and stiffness and their apparent *vibration* is in fact based on wave propagation along their length and respectively across their surface.

Nevertheless, physicists often successfully treat such systems as hypothetical mass–spring systems, especially if effects due to their vibration-like properties are to be studied and their wave-like behavior can be ignored.

2.1.1 Mass–Spring Systems

A mass–spring system is governed by an equation of motion where any inertial force $F_\mathrm{i} = ma = m\mathrm{d}v/\mathrm{d}t = m\mathrm{d}^2z/\mathrm{d}t^2$ of a point mass m (displacement z, velocity v, acceleration a) is always balanced by a spring force $F_\mathrm{s} = -Ez$, which acts against the inertial force and which has a magnitude proportional to the displacement z with proportionality constant E, known as the *spring constant*. We obtain the linear second-order ordinary differential equation

$$m\frac{\mathrm{d}^2z}{\mathrm{d}t^2} + Ez = 0\,. \tag{2.1}$$

With some good intuition and perhaps some trial and error we find a solution for z (or look it up in any book)

$$\begin{aligned} z_1(t) &= \sin\omega t \\ \frac{\mathrm{d}z_1}{\mathrm{d}t} &= \omega\cos\omega t \\ \frac{\mathrm{d}^2z_1}{\mathrm{d}t^2} &= -\omega^2\sin\omega t\,. \end{aligned} \tag{2.2}$$

Substituting this solution into (2.1) proves the correctness of our initial formulation and yields an expression for the angular frequency $\omega = 2\pi f$

$$\begin{aligned} -m\omega^2\sin\omega t + E\sin\omega t &= 0 \\ \omega &= \sqrt{\frac{E}{m}}\,. \end{aligned} \tag{2.3}$$

As it works with $\sin\omega t$ we are tempted to try the same with $\cos\omega t$

$$\begin{aligned} z_2(t) &= \cos\omega t \\ \frac{\mathrm{d}z_2}{dt} &= -\omega\sin\omega t \\ \frac{\mathrm{d}^2z_2}{\mathrm{d}t^2} &= -\omega^2\cos\omega t\,. \end{aligned} \tag{2.4}$$

We can see that both solutions work in a similar way. Knowing that any linear combination of possible solutions is again a solution, we can formulate a more general solution according to

$$z(t) = A\sin\omega t + B\cos\omega t\,. \tag{2.5}$$

It is often convenient to rewrite (2.5) as

$$z(t) = C\cos(\omega t + \phi) \tag{2.6}$$

thus replacing the linear combination $A\sin x + B\cos x$ by the single harmonic function $C\cos(x+\phi)$ with an amplitude $C = \sqrt{A^2+B^2}$ and a phase angle ϕ satisfying $\tan(\phi + \pi/2) = B/A$.

This result tells us that the displacement of the mass (or the length of the spring) oscillates harmoniously with an angular frequency ω, which only depends on the stiffness E of the spring and the mass m. The amplitude C and the initial phase ϕ can be determined when the initial conditions $z(0)$, the initial displacement, and $z'(0)$, the initial velocity, are known.

Differentiating the solution for $z(t)$ from (2.6) twice gives us solutions for the velocity $v(t)$ and acceleration $a(t)$, both again harmonic functions with the same angular frequency ω but different amplitudes.

$$\begin{aligned} z'(t) = v(t) &= -\omega C\sin(\omega t+\phi) \\ &= \omega C\cos\left(\omega t + \phi + \frac{\pi}{2}\right) \\ z''(t) = a(t) &= -\omega^2 C\cos(\omega t+\phi) \\ &= \omega^2 C\cos(\omega t+\phi+\pi)\,. \end{aligned} \tag{2.7}$$

The amplitude of a sinusoidal velocity at a given frequency ω can be derived by multiplying the amplitude C of the displacement by ω. To get the acceleration a multiplication with ω^2 is required. Each differentiation step shifts the phase by $\pi/2 = 90°$.

Using Euler's formula $\mathrm{e}^{\mathrm{i}x} = \cos x + \mathrm{i}\sin x$ (imaginary unit $\mathrm{i} = \sqrt{-1}$) and $\hat{C} = C\mathrm{e}^{\mathrm{i}\phi}$ (2.6) can be transformed into exponential form (with Re being the real part of a complex number, and complex numbers marked by the superscript symbol ˆ) according to

$$z(t) = \mathrm{Re}(C\,\mathrm{e}^{\mathrm{i}(\omega t+\phi)}) = \mathrm{Re}(\hat{C}\,\mathrm{e}^{\mathrm{i}\omega t})\,. \tag{2.8}$$

It can easily be verified that not only is the real part of the complex exponential from (2.8) a solution of our differential equation but so too is the imaginary part, and even the complex exponential itself

$$\begin{aligned} z(t) &= \hat{C}\,\mathrm{e}^{\mathrm{i}\omega t} \\ \frac{\mathrm{d}z}{\mathrm{d}t} &= \mathrm{i}\omega\hat{C}\,\mathrm{e}^{\mathrm{i}\omega t} \\ \frac{\mathrm{d}^2z}{\mathrm{d}t^2} &= -\omega^2\hat{C}\,\mathrm{e}^{\mathrm{i}\omega t}\,. \end{aligned} \tag{2.9}$$

This makes differentiation and integration very easy and allows for dealing with constant phase differences in a very elegant way. The magnitude of the complex coefficient $\hat{C}$ represents a scale factor for the unit amplitude of $e^{i\omega t}$ and its time-invariant phase angle ϕ adds like an initial phase to any momentary phase of $e^{i\omega t}$.

It should be remembered here that complex numbers are multiplied by multiplying their magnitudes and adding their phases. To only scale an amplitude the complex exponential has to be multiplied with a real number having 0 phase. To only phase shift a complex exponential it has to be multiplied with another complex exponential $e^{i\phi}$, which represents the phase angle ϕ and has a magnitude of unity.

Imaginary Exponents

It is important to understand Euler's correspondence because later on complex exponentials will be used very often to represent harmonic functions of time or space. From the Taylor series expansions we see

$$
\begin{aligned}
e^{z} &= 1 + \frac{z}{1!} + \frac{z^2}{2!} + \frac{z^3}{3!} + \cdots = \sum_{n=0}^{\infty} \frac{z^n}{n!} \\
\cos z &= 1 - \frac{z^2}{2!} + \frac{z^4}{4!} - \cdots = \sum_{n=0}^{\infty} \frac{(-1)^n z^{2n}}{(2n)!} \\
\sin z &= z - \frac{z^3}{3!} + \frac{z^5}{5!} - \cdots = \sum_{n=0}^{\infty} \frac{(-1)^n z^{2n+1}}{(2n+1)!} \, .
\end{aligned}
\tag{2.10}
$$

Euler discovered that the series representing e^{ix} could also be obtained when the series expansions of $\cos x$ and $i \sin x$ are added (published in 1748 [2.1]). This can be easily verified by substituting $z \to ix$ in the first and $z \to x$ in the second and third row of (2.10).

The current notion that a complex number represents a point in the complex plane was developed more than half a century after Euler's formula, and it was *Gauss* in 1831 [2.2] who recognized the importance of that interpretation.

Each complex number has a real part and an imaginary part, which is a multiple of the imaginary unit i. The complex plane has a real and an imaginary axis corresponding to the x and y-axis of other coordinate systems.

The complex term $e^{i\theta}$ with its real part $\cos\theta$ and its imaginary part $\sin\theta$ describes one point on the unit circle in the complex plane (Fig. 2.1). As $\theta = \omega t + \phi$ increases with time t by an interval of 2π the point will describe one full cycle on the unit circle. At time $t = 0$ the momentary phase angle θ is the initial phase angle ϕ.

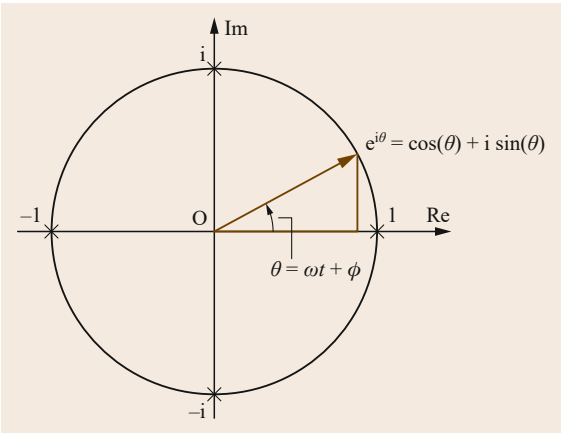

Fig. 2.1 Complex exponentials

We can also say, $\hat{C}\,e^{i\omega t}$ is a rotating pointer in the complex plane. It rotates around the origin as time t increases. Its length $|\hat{C}|$ corresponds to the amplitude of the harmonic function and the pointer's angle with the positive real axis is the momentary phase. The momentary signal displacement is the real part of the pointer. The imaginary part of the results can be simply disregarded. Its mere purpose was to allow the use of exponential terms, which can be differentiated, integrated, and multiplied very nicely.

If $\hat{C}$ is complex and not real then an initial phase at $t = 0$ can be specified. The constant phase angle of the complex amplitude $\hat{C}$ is simply added to the phase of the rotating pointer. A signal with amplitude 10 and 0 phase at $t = 0$ like $10\sin(\omega t)$ can be written as $\mathrm{Re}(-10ie^{i\omega t})$. The complex amplitude $-10i$ scales the signal amplitude from unity and shifts the initial phase by $-\pi/2$. This is necessary because for this case we want to represent $\sin(\omega t)$ and not $\cos(\omega t)$, the real part according to Euler.

The term $e^{-i\omega t}$ itself is a unity pointer, rotating with the same speed but in the opposite direction. If we add $e^{i\omega t}$ and $e^{-i\omega t}$ the imaginary parts always cancel out while the real parts add up. The transition from the complex domain to the domain of real physical quantities and harmonic functions according to (2.8) can therefore also be made according to

$$
z(t) = \frac{C}{2}\left(e^{i(\omega t+\phi)} + e^{-i(\omega t+\phi)}\right) = C\cos(\omega t+\phi) \, .
\tag{2.11}
$$

One very nice outcome of using this transformation is that $de^{i\omega t}/dt = i\omega e^{i\omega t}$ and $d^2e^{i\omega t}/t^2 = -\omega^2 e^{i\omega t}$. This translates differential equations in the time domain into simple algebraic equations.

2.1.2 Forced Vibration

Now we extend the equation of motion for a single mass system (2.1) by adding an external driving force F and a damping force that acts against the inertial force, which is proportional to the velocity $v = \mathrm{d}z/\mathrm{d}t$ with a proportionality constant D

$$m\frac{\mathrm{d}^2 z}{\mathrm{d}t^2} = F - D\frac{\mathrm{d}z}{\mathrm{d}t} - Ez\,. \tag{2.12}$$

The equation of motion (2.12) has been reordered here to make it more clear that any change of momentum (mass times acceleration) is due to a resulting force acting on the mass. The resulting force is the sum of an external driving force F and two other forces, a frictional and an elastic force, both of them resisting the movement.

Assuming a harmonic driving force $F = \hat{F}\,\mathrm{e}^{\mathrm{i}\omega t}$ we can again try the solution given by $z = \hat{Z}\,\mathrm{e}^{\mathrm{i}\omega t}$, $\hat{F}$ and $\hat{Z}$ being complex coefficients determining the amplitude and initial phase of the oscillating force F and displacement z. This leads to an equation for $\hat{Z}$

$$-\omega^2 m\hat{Z} = \hat{F} - \mathrm{i}\omega D\hat{Z} - E\hat{Z} \tag{2.13}$$

with a solution

$$\hat{Z}(\omega) = \frac{\hat{F}}{E + \mathrm{i}\omega D - m\omega^2}\,. \tag{2.14}$$

By substituting $D \to |\hat{F}|/(\omega_0 Q)$ and $\omega \to \omega_0$ into (2.14) it is easy to show that the damping factor D is related to a resonance quality factor Q, which is the amplitude near resonance where $\omega = \omega_0$, according to $Q = |F|/(\omega_0 D)$ with $\omega_0 = \sqrt{E/m}$, the eigenfrequency of the undamped free system according to (2.3).

Amplitude and phase of $\hat{Z}$ have been plotted in Fig. 2.2 for $m = 1, F = 1, E = 1$ and $Q = 5$. It can be seen that there is a maximum near the eigenfrequency ω_0 of the undamped system. At this frequency there is also a phase transition from 0 to $-\pi$. If the damping is low, Q and therefore the resonance amplitude can become very high. On the other hand, when there is high damping and low Q, no resonance occurs but there is still a phase of $-\pi/2$ and an amplitude of Q at $\omega = \omega_0$.

2.1.3 Linearity

In solving the differential equation above we assumed that any resulting displacement had to be a sinusoidal motion at a single frequency, if the stimulus force is sinusoidal at the same frequency. This way all time-dependent terms canceled out and we obtained a resulting amplitude and phase as a function of the stimulus frequency.

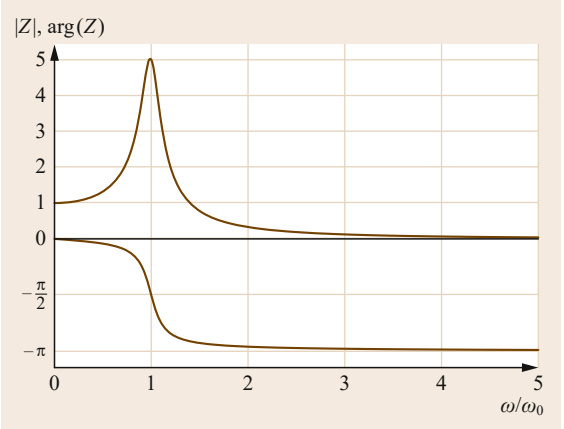

Fig. 2.2 Resonance magnitude and phase

This result seems to be very limited because we know that real systems are not stimulated at a single frequency by a sinusoidal force. The violin bow vibrates a string in a saw-tooth manner, which is far from being sinusoidal. The reed instruments are stimulated by an airflow that is cut off whenever the reed closes the mouthpiece. The same is true for a brass player's lips. In reality there are no sinusoidal stimulus forces! Are our above solutions therefore useless?

Fortunately most real systems are linear, at least, if amplitudes are not too high. This means, that the effect of different stimulus signals can be additively superimposed. As long as any real stimulus signal can be represented by a sum of sinusoidal signals, it is possible to calculate the response to the stimulus components separately and subsequently add them in order to get the system response to a real stimulus.

This is exactly how a frequency domain solution is applied. Any periodic signal F (e.g., sawtooth, rectangular, pulse train or any other repetitive shape) can be represented by a weighted sum of strictly harmonic sine or cosine components (partials) at integer multiples of the fundamental frequency $\omega = 2\pi f$.

This is called Fourier decomposition and can be described according to

$$F(\omega t) = \sum_{n=0}^{\infty} A_n \sin(n\omega t) + B_n \cos(n\omega t) \tag{2.15}$$

or

$$F(\omega t) = \sum_{n=0}^{\infty} C_n \cos(n\omega t + \phi_n) \tag{2.16}$$

which is equivalent if $\tan(\phi_n + \pi/2) = B_n/A_n$ and $C_n = \sqrt{A_n^2 + B_n^2}$.

With Euler's formula and $D_n = C_n e^{i\phi_n}$ we can also write

$$F(\omega t) = \mathrm{Re}\left(\sum_{n=0}^{\infty} D_n e^{in\omega t}\right). \tag{2.17}$$

Knowing the coefficients D_n of the frequency components of any periodic stimulus signal, it is possible to use the frequency domain solution to determine the response to all the partial stimulus components and add them together to obtain the real world system response. The coefficients D_n of the Fourier-series representation of any periodic signal $s(t)$ with a period T can be calculated according to

$$D_n = \frac{1}{T}\int_{t_0}^{t_0+T} s(t) e^{\frac{-i2\pi nt}{T}} dt \tag{2.18}$$

or obtained from a mathematics handbook.

We mentioned before that linearity can be assumed as long as amplitudes are not too high. But what are the limits? Let us look at the single mass–spring system. The spring was characterized by the proportionality between force and length change ΔL of the spring. But this proportionality no longer exists when the spring is significantly deformed. At the extreme when the spring wire is completely straightened, the length will no longer change at all. If we still increase the force the wire will yield and eventually break. The stiffness of the spring obviously depends on how much it has already been elongated or compressed.

Figure 2.3 shows the dependency between length and force of a real spring. It starts to become nonlinear at a certain compression and elongation. Similar curves are valid for elastic fluids or solids. Wood, for instance, is only elastic between certain limits. Beyond these limits it becomes very stiff until it breaks.

Even air loses its ideal elasticity if the pressure becomes so high that the resulting local temperature increase can no longer be neglected. The latter effect contributes to the nonlinear wave steepening in brass wind instruments, which is known to even create shock waves at the fortissimo level [2.3].

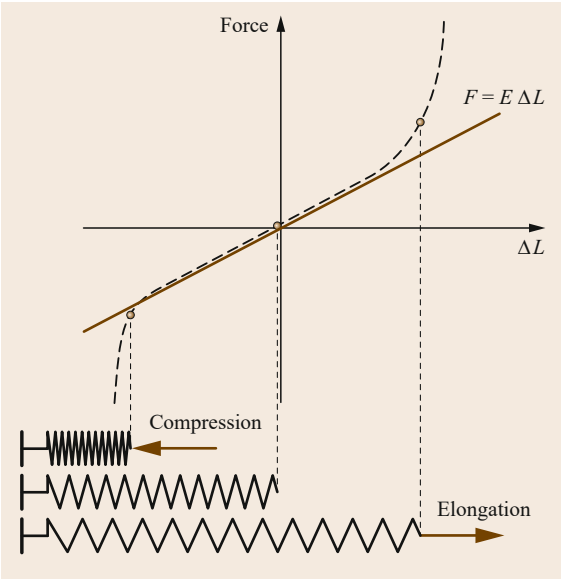

Fig. 2.3 Linearity range of spring

Linearity is also jeopardized when there are collisions with other solid objects, for instance, when amplitudes exceed a certain threshold. This can occur when strings collide with the fingerboard or reeds with the mouthpiece.

Once linearity is lost simple frequency domain solutions can no longer be obtained. Systems will respond with new frequency components that are not part of the stimulus signal, but which typically form higher harmonics of the stimulus partials. This effect is called nonlinear distortion. Subharmonics and other combination tones can also be created, which is called intermodulation distortion.

2.2 Waves

As previously explained, waves are coupled vibrations, distributed and propagating in one, two or three dimensions. If these distributed mass points oscillate in a direction parallel to the direction of wave propagation then this kind of wave is called a longitudinal wave. Waves of this type are often referred to as compressional waves. Sound waves in a medium with low viscosity like air are typical examples for this wave type.

In materials where significant shear forces can occur, for example in solids, local oscillations may also be perpendicular to the direction of wave propagation. Such waves are referred to as transverse waves or shear waves. Waves on strings, membranes or, most typically, on a water surface are examples of such types of waves.

Electromagnetic waves, such as radio waves or light waves, are also transverse waves because oscillating electric and magnetic field vectors are both perpendicular to the overall propagation direction. Nevertheless, there remains another degree of freedom due to the ax-

ial symmetry of a light beam. If there is a single plane containing all oscillating field vectors then the electromagnetic wave is said to be linearly polarized. The acoustical equivalent is a vibrating string with all string segments oscillating in the same direction, for instance vertically to the soundboard, such as the case for a piano string having just been struck by the hammer. During decay this polarization plane can rotate after some time and change from the vertical to the horizontal. This often happens in pianos or guitars and causes the very characteristic shape of their decay curve.

For the sake of completeness it should be mentioned that light or other electromagnetic waves can also exhibit circular polarization. This means that the field vectors no longer oscillate but rotate around the axis at a certain angular velocity depending on the wave length. Such a wave phenomenon can also be observed on vibrating strings, however, it does not seem to have much significance in musical acoustics. The more general elliptic polarization is somewhere between linear and circular polarization.

In addition to longitudinal and transverse waves, as described above, there is also another type of wave. In these waves, the microscopic oscillation has the characteristic of a rotation around an axis. If this rotary oscillation propagates along this axis, this kind of wave is usually referred to as torsional wave. Such kind of waves can be observed on bowed violin strings although their acoustic effects are clearly of higher order compared to dominant transverse waves.

Huygens [2.4] formulated his well-known principle that every point of such a continuum reached by a wave front is a source of a new bidirectional (1-D), circular (2-D) or spherical (3-D) wave front. The overall wave pattern can always be obtained as the superposition of all such secondary wavelets.

Superposition requires linearity as already discussed in the previous section. If sound waves – just like waves in general – have very small amplitudes, which means that the periodic fluctuations of the related physical quantities are small compared to their quiescent value, then oscillations can be treated as minor perturbations of the equilibrium state of a medium. On that condition second and higher-order terms can be neglected and a purely linear system can be assumed.

In such a system waves caused by different stimuli can be superimposed additively and complex wave shapes can be analyzed by decomposing them into single simpler shapes, called modes, attributed to a single stimulus. Linear systems also exhibit the property of scalability, that means, if a stimulus is scaled in amplitude then the response will be scaled by the same factor.

The superposition principle can therefore be applied to wave shapes in space and not only to stimulus and response signals in the time domain.

If we take a spatial snapshot of a steady state wave excited by a nonsinusoidal stimulus at any given time point t, the superposition principle allows us to decompose the observed deformation profile into a weighted sum of profiles, which would occur if the system had been separately stimulated by the sinusoidal frequency components of the composite stimulus.

Even transient wave phenomena can be additively superimposed if the system is linear. A stone thrown into the water will trigger circular wave fronts propagating radially from the center. A second stone thrown nearby will create a completely independent wave pattern. Here where the two patterns overlap, the total displacement of the water surface will simply be the sum of the wave displacements caused by the two independent events.

2.2.1 Reflection

Usually waves do not propagate in an infinite medium. Sooner or later they will reach a boundary where a certain condition of the wave is enforced. For instance, any transverse displacement of a vibrating string will be forced to 0 if the end of the string is rigidly mounted. In the same way longitudinal oscillation of air molecules will be forced to 0 at any rigid wall hit by the wave.

On the other hand, transverse water waves can also be observed to double in amplitude at a quay wall, which throws them back or reflects them, to use the terminology of physics. The same will happen to an acoustic sound pressure wave striking against a sufficiently large wall perpendicular to the direction of sound propagation.

This can be qualitatively and quantitatively understood when the superposition principle is considered. What we physically observe is the superposition of a forward traveling wave and a backward traveling wave, which is created at the boundary of the wave medium by reflection.

Obviously there are two kinds of reflection: one that extinguishes the original wave at the boundary and another one that doubles its amplitude. The first one is called *reflection at the closed or fixed end* and the second is called *reflection at the open end*.

The difference between the two types is the sign of the reflected wave. In the first case the reflected wave has the opposite direction and opposite sign from the impinging wave. Both components will therefore compensate each other at the boundary. In the *open end* case the reflected wave has the opposite direction but same

sign. Both components will interfere constructively and therefore double the amplitude at the boundary.

In reality there are many more than just these two types. Everything in between these extremes is possible. The realistic case is that a part of the incoming wave will pass through the boundary while only the remaining part will be reflected.

This so-called scattering at boundaries or discontinuities is commonly described by a complex factor known as the *reflectance*. Its magnitude, the reflection factor, as well as its phase are frequency dependent. The phase can be anything between 0 (reflection with same sign) and π (reflection with opposite sign).

2.2.2 Standing Waves

For establishing a resonance at least two reflections are needed. Primary resonances usually occur between two reflecting boundaries. Waves can recirculate between the boundaries until their energy is dissipated by non-ideal reflection conditions or propagation losses due to inner or outer friction usually subsumed as *damping*.

If the distance between those boundaries is such that a wave after a complete round trip has again the original phase then constructive interference takes place during recirculation and a standing wave of maximum amplitude is observed. The formation of standing waves therefore requires a certain relationship between the round trip distance, the wavelength, and the type of reflection on both sides. A standing wave is characterized by alternating regions of minimum and maximum wave amplitude, so-called nodes and antinodes, which do not move in space.

As wavelength $\lambda = c/f$ is a function of frequency f the condition for the occurrence of standing waves will – for a given wave propagation or phase speed c – only be met at a certain number of frequencies called resonance frequencies. As reflection at a fixed end inverts the wave, it has the same effect as an increase of the round trip distance by half a wavelength.

This leads us to the lowest air resonance f_0 (*fundamental frequency*) of a tube with length L, which is closed on one end and open on the other. A clarinet with all tone holes closed, for instance, corresponds to this case, as it is a roughly cylindrical tube, closed by the reed on the mouthpiece side and open on the other side. Reflection at one of the ends already inverts the wave, so we need to invert just one more time during a round trip in order to satisfy the reinforcement condition required by resonance.

The round trip distance $2L$ must therefore be equal to half a wavelength. The length therefore corresponds to a quarter wavelength or $\lambda = 4L$, from which the fundamental frequency $f_0 = c/4L$ can be calculated. Higher resonances at frequencies f_n will require that $2L = \lambda/2 + n\lambda$ or $f_n = c(2n+1)/4L$. This leads to a sequence of higher resonances with frequencies of 3, 5, 7, ... times the fundamental frequency f_0 and explains why clarinets overblow into the twelfth (three times f_0) and why their sound does not contain many harmonic components at even multiples of f_0.

Flutes are cylindrical tubes with two open ends. The round trip distance $2L$ must therefore correspond to any multiple of a complete wavelength λ, which results in a fundamental frequency $f_0 = c/2L$, one octave higher than for a clarinet of the same length. The frequencies of higher resonances can be calculated from $f_n = (n+1)c/2L = (n+1)f_0$, which leads to a sequence of overtones at 2, 3, 4, ... times the fundamental frequency. This explains why flutes overblow into the octave and why their sound does contain odd and even multiples of the fundamental.

The same equations apply to vibrating strings fixed at both ends, which enforces displacement nodes at the bridge and nut. However, the propagation speed c of a transverse wave on a taut string is much different from the sound speed in air, and it strongly depends on string tension and mass. Higher resonances of vibrating strings are called *flageolet notes* and they will also sound at 2, 3, 4, ... times the fundamental frequency.

The assumption that strings are fixed at both ends or that sound waves are perfectly reflected at an open end or at the mouthpiece side of trumpets or clarinets, where those instruments are more or less closed by the player's lips or by the reed, is not at all justified in real instruments. Anyhow, it is good to understand the idealized case before starting to analyze more realistic conditions.

Resonances in two-dimensional objects like circular membranes (timpani, banjo resonator) are important but nevertheless much more difficult to model analytically. In order to analyze the quality of real sound boards and complete resonators of stringed instruments or even concert halls, numerical methods and adequate computational capacity are required.

2.2.3 Linear Regime

Whether the linearity assumption is valid for any real world system can be examined by stimulating that system with a sinusoidal signal at a certain frequency. If frequencies different from the stimulus frequency can be observed in steady state – typically higher harmonics generated by a kind of nonlinearity like collision or saturation effects – then the system is not linear.

In the nonlinear case system responses will also no longer be perfectly proportional to the stimulus amplitude. In acoustics and structural mechanics linearity

will usually be observed for small amplitude stimulus signals and will gradually degrade when stimulus amplitudes tend to exceed a certain *linear* range often called the *linear regime* of a system.

However, it has to be noted that the linear regime has very blurred boundaries, and even at small amplitudes nonlinear effects like wave steepening can accumulate over greater distances and eventually become notable [2.5]. Wave steepening occurs when the wave propagation speed depends on the wave variable. It is responsible for the steepening and breaking of water waves near the shore.

2.3 Wave Equations 1-D

Wave propagation is omnipresent in music acoustics. In this section it will be shown how different mechanisms related to sound generation and propagation in musical instruments can be described analytically.

The derivation of practically useful analytic expressions could (and should) start from the fundamental laws of fluid dynamics or structural mechanics. The many terms of these conservation laws need to be carefully inspected in order to find out which ones may safely be neglected under certain conditions and which ones need to be taken into account. The symmetry of the problem and its degrees of freedom have to be considered and an appropriate coordinate system has to be chosen. With this approach a system of much simpler equations can usually be obtained which sometimes, but not always, has a chance of being solved analytically.

However, this systematic approach is not followed here because it requires much prior knowledge in physics and mathematics and it does not necessarily lead to an intuitive understanding. Instead, it will be demonstrated here, how the same results can be obtained by studying simple one-dimensional problems and applying obvious fundamental laws in a heuristic way.

It will be shown that the analytic treatment of vibrating strings, oscillating air columns, longitudinal waves in solids and even torsional waves will lead to structurally very similar expressions. This class of differential equations are called *wave equations*.

The analytic and numerical solution of the obtained wave equations and its practical implications will be dealt with in a following chapter of this book.

2.3.1 Transverse Waves on Strings

Chordophones are characterized by a sound generation mechanism based on vibrating strings. An analytic description of vibrating strings does not primarily depend on how the string is excited. Whether the string is plucked, struck by a hammer or bowed, string resonances and possible vibration modes can be calculated in the same way.

There are differences between thin guitar and heavy piano strings due to different stiffness and mass distribution but for now we are going to ignore such effects to keep things as simple as possible. We even ignore the primary purpose of vibrating strings in musical instruments, which is to transmit sound energy through the bridge to the resonator in order to radiate sound.

We will first study an infinitely thin, perfectly flexible string with no inner or outer friction losses and with a constant mass distribution along its length. The string displacement is assumed to be very small compared to the string length so that the tension does not change when the string is displaced.

Figure 2.4 shows a string taut between two fixed points on the x-axis. The highlighted segment represents an infinitesimal small segment of length $\mathrm{d}s \approx \mathrm{d}x$ located at segment position x. The big arrows labeled with T are the stretching and restoring forces, which are caused by the tension of the string. The local string displacement at the left side of the segment is y and at the right side $y + \mathrm{d}y$.

The segment slope gradually changes from $y' = \partial y/\partial x$ at the left side to $y' + \partial^2 y/\partial x^2 \mathrm{d}x$ at the right side of the segment. The curvature $\partial^2 y/\partial x^2$ multiplied with the segment length $\mathrm{d}x$ gives the change in slope across the segment.

The slope is important because it determines the y-axis component of the tension force T on both sides of the segment. The resulting force in the y-direction is the sum of the y-axis components of the tension forces T left and right of the segment, and this is T times the difference in slope due to the opposite direction of T at both sides of the segment.

The *equation of motion* (2.19) shows how the resulting driving force on the right side counteracts the

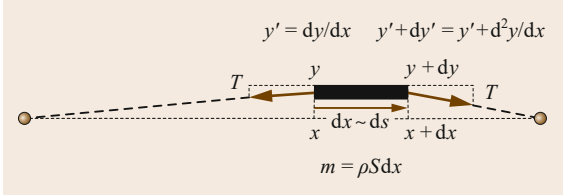

Fig. 2.4 Transverse wave on a string

inertial force on the left side,

$$m\frac{\partial^2 y}{\partial t^2} = T\frac{\partial^2 y}{\partial x^2}\mathrm{d}x\,. \tag{2.19}$$

The assumption that tension T does not depend on the displacement y is only justified for very small displacements. It is known from experience that a guitar string after having been plucked strongly will drop in pitch as the amplitude decays. The initially higher pitch is because of the increased tension that comes with large displacements.

With segment mass $m = \rho S\mathrm{d}s \approx \rho S\mathrm{d}x$, ρ being the mass density and S the cross-sectional area, we obtain (2.20), which is the wave equation for the ideal string. $T/\rho S = c^2$ determines the phase speed of a transverse wave along the string,

$$\rho S\frac{\partial^2 y}{\partial t^2} = T\frac{\partial^2 y}{\partial x^2}\,. \tag{2.20}$$

2.3.2 Plane Waves in Air

Sound waves in air with plane or at least almost plane wave fronts can be observed at large distances from a point source or inside a straight duct with constant cross-sectional area. The latter case corresponds to the interior of cylindrical sections of brass wind instruments and to certain cylindrical wind instruments, like flutes and clarinets.

The importance of the plane wave model is due to the fact that wind instruments with arbitrary bore profiles can be treated as a sequence of short cylindrical slices with discontinuities in the cross-sectional areas in between them. This is called *stepped tube* discretization and allows to model wave propagation in any real wind instrument in a relatively realistic way.

It turns out that the influence of bends on acoustical characteristics is small and even the actual cross-sectional shape does not largely matter, so it is usually sufficient to only deal with the cross-sectional area. It may seem surprising, but even the vocal tract of singers, the cavity between vocal folds and lip orifice and respectively nostrils, is usually modeled by an approximately 17 cm long straight stepped tube consisting of cylindrical slices.

Figure 2.5 shows an infinitesimal small segment of an arbitrary acoustical wave guide. As we are dealing with a longitudinal wave now, the particle displacement ξ and the fluid velocity v are parallel to the x-axis, the direction of wave propagation. The length of the segment is $\mathrm{d}x$ and the corresponding air mass $m = \rho S\mathrm{d}x$, ρ being the air density, S the cross-sectional area, and $\mathrm{d}x$ the infinitesimal length of the segment.

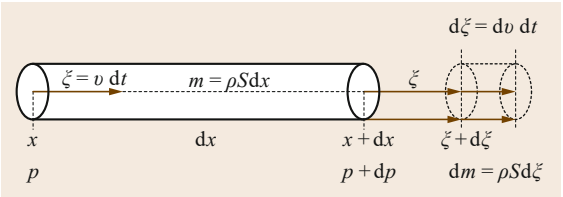

Fig. 2.5 Longitudinal plane waves in air

This air mass is accelerated by the pressure force $-S\mathrm{d}p$, which is the difference between the pressure forces at the left and right side of the segment. The negative sign comes from the fact that a positive $\mathrm{d}p$ (right side pressure is higher than left side pressure) will accelerate the air towards the left side. The equation of motion is therefore

$$m\frac{\partial^2 \xi}{\partial t^2} = -S\mathrm{d}p\,. \tag{2.21}$$

With $v = \partial\xi/\partial t$ we can write

$$\rho\frac{\partial v}{\partial t} = -\frac{\partial p}{\partial x}\,. \tag{2.22}$$

Now we need to focus on the pressure p. The fundamental law of fluid dynamics $pV^\kappa = \text{const.}$ (with volume V and $\kappa = C_\mathrm{p}/C_\mathrm{V}$, the ratio of heat capacitances C at constant pressure and constant volume), which is valid for adiabatic processes and ideal gases, gives us a relation between pressure p and mass density $\rho = m/V$,

$$pV^\kappa = p_0 V_0^\kappa\,, \tag{2.23}$$

$$\frac{p}{\rho^\kappa} = \frac{(p_0+\hat{p})}{(\rho_0+\hat{\rho})^\kappa} = \frac{p_0}{\rho_0^\kappa}\,. \tag{2.24}$$

With p_0, V_0 and ρ_0 we designate the atmospheric equilibrium conditions while $\hat{p}$ and $\hat{\rho}$ represent small time varying quantities, treated as minor perturbations of the equilibrium state hence

$$\frac{p_0+\hat{p}}{p_0} = \left(\frac{\rho_0+\hat{\rho}}{\rho_0}\right)^\kappa\,. \tag{2.25}$$

A first-order approximation $\hat{p} = \hat{\rho}\partial\hat{p}/\partial\hat{\rho}$ for $\hat{p} << p_0$ and $\hat{\rho} << \rho_0$ yields the proportionality between p and ρ

$$\hat{\rho} = \hat{p}\frac{\rho_0}{\kappa p_0}\,. \tag{2.26}$$

We need this proportionality because the continuity equation describing the conservation of mass relates a density change with a velocity gradient $\partial v/\partial x$ according to

$$\frac{\partial\rho}{\partial t} = -\rho_0\frac{\partial v}{\partial x}\,. \tag{2.27}$$

Equation (2.27) states that any increase or decrease in density $\rho = mV^{-1}$ per second must be due to a velocity gradient, which decreases or increases the fluid volume $V = S\mathrm{d}x$ over time by $\mathrm{d}V = S\Delta v\mathrm{d}t$ because its right boundary travels faster or slower than its left boundary. The mass in that fluid element must be constant (for continuity). With $\Delta v = \partial v/\partial x\,\mathrm{d}x$ we obtain the volume change rate $\mathrm{d}V/\mathrm{d}t = S\partial v/\partial x\,\mathrm{d}x$. Using $\mathrm{d}\rho/\mathrm{d}t = (\mathrm{d}\rho/\mathrm{d}V)(\mathrm{d}V/\mathrm{d}t)$ and $\mathrm{d}\rho/\mathrm{d}V = -mV^{-2}$, (2.27) can be derived without difficulty.

Differentiating (2.22) with respect to x and differentiating (2.27) with respect to t will allow to eliminate the v related terms. Substituting ρ according to (2.26) leads to the wave equation for the sound pressure p

$$\frac{\partial^2 p}{\partial t^2} = \frac{\kappa p_0}{\rho_0}\frac{\partial^2 p}{\partial x^2}\,, \tag{2.28}$$

where $\kappa p_0/\rho_0 = c^2$ determines the phase speed of a longitudinal plane wave.

Differentiating (2.22) with respect to t and differentiating (2.27) with respect to x and substituting ρ according to (2.26) will allow to eliminate the p related terms. This leads to the wave equation for the sound velocity v

$$\frac{\partial^2 v}{\partial t^2} = \frac{\kappa p_0}{\rho_0}\frac{\partial^2 v}{\partial x^2}\,. \tag{2.29}$$

The phase speed of the sound velocity wave is, as expected, the same as for the sound pressure wave.

Equation (2.22) gives us a relation between the pressure p and fluid velocity v. If we assume the pressure $p(x,t) = A\,\mathrm{e}^{-\mathrm{i}kx}\mathrm{e}^{\mathrm{i}\omega t}$ to be a forward traveling harmonic wave function then the partial derivative with respect to x is $p_\mathrm{x} = -\mathrm{i}kp$. If the pressure is harmonic then the velocity must be harmonic also. From $v(x,t) = C\,\mathrm{e}^{-\mathrm{i}kx}\mathrm{e}^{\mathrm{i}\omega t}$ follows $v_\mathrm{t} = \mathrm{i}\omega v$. Substituting both p_x and v_t in (2.22) yields $\rho\omega v = kp$. With $k = \omega/c$ we obtain

$$\rho c = \frac{p}{v}\,. \tag{2.30}$$

A backward traveling pressure wave according to $p(x,t) = B\,\mathrm{e}^{\mathrm{i}kx}\mathrm{e}^{\mathrm{i}\omega t}$ would yield $p_\mathrm{x} = \mathrm{i}kp$, eventually resulting in $\rho\omega v = -kp$. This reminds us to draw opposite velocity arrows for the forward and backward traveling waves in order to keep the characteristic impedance of the medium $Z_0 = p/v = \rho c$ positive in both cases.

2.3.3 Longitudinal Waves in Solids

Longitudinal waves in piano strings are widely known to be an issue as they are clearly audible and generally not related to the normal harmonic spectrum of the string. Piano makers had to spend a lot of effort to control the pitch of longitudinal string modes in a way to let them match one of the harmonic overtones.

Longitudinal waves are stimulated by the hammer because any local transverse displacement is inevitably connected to a local length strain, which propagates as a longitudinal wave. The nonlinear coupling of transverse and longitudinal waves generates a wealth of so-called *phantom partials* contributing to the specific piano timbre especially in the lower registers [2.6, 7].

The difference between longitudinal waves in fluids and solids is small, so Fig. 2.5 may as well serve as a template for the treatment of longitudinal waves in solids, like strings and thin bars. Equation (2.21), the equation of motion, is again the starting point for the derivation. Instead of the air pressure p and the air pressure difference $\mathrm{d}p$ we have the stress due to the relative length change given by $f/S = E\partial\xi/\partial x$, f being the force and E the Young's modulus or a spring constant.

A difference between the right and left-sided stress $\mathrm{d}f/S = E\partial^2\xi/\partial x^2\,\mathrm{d}x$ will accelerate the mass $m = \rho S\mathrm{d}x$ like $\mathrm{d}p$ does in fluids.

This leads again to a wave equation for the displacement ξ according to

$$\frac{\partial^2 \xi}{\partial t^2} = \frac{E}{\rho}\frac{\partial^2 \xi}{\partial x^2} \tag{2.31}$$

with a phase propagation speed $c = \sqrt{E/\rho}$.

2.3.4 Torsional Waves in Bars

Torsional vibrations are not very common in musical acoustics but there are certain cases where they have some significance. Bowed strings, for instance, are stimulated into torsional vibrations especially during transients like onset and bow change. This has considerable influence on minimum bow force and other parameters of the bow–string interaction [2.8].

It is known that free reeds and even beating reeds, like clarinet or saxophone reeds, do have a certain inclination to exhibit torsional vibration modes. However, players try to avoid those modes during normal playing because they do not sound nice. Investigations imply that resistance against torsional vibrations is related to subjective quality measures [2.9].

Torsional waves in bars or rods can be treated very similarly to compression waves. Mass m translates to a polar moment of inertia $\rho I_\mathrm{p}\mathrm{d}x$, acceleration translates into angular acceleration $\partial^2\theta/\partial t^2$, and the driving force is the net torque $\partial T/\partial x\,\mathrm{d}x$ acting on an infinitesimal small segment of length $\mathrm{d}x$ (refer to Fig. 2.6).

The torque T is related to the twist angle θ by $T = J\partial\theta/\partial x$, with $J = GK_T$ being the torsional rigid-

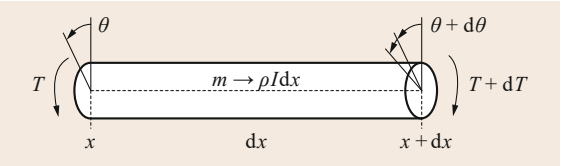

Fig. 2.6 Torsional waves in a rod

ity, a product of the shear modulus G and a geometry factor K_T.

The wave equation for the angular displacement, the twist angle θ of torsional waves becomes

$$\frac{\partial^2\theta}{\partial t^2} = \frac{G K_T}{\rho I_\mathrm{p}} \frac{\partial^2\theta}{\partial x^2} \,. \tag{2.32}$$

The phase propagation speed is $c = \sqrt{G K_T/\rho I_\mathrm{p}}$.

The shear modulus G is often related to the Young's modulus E and Poisson's ratio ν according to $G = E/(2+2\nu)$. K_T/I_p is related to the geometric shape of the cross-section. According to [2.10] it is approximately 1 for a circular cross-section or a circular tube, 0.92 for a square, 0.74 for a rectangle with width $w = 2h$ and $2h/w$ for plates with a width w more than 6 times the height h.

Moment of Inertia

The polar moment of inertia of any plane shape with respect to a certain point is its resistance against being twisted around an axis through that point perpendicular to the plane. Each area element $\mathrm{d}A$ inside the boundaries of that shape contributes a certain inertial force $\mathrm{d}F$ causing an inertial moment $\mathrm{d}M = r\mathrm{d}F$, r being its distance from the rotation center.

The inertial force $\mathrm{d}F$ depends on the mass of that element and its acceleration $\mathrm{d}v/\mathrm{d}t$. A certain angular acceleration $\mathrm{d}^2\theta/\mathrm{d}t^2$ will accelerate a point mass in a tangential direction, but the physical acceleration will not be equal to the angular acceleration because the tangential displacement is proportional to the radius r. Therefore we obtain the relation $\mathrm{d}v/\mathrm{d}t = r\mathrm{d}^2\theta/\mathrm{d}t^2$. Physical and angular acceleration will only be identical for a radius of 1 m because there the arc length in meters and the angle θ in radians are the same.

If the mass distribution over area, the area density ρ_A, is constant it makes sense to just consider the shape. The polar moment of inertia of a massless plane shape is therefore the area integral, a two-dimensional sum, over the contributions of all area elements inside the boundary

$$I_\mathrm{p} = \frac{1}{m}\int \mathrm{d}M = \int_\mathrm{A} r^2 \mathrm{d}A \,. \tag{2.33}$$

2.3.5 Transverse Waves on Bars

Figure 2.7 shows a small section of a bar, thick enough to provide a shape restoring force due to its inner bending stiffness. This makes the main difference from a perfectly flexible string, which has no shape restoring force other than the tension forces acting at the two ends.

The case of a string without stiffness is an ideal situation just like a bar without any external forces. At least gravity and bearing or clamping forces will act on any real bar. Although it is enlightening to deal with ideal cases, practically we will always have to work with combinations and with violations of simplifying assumptions.

Let us think of the bar as if it were a bundle of thin independent wires with quadratic cross-sections and 0 stiffness glued together at least at both ends. If we try to bend the bar then the outer wires will be stretched while the inner wires will be compressed. It is obvious that there is also a central layer of wires, which will be bent but do not change their lengths.

Regardless of the actual cross-sectional shape of the bar, the length change and therefore the strain of the wires only depends on their distance r from the central axis. So we can also think of the bar as a composite with many thin layers without stiffness characterized by their distance from a central layer containing the axes of all cross-sections.

By bending, each slice will be deformed in a way that the left and right boundaries are no longer parallel. This angle $\mathrm{d}\theta$ is related to the curvature of the center line. The slope of the center line is $\partial y/\partial x$ and if there is a curvature $\partial^2 y/\partial x^2$ then the difference in slope between the left and right boundary is $\partial^2 y/\partial x^2 \mathrm{d}x$. If the angle is small then $\tan\theta \approx \theta$, so $\tan(\theta + \mathrm{d}\theta) - \tan\theta \approx \mathrm{d}\theta$.

If we multiply $\mathrm{d}\theta$ with r we get an arc length that is the length change of the layer at distance r from the axis. The relative length change or strain $r\mathrm{d}\theta/\mathrm{d}x$ of a single filament at distance r to the center layer is proportional to the related force. Note that the deformation is small so we can approximate the actual arc length

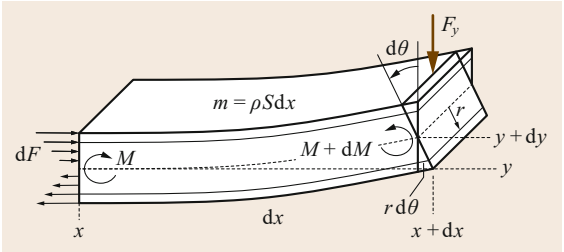

Fig. 2.7 Bending of a bar

of the central layer ds by dx. With Young's modulus E as the proportionality factor the force contribution is then $\mathrm{d}F = E r \mathrm{d}\theta/\mathrm{d}x$. The contribution to the total bending moment $\mathrm{d}M = r\mathrm{d}F = Er^2\mathrm{d}\theta/\mathrm{d}x$.

Now we need to sum up over all contributions to obtain the total moment acting on the cross-section S. Compression forces above and expansion forces below the bending axis have opposite orientation but they act in the same sense of rotation, so if r is always a positive distance, length change, strain, force and moment will always be positive and sum up correctly. The total moment at a cross-section S is therefore $M = \int_\mathrm{A} \mathrm{d}M\mathrm{d}A = E\mathrm{d}\theta/\mathrm{d}x \int_\mathrm{A} r^2\mathrm{d}A$.

Following the derivation of (2.33), it should be straight forward to derive an axial moment of inertia I_a for the cross-sectional area with respect to a bending axis

$$I_\mathrm{a} = \frac{1}{m}\int \mathrm{d}M = \int_\mathrm{A} r^2 \mathrm{d}A \,. \tag{2.34}$$

Again the variable r designates the radius of rotation, but this time it is the shortest distance to the axis because the axis is in the plane of the rotating shape.

For a rectangular bar with thickness h and width w we obtain $I_\mathrm{a} = wh^3/12$. For a circular rod with radius r we obtain $I_\mathrm{a} = r^4\pi/4$ and for a tube with inner radius r_i and outer radius r_o we obtain $I_\mathrm{a} = (r_\mathrm{i}^2 + r_\mathrm{o}^2)(r_\mathrm{o}^2 - r_\mathrm{i}^2)\pi/4$.

With this axial moment of inertia I_a and the substitution $\mathrm{d}\theta \to \partial^2 y/\partial x^2\,\mathrm{d}x$ we obtain $M = I_\mathrm{a} E \partial^2 y/\partial x^2$.

This moment depends on x and may therefore not be the same at the left and right side of a slice. Any ΔM must be compensated by an external moment $\mathrm{d}xF_y = \partial M/\partial x\,\mathrm{d}x$, which is supplied by the inertia of the segment. The vertical force component that is responsible for any vertical displacement of the bar has the same magnitude but opposite sign. F_y depends again on x so we can write

$$\frac{\partial F}{\partial x}\mathrm{d}x = \frac{\partial M}{\partial x} = I_\mathrm{a} E \frac{\partial^3 y}{\partial x^3} \,. \tag{2.35}$$

With the equation of motion

$$m\frac{\partial^2 y}{\partial t^2} = -\frac{\partial F}{\partial x}\mathrm{d}x \,, \tag{2.36}$$

and $m = \rho S \mathrm{d}x$ we obtain

$$\frac{\partial^2 y}{\partial t^2} = -\frac{E}{\rho}\frac{I_\mathrm{a}}{S}\frac{\partial^4 y}{\partial x^4} \,. \tag{2.37}$$

This is not a second-order wave equation like those that we obtained in the other cases. As will be shown later, the propagation speed is no longer constant but frequency dependent. This is a significant complication as it leads to dispersion. Composite waves become distorted as they travel along the medium. Unfortunately it is often required to include such a nonzero stiffness term in wave equations of real strings.

2.4 Solution for 1-D-Waves

Solving a differential equation is generally not a straight forward approach. For many types of differential equations templates for possible solutions are known. Such a template is a quite general expression with a certain number of unknown constants or unknown functions. This means that only the shape of a solution is known, but the unknowns are undetermined. It is easy to verify that these templates provide solutions to differential equations, if those stay correct after the substitution.

The unknown constants and functions must be determined by using whatever is known about the actual problem. Waves propagate equally in all one-, two- and three-dimensional spaces. Where and how the boundary conditions are embedded make the difference when looking at different cases.

A vibrating string has only a few boundary conditions, namely where and how the string is terminated. It makes a difference whether the ends are clamped or movable and how much tension is applied to the string. Other systems might have more complicated boundary conditions. In concert halls, for instance, it is not easy at all to define the boundary of the acoustic space.

It will be shown here how the wave equations can be solved analytically for the presented one-dimensional cases.

2.4.1 General Solution

The most general solution of the one-dimensional wave equation

$$\frac{\partial^2 F}{\partial t^2} = c^2 \frac{\partial^2 F}{\partial x^2} \,, \tag{2.38}$$

has the shape

$$F(x,t) = f(u) + g(v) \,, \tag{2.39}$$

with $u = ct - x$ and $v = ct + x$. This is the superposition of a forward traveling wave of any shape f and a back-

ward traveling wave of any shape g, both traveling with speed c in opposite directions.

Before we proceed we will introduce a very convenient way to write partial derivatives saving space and making them easier to read, for instance

$$\begin{aligned}
\frac{\partial F}{\partial t} &\to F_t \,, \\
\frac{\partial f}{\partial u} &\to f_u \,, \\
\frac{\partial g}{\partial v} &\to g_v \,, \\
\frac{\partial^2 F}{\partial t^2} &\to F_{tt} \,, \\
\frac{\partial^2 F}{\partial u, \partial v} &\to F_{uv} \\
&\dots
\end{aligned} \tag{2.40}$$

Using this notation it is straight forward to prove the correctness of the ansatz above

$$\begin{aligned}
F_t &= f_u u_t + g_v v_t = c(f_u + g_v) \\
F_{tt} &= f_{uu} u_{tt} + g_{vv} v_{tt} = c^2 (f_{uu} + g_{vv}) \\
F_x &= f_u u_x + g_v v_x = f_u(-1) + g_v(1) \\
F_{xx} &= f_{uu} u_{xx} + g_{vv} v_{xx} = f_{uu} + g_{vv} \\
F_{tt} &= c^2 F_{xx} \quad \text{(q.e.d.)} \,.
\end{aligned}$$

At a boundary the function F is not free to take on any value. Instead, the sum of the forward traveling wave f and backward traveling wave g must satisfy the physical constraints there. For a string with length L and fixed ends at $x = 0$ and $x = L$ this means that the reflected wave g must have the same magnitude and the opposite sign of the forward wave f at both ends of the string to satisfy the boundary condition $F(0, t) = F(L, t) = 0$.

In order to make things as simple as possible, we let $f = A\cos(k(ct - x))$ and $g = B\cos(k(ct - x))$ be harmonic functions. This is not a painful restriction because the superposition principle allows us to analyze any periodic function of arbitrary shape as a weighted sum of harmonic components. We define the wave number $k = \omega/c = 2\pi/\lambda$ as the number of wavelengths λ per $2\pi m$. This is analogous to the angular frequency $\omega = 2\pi/T$, which is the number of periods T per 2π s.

As already discussed in Sect. 2.1.1 we will interpret harmonic functions as real parts of complex exponentials and write

$$F(x, t) = \mathrm{Re}\left(A\,\mathrm{e}^{\mathrm{i}(\omega t - kx)} + B\,\mathrm{e}^{\mathrm{i}(\omega t + kx)}\right) . \tag{2.41}$$

Transforming the sum in the exponent into a product of exponentials allows us to factor out the time-dependent terms

$$F(x, t) = \mathrm{Re}\left(\left(A\,\mathrm{e}^{-\mathrm{i}kx} + B\,\mathrm{e}^{\mathrm{i}kx}\right)\mathrm{e}^{\mathrm{i}\omega t}\right) . \tag{2.42}$$

A and B are referred to as the complex amplitudes of the forward and backward traveling waves, respectively. They have to be determined using the available information about the boundary conditions.

2.4.2 Propagation

To be more specific, let us now return to the case of acoustic plane wave propagation in cylindrical ducts. Other one-dimensional wave equations derived above are treated likewise.

Acoustic plane waves are usually characterized by the sound pressure p, which varies over time and along the length of the tube. It does not vary across planes perpendicular to the direction of propagation. The so-called plane wave fronts allow us to treat the tube as a one-dimensional problem.

The same is true for the acoustic flow u, which is defined as the fluid velocity v times the cross-sectional area S. It is also called acoustic volume flow. It has the unit m^3/s and it is related to the oscillating fluid flow. It must be continuous over cross-sectional area changes while the fluid velocity will jump at discontinuities of the tube diameter.

Pressure p and acoustic volume flow u are related according to (2.30) and both satisfy wave equations according to (2.38) with $F \to p$ and $F \to u$. Valid solutions for the pressure p and for the flow u can be written as

$$\begin{aligned}
p(x, t) &= \left(A\,\mathrm{e}^{-\mathrm{i}kx} + B\,\mathrm{e}^{\mathrm{i}kx}\right)\mathrm{e}^{\mathrm{i}\omega t} \,, \\
u(x, t) &= \frac{S}{\rho c}\left(A\,\mathrm{e}^{-\mathrm{i}kx} - B\,\mathrm{e}^{\mathrm{i}kx}\right)\mathrm{e}^{\mathrm{i}\omega t} \,.
\end{aligned} \tag{2.43}$$

The negative sign of the backward traveling term for $u(x, t)$ is due to the opposite velocity arrow for forward and backward traveling waves. This has already been discussed for (2.30).

If we adopt this solution to known boundary conditions we can learn more. A cylindrical tube of length L, which is open at both ends (like a flute) enforces minimum pressure at both ends. Likewise, a string with length L that is fixed on both ends must have 0 displacement there: $p(0) = 0$ and $p(L) = 0$ and $y(0) = 0$ and $y(L) = 0$, respectively. This condition holds for any point in time.

Thus we obtain

$$\begin{aligned}
0 &= A\,\mathrm{e}^{-\mathrm{i}k0} + B\,\mathrm{e}^{\mathrm{i}k0} \,, \\
0 &= A\,\mathrm{e}^{-\mathrm{i}kL} + B\,\mathrm{e}^{\mathrm{i}kL} \,,
\end{aligned} \tag{2.44}$$

which leads to $A = -B$ and $e^{-ikL} = e^{ikL}$. The latter condition equates a clockwise and an anti-clockwise rotating arrow. It can only be met for $kL = n\pi$. With $k = \omega/c = 2\pi f/c$ we obtain so-called normal modes at angular frequencies $f_n = nc/2L$. On stringed instruments those are called *flageolet notes* and any linear combination of them can occur in steady state.

To derive the acoustical properties p and u at any point x of the duct assuming they are known at another point x_1, a distance d away, requires substitution of $x = x_1 - d$ into (2.43). With $Z_c = \rho c/S$ for the characteristic impedance we obtain

$$p = \cos(kd)p_1 + i\sin(kd)Z_c u_1 \,, \tag{2.45}$$

and

$$u = i\sin(kd){Z_c}^{-1}p_1 + \cos(kd)u_1 \,. \tag{2.46}$$

We can define the acoustical impedance Z and again derive its projection along the duct

$$Z = \frac{p}{u} = \frac{\cos(kd)Z_1 + i\sin(kd)Z_c}{i\sin(kd)Z_c^{-1}Z_1 + \cos(kd)} \,. \tag{2.47}$$

These results are extremely useful as p, u and Z at the end of a wind instrument are at least approximately known. If it is closed, which is the case in certain stopped pipes, u is nearly 0 and Z very large. If it is more or less open then p is very small and Z approximates 0. It is possible to determine this impedance at the end of any arbitrary duct either by analytical means or by measurements.

Once this so-called termination impedance Z_{trm} is known, it can be back propagated to the mouthpiece where it becomes the load impedance of the sound generator. The sound generator is a pressure sensitive valve either represented by the player's vibrating lips or by an oscillating reed, which modulate the air flow periodically. In flutes or certain organ pipes it is an unstable air jet (air reed), which oscillates around the edge of the labium due to its interaction with the sound pressure field in its vicinity.

It should be mentioned here that a discontinuity in the tube, meaning a sudden change in cross-sectional area from $S = S_L$, left of the discontinuity, to $S = S_R$, right of it, cannot cause any change in p, u and therefore in Z. This follows from the continuity equations for mass and momentum. What changes is the characteristic impedance Z_c.

This allows one to decompose a complete instrument with varying cross-section into a sequence of short cylindrical slices with different lengths and characteristic impedances Z_c. The known termination impedance can then be propagated back to the mouthpiece.

The impedance there is commonly called input impedance and is numerically evaluated for all frequencies of interest in the whole playing range. The input impedance magnitude spectrum shows all resonances of a wind instrument and is therefore related to its intonation and to other quality measures.

2.4.3 Input Impedance

The input impedance Z_{in} is the complex ratio of the acoustic pressure p_{in} and flow u_{in} at the input plane. Its magnitude $|Z_{in}|$ is the amplitude ratio $|p_{in}|/|u_{in}|$ and its phase angle corresponds to the phase difference between p_{in} and u_{in}. A positive phase of Z_{in} means p_{in} is ahead of u_{in}.

In wind instruments it is usually a time varying flow that excites the air column. Depending on the input impedance of the instrument this flow signal will create a certain sound pressure signal at the entry plane of that resonator tube.

A small input impedance magnitude means that the input pressure building up in response to a flow stimulus is weak. At resonance frequencies there is a high input impedance magnitude. A rather tiny flow will already be sufficient to produce an enormous sound pressure in the mouthpiece.

Why is the input impedance so sensitive to frequency? Let us now start to stimulate a very long cylindrical tube. Initially, there is no backward traveling wave. We stimulate a forward traveling pressure wave by injecting an oscillating acoustic flow. The pressure amplitude in response to the flow stimulus will not be frequency dependent.

According to (2.30) and with $u = vS$ the pressure amplitude p will be $\rho c/S$ multiplied by the flow amplitude u. The pressure wave will propagate at phase speed c to the open end. An open end enforces 0 pressure. This condition requires for the backward traveling wave to be phase shifted by an angle of π at the reflection plane. Eventually the backward traveling wave reaches the front end. The physical pressure is now the sum of the forward traveling wave and the arriving backward traveling wave.

Whether we obtain constructive or destructive interference will depend on the phase relationship between the two traveling waves. Since wavelength is a function of frequency, we will obtain an almost perfect annihilation only for a set of frequencies where twice the tube length is an exact integer multiple of one wavelength $\lambda = c/f$. Note that one should not forget the sign inversion at the open end! If twice the tube length is an integer multiple of one wavelength plus half a wavelength, then we will obtain perfect amplification.

Maxima in the input impedance magnitude spectrum therefore mark frequencies at which perfect amplification takes place during regeneration. Minima occur at frequencies in between where forward and backward waves annihilate each other.

As the tube length matches an odd integer multiple of a quarter wavelength at resonance, 0 transitions of forward and backward traveling waves coincide and do not move at all. The physical pressure profile exhibits places with 0 amplitude, the pressure nodes and places with maximum pressure fluctuations, the pressure antinodes.

As theses places do not move, we call these wave patterns *standing waves*. They exclusively occur at resonance frequencies. Inserting a probe microphone into our tube would reveal nodes and antinodes as stable regions of minimum and maximum sound pressure level.

In mechanical systems such as strings we usually speak of the *driving point impedance*. It is the ratio of a driving force F and a resulting velocity v. Keeping in mind the correspondences between force F and sound pressure p and between velocity v and acoustic flow u, we can translate whatever was said above.

The resonances of the cylindrical air column are directly related to the vibration modes of a taut string – guitarists refer to them as *flageolet tones*. There is one difference when strings are considered. Strings are fixed at both ends, while most wind instruments are played with one closed and one open end. The open end of a trumpet fixes the sound pressure p to 0 but lets the fluid velocity v and respectively the acoustic flow u *open*. A fixed end or *node* for the pressure corresponds to a free end or *antinode* for the flow and vice versa.

Taking this into account we can make a comparison: Trumpets are stimulated by a small flow injected near a flow node and it therefore requires an input impedance maximum to get a strong pressure signal there. Flutes are stimulated by a small sound pressure near an open embouchure hole, a pressure node. They require an impedance minimum to stimulate a significant acoustic flow there.

Mechanical systems such as strings are stimulated by a small force. A driving point impedance minimum will maximize the velocity at the driving point. The smaller the impedance the less force is required to stimulate a certain velocity. Mechanical systems have their resonances at driving point impedance minima also called *mobility* maxima.

Magnitude and phase of the impedance curve at resonance frequencies are connected to many musical features, e.g., intonation, response, efficiency and sound timbre. Measured or calculated input or driving point impedance spectra can therefore be used to assess or predict quality related characteristics of musical instruments.

Bore reconstruction starting from acoustical input impedance measurements is another important application where accurate modeling of input impedance is essential. A practical method based on optimization has been developed by the author [2.11].

2.4.4 Radiation Impedance

As already stated above, prior knowledge of the boundary conditions at the reflecting far end leads to the termination impedance, which is required to determine the input impedance.

We will elaborate on the radiation impedance of an open tube because it is one of the few cases where some analytic expression can be found. It is much more difficult to derive an expression for the bridge impedance of violins or pianos with their irregular three-dimensional resonators. However, this bridge impedance is the termination impedance of the strings and is required to accurately calculate the dynamic behavior of a bowed, plucked or struck string, resulting in properties like sound timbre or sustained tones.

Fortunately it is not very difficult to measure driving point impedances at the ends of the vibrating part of piano strings or at a guitar or violin bridge. Measured data can therefore replace missing analytical expressions.

The open end of a wind instrument is a velocity antinode and in a first-order approximation wave fronts are often assumed to be plane. This allows us to treat the fluid layer at the open mouth as if it was a vibrating piston radiating into the three-dimensional space.

To keep things simple an infinite baffle is often introduced with a circular disk of it being the vibrating piston. This allows one to neglect backward radiation into the half space behind the radiation plane and other related challenges.

An expression for a piston radiator terminated in an infinite baffle was given by *Rayleigh* in [2.12].

Piston Without Baffle

A first-order approximation for a piston radiator without baffle was proposed by *Levine* [2.13] and evaluates numerically to

$$\frac{p_\mathrm{T}(\mathrm{i}\omega)}{u_\mathrm{T}(\mathrm{i}\omega)} = Z_\mathrm{T} = Z_{\mathrm{c,T}}\left(\left(\frac{\omega R_\mathrm{T}}{2c}\right)^2 + \mathrm{i}\left(\frac{0.61\omega R_\mathrm{T}}{c}\right)\right) \tag{2.48}$$

with $R_\mathrm{T} = \sqrt{S_\mathrm{T}/\pi}$, $Z_{\mathrm{c,T}} = \rho c/S_\mathrm{T}$ and S_T being the cross-sectional area of the open end.

Because of the one-dimensional assumptions higher-order vibrational modes are not taken into account here. The validity of the plane wave model is limited by the first cut-off frequency ω_{cutoff}, which is usually most restrictive at the open mouth of the instrument. The cut-off frequency can be calculated from $R_{\text{T}}\omega_{\text{cutoff}}/c \approx 1.84$.

Caussé proposes an approximation for the radiation impedance of a piston radiator without baffle valid up to $\omega < 3.5c/R_{\text{T}}$ in [2.14].

Pulsating Part of Sphere

The approach of *Helie* and *Rodet* [2.15] is based on spherical wave propagation, which matches quite realistically the conditions at the end of the bell of a typical brass wind instrument. The exit wave front is treated as a pulsating portion of a sphere radiating into an anechoic three-dimensional environment with no baffle.

In order to use this result in a plane wave context the surface of the pulsating spherical cap has to be flattened and scaled in order to match the cross-sectional area of the exit wave front of the plane wave model.

Unfortunately, even the numeric evaluation of that model is quite demanding as it is represented by a slowly converging sum of terms involving spherical Hankel functions h_n as well as Legendre polynomials P_n of high order N. Helie and Rodet calculated the sum with $N = 200$ terms. With θ being the flare angle and $\nu = fr/c = f/(\pi f_{\text{cutoff}})$ the normalized frequency, a normalized radiation impedance $Z^*_{\text{rad}} = Z_{\text{rad}}/Z_{\text{c}}$ (Z_{c} being the characteristic specific impedance ρc) is given by

$$Z^*_{\text{rad}} = -\frac{2\text{i}}{1-\cos(\theta)} \sum_{n=0}^{\text{N}} \frac{\gamma(n, 2\pi\nu)\mu(n,\theta)^2}{2n+1} , \tag{2.49}$$

with

$$\mu(n,\theta) = \frac{1}{2}(P_{n-1}(\cos(\theta)) - P_{n+1}(\cos(\theta))) , \tag{2.50}$$

and

$$\gamma(n,\omega) = \frac{\omega h^{(2)}_n(\omega)}{n h^{(2)}_n(\omega) - \omega h^{(2)}_{n+1}(\omega)} . \tag{2.51}$$

The expression for the radiation impedance Z_{rad} for real frequencies f, radius r, speed of sound c, and density ρ becomes

$$Z_{\text{rad}} = -\frac{2\text{i}\rho c}{1-\cos(\theta)} \sum_{n=0}^{\text{N}} \frac{\gamma\left(n, \frac{2\pi fr}{c}\right)\mu(n,\theta)^2}{2n+1} . \tag{2.52}$$

2.4.5 Reflection and Transmission

Any variation of the characteristic impedance Z_{c} has the effect that waves get partially reflected and transmitted at each discontinuity. It might be of interest, how much is reflected and how much is transmitted at a discontinuity given by a ratio $S_{\text{L}}/S_{\text{R}}$ of the area S of the bore cross-section.

By means of (2.43) we can write two equations matching the left and right-sided pressures and volume velocities. For this purpose we substitute $S = S_{\text{L}}$, $A = A_{\text{L}}$, $B = B_{\text{L}}$ on the left sides and $S = S_{\text{R}}$, $A = A_{\text{R}}$, $B = B_{\text{R}}$ on the right sides. Simplified we obtain $A_{\text{L}} + B_{\text{L}} = A_{\text{R}} + B_{\text{R}}$ and $(A_{\text{L}} - B_{\text{L}})S_{\text{L}} = (A_{\text{R}} - B_{\text{R}})S_{\text{R}}$. The reflection coefficient $A_{\text{L}}/B_{\text{L}}$ for a forward traveling wave ($B_{\text{R}} = 0$) can now be calculated to

$$\frac{A_{\text{L}}}{B_{\text{L}}} = \frac{\frac{S_{\text{L}}}{S_{\text{R}}} - 1}{\frac{S_{\text{L}}}{S_{\text{R}}} + 1} . \tag{2.53}$$

In the same way, a transmission coefficient $A_{\text{R}}/A_{\text{L}}$ can be determined as

$$\frac{A_{\text{R}}}{A_{\text{L}}} = \frac{\frac{2S_{\text{L}}}{S_{\text{R}}}}{\frac{S_{\text{L}}}{S_{\text{R}}} + 1} . \tag{2.54}$$

2.4.6 Wall Losses

The solution $A\text{e}^{\text{i}(\omega t - kx)} + B\text{e}^{\text{i}(\omega t + kx)}$ describes lossless propagation. Amplitudes do not decay over time and both forward and backward traveling waves do not diminish as they are traveling.

In reality waves suffer from significant friction losses in a thin shear layer near the wall where a velocity gradient exists due to the finite viscosity of the air. Thermal energy is lost to the environment, which reduces the amplitude of the waves while they are traveling.

There are also losses due to volume viscosity but these are only significant when sound propagates over very large distances. A third source of loss is due to heat transfer between over-pressure and under-pressure zones, but this only concerns very low frequencies and can usually be ignored.

Exponential damping of forward and backward propagating waves can be described by using a complex wave number $k = \alpha - \text{i}\beta$. With this expression the spatial term of the solution $\text{e}^{\pm\text{i}kx} = \text{e}^{\pm\text{i}\alpha x}\text{e}^{\pm\beta x}$ becomes an arrow in the complex plane with a spatially rotating phase angle αx and an amplitude, which changes exponentially with βx. The forward propagating wave $\text{e}^{-\text{i}kx}$ decays exponentially with growing x while the backward propagating wave $\text{e}^{\text{i}kx}$ decays exponentially in the negative x-direction.

Unfortunately, with this wave number k being complex (and not purely imaginary) it is no longer possible to separate real and imaginary parts according to Euler's law. Equations (2.45)–(2.47) have therefore to be replaced. With $\cosh = \mathrm{e}^{x} + \mathrm{e}^{-x}/2$ and $\sinh = \mathrm{e}^{x} - \mathrm{e}^{-x}/2$ and $k \to \Gamma$ we obtain instead

$$p = \cosh(\Gamma d)p_1 + \sinh(\Gamma d)Z_\mathrm{c}u_1 \,, \tag{2.55}$$

$$u = \frac{1}{Z_\mathrm{c}}\sinh(\Gamma d)p_1 + \cosh(\Gamma d)u_1 \,, \tag{2.56}$$

$$Z = \frac{\cosh(\Gamma d)Z_1 + \sinh(\Gamma d)Z_\mathrm{c}}{\frac{\sinh(\Gamma d)Z_1}{Z_\mathrm{c}} + \cosh(\Gamma d)} \,. \tag{2.57}$$

We will now switch to matrix notation. Equations (2.55) and (2.56) can be understood as a vector $(p, u)^\top$ being the product of a 2 by 2 matrix $\mathbf{A}_i$ representing the projection laws with a vector $(p_1, u_1)^\top$ representing the termination conditions.

The projection equations for the i-th section of a certain sequence of cylindrical slices can be written in matrix notation as

$$\begin{pmatrix} p_i(\mathrm{i}\omega) \\ u_i(\mathrm{i}\omega) \end{pmatrix} = \mathbf{A}_i(\mathrm{i}\omega) \begin{pmatrix} p_{i+1}(\mathrm{i}\omega) \\ u_{i+1}(\mathrm{i}\omega) \end{pmatrix} \tag{2.58}$$

with

$$\mathbf{A}_i(\mathrm{i}\omega) = \begin{pmatrix} a_{i,11}(\mathrm{i}\omega) & a_{i,12}(\mathrm{i}\omega) \\ a_{i,21}(\mathrm{i}\omega) & a_{i,22}(\mathrm{i}\omega) \end{pmatrix} \tag{2.59}$$

or according to (2.55) and (2.56) more specifically

$$\mathbf{A}_i(\mathrm{i}\omega) = \begin{pmatrix} \cosh(\Gamma d) & \sinh(\Gamma d)Z_\mathrm{c} \\ \frac{1}{Z_\mathrm{c}}\sinh(\Gamma d) & \cosh(\Gamma d) \end{pmatrix} . \tag{2.60}$$

Multiple projections along several segments can be expressed by the product matrix of all elements. This can easily be cross-checked by eliminating p_{i+1} and u_{i+1} from the system

$$\begin{pmatrix} p_i \\ u_i \end{pmatrix} = \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \begin{pmatrix} p_{i+1} \\ u_{i+1} \end{pmatrix} \tag{2.61}$$

$$\begin{pmatrix} p_{i+1} \\ u_{i+1} \end{pmatrix} = \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{pmatrix} \begin{pmatrix} p_{i+2} \\ u_{i+2} \end{pmatrix} . \tag{2.62}$$

The whole instrument can therefore be represented by a single system matrix

$$\mathbf{A}(\mathrm{i}\omega) = \prod_{i=1}^{L} \mathbf{A}_i(\mathrm{i}\omega) \,. \tag{2.63}$$

The model for cylindrical elements has been generalized for conical segments and spherical wave propagation. It was originally published by *Mapes-Riordan* [2.16] but its notation is adapted here. It is based on work published by *Keefe* [2.17–19], *Caussé* et al. [2.14] and *Benade* [2.20].

The projection matrix of a single conical element has been derived by Mapes-Riordan as

$$\begin{aligned} a_{i,11} &= \frac{x_{i+1}}{x_i}\left(C - \frac{D}{\Gamma x_{i+1}}\right) \\ a_{i,12} &= \frac{x_i}{x_{i+1}} Z_\mathrm{c} D \\ a_{i,21} &= \frac{D}{Z_\mathrm{c}}\left(\frac{x_{i+1}}{x_i} - \frac{1}{(\Gamma x_i)^2}\right) + \frac{C}{Z_\mathrm{c}}\frac{\Gamma L}{(\Gamma x_i)^2} \\ a_{i,22} &= \frac{x_i}{x_{i+1}}\left(C + \frac{D}{\Gamma x_i}\right) \end{aligned} \tag{2.64}$$

with

$$\begin{aligned} C &= \cosh(\Gamma L) \,, \\ D &= \sinh(\Gamma L) \,, \\ \Gamma &= k\left(1.045 r_\mathrm{v}^{-1} + \mathrm{i}\left(1 + 1.045 r_\mathrm{v}^{-1}\right)\right) \,, \\ k &= \frac{\omega}{c} \,, \\ r_\mathrm{v} &= \sqrt{\frac{\rho\omega S_\mathrm{m}}{\eta\pi}} \,, \\ Z_\mathrm{c} &= Z_{\mathrm{c,i}}\left(\left(1 + 0.369 r_\mathrm{v}^{-1}\right) - \mathrm{i}0.369 r_\mathrm{v}^{-1}\right) \,, \\ Z_{\mathrm{c,i}} &= \frac{\rho c}{S_\mathrm{i}} \,, \end{aligned}$$

with ρ being the equilibrium gas density, ω the radian frequency, η the shear viscosity coefficient, c the sound velocity, S_m the cross-sectional area at the center and S_i the spherical area at the input end of the conical element, x_i the radius of the input spherical sector, x_{i+1} the radius of the output spherical sector, and L the distance between the two spheres.

The limit for $x_i \to \infty$ and $x_{i+1} \to \infty$ comes very close to the expression already derived for a cylindrical tube.

2.5 Stiffness

Equation (2.37) for the stiff bar is a fourth-order partial differential equation, which does not allow us to construct a general solution presuming constant phase velocity. We can still assume linearity, which means that a harmonic stimulus with a single frequency can only excite a harmonic motion of the same frequency.

With a displacement $y(x,t) = \mathrm{Re}(F(x)\mathrm{e}^{\mathrm{i}\omega t})$ we get $y_{tt} = -\omega^2 y$ and with (2.37) in short form $y_{tt} = -y_{xxxx} EI_\mathrm{a}/\rho S$ using the abbreviation $v^4 = \omega^2 EI_\mathrm{a}/\rho S$ we obtain

$$F_{xxxx} = \frac{\rho}{E}\frac{S}{I_\mathrm{a}}\omega^2 F = \frac{\omega^4}{v^4}F \qquad (2.65)$$

where v corresponds to the phase velocity c which is not constant but proportional to $\sqrt{\omega}$ and to $\sqrt{c_\mathrm{L}} = \sqrt{E/\rho}$, c_L being the phase velocity of a longitudinal wave in that bar.

With a spatial distribution $F(x) = A\,\mathrm{e}^{\gamma x}$ and $F_{xxxx} = \gamma^4 F$ we get

$$\gamma^4 = \frac{\omega^4}{v^4} = k^4 \,. \qquad (2.66)$$

This gives us two solutions $\gamma^2 = \pm k^2$ and from that we get the four solutions $\gamma = \pm k$ and $\gamma = \pm \mathrm{i}k$. In the complete solution for $y(x,t)$ we have to add all possibilities and we get

$$\begin{aligned} F(x) &= A\,\mathrm{e}^{kx} + B\,\mathrm{e}^{-kx} + C\,\mathrm{e}^{\mathrm{i}kx} + D\,\mathrm{e}^{-\mathrm{i}kx} \,, \\ y(x,t) &= \mathrm{Re}\left(F(x)\mathrm{e}^{\mathrm{i}\omega t}\right) \,. \end{aligned} \qquad (2.67)$$

The unspecified four constants have to be determined from the boundary conditions. If the bar is clamped then the displacement and its first derivative there, the slope, is forced to be 0. If it is only supported then the displacement and the second derivative must be 0. A supported end does not fix the slope, and therefore cannot transmit any torque. A free end can move freely and it can have any slope, but there cannot be any torque nor shearing force, so the third and fourth derivative must be 0.

The wave equation for transverse waves in a taut string can also be augmented by the fourth-order stiffness term. Remember that (2.20) is a conservation law. Any acceleration of the mass of a string segment must be due to forces. Initially only the restoring force of the string tension has been taken into account. Now we add the additional restoring force due to stiffness

$$\rho S y_{tt} = T y_{xx} - EI_\mathrm{a} y_{xxxx} \,. \qquad (2.68)$$

According to *Morse* in [2.21] it can be shown that a stiff string has eigenfrequencies that are no longer integer multiples of the fundamental. Frequency ratios of higher partials are stretched and their pitch becomes sharper with decreasing wavelength. *Fletcher* and *Rossing* present Morse's solution for a stiff string clamped at both ends in [2.10] as

$$\omega_n = n\pi\frac{c}{L}\sqrt{1 + n^2\pi^2\alpha^2}(1 + 2\alpha + 4\alpha^2) \qquad (2.69)$$

with $\alpha = \sqrt{\epsilon}/L$ and $\epsilon = EI_\mathrm{a}/T$.

Valette derives the eigenfrequencies of a supported (hinged) stiff string in [2.22]

$$\omega_n = n\pi\frac{c}{L}\sqrt{1 + n^2\pi^2\alpha^2} \,. \qquad (2.70)$$

A good review of such results for several different boundary conditions can be found in [2.23].

3. Waves in Two and Three Dimensions

Wilfried Kausel

This chapter deals with the generalization of the wave equation to describe wave propagation on two-dimensional surfaces and sound waves in a three-dimensional space. Again linearity is postulated, which is only justified if amplitudes are sufficiently small. It will be shown how wave equations can be derived for rectangular and circular membranes, plates and disks and how analytic results can be obtained for a three-dimensional case with relatively simple boundary conditions. This chapter will also review techniques for the calculation of resonance frequencies and for the prediction of associated modal shapes.

3.1 Waves on a Surface

Here we will generalize the one-dimensional wave equation to two dimensions and simultaneously further develop the mathematics that are needed to do that. This way we will be able to approximately describe vibrations of piano sound boards, timpani membranes and of several other percussion instruments. Finally we will cover the most general case of sound wave propagation in the free three-dimensional space.

3.1.1 Rectangular Membrane

Recalling the derivation of transverse string vibrations, we will find many similarities in the two-dimensional case of Fig. 3.1. The string tension T, a force stretching each string element, now becomes the surface tension T_S, a force per unit length, from which two pairs of forces, $\pm T_S\,\mathrm{d}x$ and $\pm T_S\,\mathrm{d}y$ can be derived that stretch each surface element tangentially in x and in y directions. The resulting z component will drive the segment mass vertically.

This uncompensated z component of the tension is caused by a curvature in the x direction ($\partial^2 z/\partial x^2 \mathrm{d}x$) and by a curvature in the y direction ($\partial^2 z/\partial y^2 \mathrm{d}y$). If there is zero curvature then there will be no resulting z component because tension vectors at opposite sides of the segment will have the same direction but opposite orientation and therefore cancel out each other.

The equation of motion can now be written as

$$m\frac{\partial^2 z}{\partial t^2} = \left(T_S\,\mathrm{d}y\frac{\partial^2 z}{\partial x^2}\mathrm{d}x + T_S\,\mathrm{d}x\frac{\partial^2 z}{\partial y^2}\mathrm{d}y\right). \tag{3.1}$$

With the mass $m = \rho_A\,\mathrm{d}x\mathrm{d}y$ of the differential segment we obtain a two-dimensional wave equation for the displacement z of a stretched membrane in Cartesian

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_3

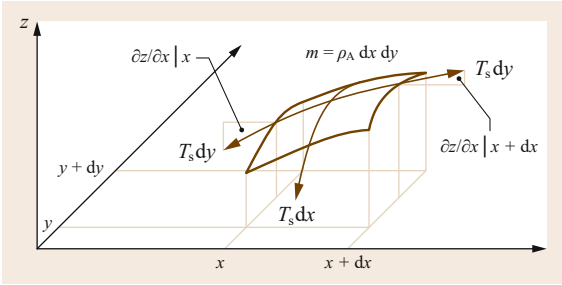

Fig. 3.1 Waves on a surface

coordinates

$$\frac{\partial^2 z}{\partial t^2} = \frac{T_S}{\rho_A}\left(\frac{\partial^2 z}{\partial x^2} + \frac{\partial^2 z}{\partial y^2}\right). \tag{3.2}$$

The phase propagation speed in x and y directions is $c = \sqrt{T_S/\rho_A}$. It is again constant for a homogeneous and isotropic membrane with constant area density ρ_A and tension.

Vector Analysis

It is now required to introduce some operators commonly used to make reading and writing of differential equations much easier, because they will frequently appear in the following sections.

We already mentioned the velocity gradient, meaning a gradual increase or decrease of the fluid velocity along a spatial dimension. It is simply the rate of change; the spatial derivative with respect to the space variable.

In the three-dimensional space the change rate per unit length can be different depending on whether we go in the x, y or z direction. If we imagine the xy-plane to be a hot wall, then the temperature change rate in the z direction (distance to the wall) will be perceptible while no change will be noticed in the x and y directions – at least if the wall is very big.

The change rate in three-dimensional space therefore becomes a vector with the components $\partial f/\partial x$, $\partial f/\partial y$ and $\partial f/\partial z$. Such a vector can be assigned to each point in space and it always points in the direction of the steepest ascent of the corresponding scalar quantity like temperature, pressure or velocity magnitude. Its length is the change rate per unit length in the indicated direction.

This vector is called the *gradient* of a scalar field $f(x, y, z)$ and we introduce the differential operator $(\partial/\partial x, \partial/\partial y, \partial/\partial z)^\top$, abbreviated by ∇ or *grad* to write gradients in two or more dimensions. A scalar field is a function that assigns a scalar value, like temperature or pressure, to all points in space.

Formally the ∇ operator is a vector and it is therefore possible to square it before it is applied to the field variable

$$\nabla^2 = \begin{pmatrix} \frac{\partial}{\partial x} \\ \frac{\partial}{\partial y} \\ \frac{\partial}{\partial z} \end{pmatrix}^2 = \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right). \tag{3.3}$$

The operator ∇^2, often written as Δ, is called the Laplace operator. Using it, the wave equation (3.2) can be rewritten as

$$\frac{\partial^2 z}{\partial t^2} = \frac{T_S}{\rho_A}\Delta z\,. \tag{3.4}$$

Applying the ∇ operator to a scalar field gives us a vector field; that means each point in space is a vector assigned to indicating the direction and strength of the steepest increase of the underlying scalar field. When we apply the ∇ operator a second time, and this is exactly what we are doing when we use the Laplace operator Δ, then we apply it to a vector field now in order to obtain a new scalar field.

First let us verify that: $(\boldsymbol{\nabla}\cdot\boldsymbol{\nabla})z = \boldsymbol{\nabla}\cdot(\boldsymbol{\nabla}z)$. This is obviously correct. In both cases we obtain a scalar result and a scalar multiplication can be done before or after the dot (inner or scalar) product.

Applying the ∇ operator to a vector field is called divergence (written as *div*). The Laplace operator therefore calculates the divergence of the gradient of a scalar field. Divergence is also called source or sink strength of the field.

If we confine each point of the vector field in an infinitesimally small cubic cage summing up and normalizing the vector components orthogonal to the faces of the cube, counting outward pointing contributions as positive and inward pointing contributions as negative, then we will obtain information about whether this volume or space element acts as a source or as a sink for the physical quantity represented by the vectors.

In the explanation of (2.27) a density change inside a small fluid element was related to a different velocity of the left and right fluid boundary. The velocity field is a vector field because velocity in general has a direction and a magnitude. In that one-dimensional case only two directions are possible, so we only need to take two opposite faces of our measurement cage into account.

If the velocity vector leaving the cage on the right side is greater then the velocity vector entering on the left side then we have a positive divergence, which was required to lower the density. We will find this equation generalized for three dimensions later as (3.13). Instead of $\partial v/\partial x$ it will contain the ∇ or *div* operator applied to the vector field $\boldsymbol{v}$.

Note that in this subsection we are working on a problem in two spatial coordinates only. All derivatives with respect to a third or higher spatial coordinate are zero. Therefore it is not necessary to define separate differential operators for the two-dimensional, three-dimensional and even more-dimensional space.

3.1.2 Circular Membrane

In order to take advantage of the symmetry of a circular membrane, it is advantageous to use a polar coordinate system with an origin in the center of the membrane. Each point of the membrane is characterized by a coordinate pair (r, θ). r determines its distance from the center point and θ specifies an angle in the range $[-\pi, \pi]$ from the r axis, an arbitrarily chosen ray extending from the center point.

The correspondence between the coordinates is given by

$$\begin{aligned} x &= r\cos\theta \\ y &= r\sin\theta \\ r &= \sqrt{x^2+y^2} \\ \tan\theta &= \frac{y}{x}\,. \end{aligned} \tag{3.5}$$

Using these correspondences to substitute x and y we can transform a function $f(x, y)$ into an equivalent function $g(r, \theta)$. In many cases the function g can be found directly, so f might not be known.

Although it would be possible to reconstruct f using the inverse transformation, we want to avoid that, because it usually leads to lengthy expressions involving $\tan^{-1}$ (arctan or inverse tangent) and ugly square root functions. Therefore we first need to transform the required differential operators into the polar coordinate system.

To make equations shorter and easier to read we will introduce a new way to write partial derivatives, according to

$$\begin{aligned} \frac{\partial f}{\partial x} &\to f_\mathrm{x}\,, \\ \frac{\partial g}{\partial r} &\to g_\mathrm{r}\,, \\ \frac{\partial^2 f}{\partial y^2} &\to f_\mathrm{yy}\,, \\ \frac{\partial^2 g}{\partial r,\partial\theta} &\to f_{\mathrm{r}\theta}\cdots\,. \end{aligned} \tag{3.6}$$

To calculate the first derivatives of any function u of two variables using the correspondences from (3.5) the chain rule of differentiation has to be applied

$$\begin{aligned} u_\mathrm{r} &= u_\mathrm{x}x_\mathrm{r} + u_\mathrm{y}y_\mathrm{r} \\ &= u_\mathrm{x}\cos\theta + u_\mathrm{y}\sin\theta \\ u_\theta &= u_\mathrm{x}x_\theta + u_\mathrm{y}y_\theta \\ &= -u_\mathrm{x}r\sin\theta + u_\mathrm{y}r\cos\theta\,. \end{aligned} \tag{3.7}$$

Multiplying one of these two equations for u_r and u_θ with $\cos\theta$ and the other one with $\sin\theta$ we can obtain u_x and u_y in terms of r and θ. This gives us the gradient of the scalar field u in polar coordinates

$$\begin{aligned} u_\mathrm{x} &= u_\mathrm{r}\cos\theta - \frac{u_\theta\sin\theta}{r} \\ u_\mathrm{y} &= u_\mathrm{r}\sin\theta + \frac{u_\theta\cos\theta}{r}\,. \end{aligned} \tag{3.8}$$

The same derivation for the second derivatives is lengthy. Therefore only the starting point and the result is given

$$\begin{aligned} u_\mathrm{rr} &= \frac{\partial}{\partial r}\left(u_\mathrm{x}\cos\theta + u_\mathrm{y}\sin\theta\right) = \cdots \\ u_{\theta\theta} &= r\frac{\partial}{\partial\theta}\left(-u_\mathrm{x}\sin\theta + u_\mathrm{y}\cos\theta\right) = \cdots \\ u_\mathrm{rr} + \frac{u_{\theta\theta}}{r^2} &= \cdots \\ \cdots &= u_\mathrm{xx} + u_\mathrm{yy} - \frac{1}{r}u_\mathrm{r}\,. \end{aligned} \tag{3.9}$$

Now we have the Laplace operator

$$\begin{aligned} \Delta &= \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \\ &= \frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial\theta^2} \end{aligned} \tag{3.10}$$

and the wave equation in polar coordinates

$$\frac{\partial^2 z}{\partial t^2} = c^2\left(\frac{\partial^2 z}{\partial r^2} + \frac{1}{r}\frac{\partial z}{\partial r} + \frac{1}{r^2}\frac{\partial^2 z}{\partial\theta^2}\right). \tag{3.11}$$

3.1.3 Rectangular Plate

Looking at the correspondence between the wave equations of a vibrating string and of a rectangular membrane, we might generalize (2.37) intuitively by replacing $\partial^4 y/\partial x^4$ by $\nabla^4 z$ and by substituting $h^2/12$ for I_a/S. The latter can been derived for a rectangular plate of thickness h by means of (2.34). This approach leads to a nearly correct equation. The correct

version is [3.1–3]

$$\frac{\partial^2 z}{\partial t^2} = -\frac{E}{\rho(1-\nu^2)}\frac{h^2}{12}\nabla^4 z\,. \tag{3.12}$$

The only small difference is the term involving the Poisson's ratio ν. When we derived the equation for the bar, we assumed a bundle of wires. We did not take into account the fact that wires that are stretched are getting thinner and wires that are compressed are getting thicker. In a bar this does not matter too much. The change in thickness is not constrained if the bar is much longer than its width and height.

In a plate with a significant width the distortion of the cross-sectional area due to length differences of top and bottom layers, expressed by the Poisson's ratio ($\nu \approx 0.3$), has to overcome higher resistance, which increases the effective stiffness.

For the same reason even compressional (longitudinal) waves propagate faster in an infinite plate than in strings or stiff bars. The effective Young's modulus is scaled by the same factor

$$c'^2 = \frac{E}{\rho(1-\nu^2)}\,. \tag{3.13}$$

3.1.4 Circular Disk

For circular disks we need to express $\nabla^4 = \Delta^2$ in (3.12) in polar coordinates. With (3.10) we obtain

$$\begin{aligned}\nabla^4 &= \left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial\theta^2}\right)^2 \\ &= \frac{\partial^4}{\partial r^4} + \frac{1}{r^2}\frac{\partial^2}{\partial r^2} + \frac{1}{r^4}\frac{\partial^4}{\partial\theta^4} \\ &\quad + \frac{2}{r}\frac{\partial^3}{\partial r^3} + \frac{1}{r^2}\frac{\partial^4}{\partial r^2\partial\theta^2} + \frac{2}{r^3}\frac{\partial^3}{\partial r\partial\theta^2}\,.\end{aligned} \tag{3.14}$$

This allows us to specify boundary conditions and solutions in terms of polar coordinates. We will do this in another section below.

3.2 Solution for Waves on a Surface

In this section it will be shown how the two-dimensional wave equation of a rectangular or circular membrane can be solved to get information about the structural vibrations of timpani membranes or thin rectangular plates like piano soundboards.

3.2.1 Rectangular Membrane

Looking at the ansatz (2.42) for the solution of a one-dimensional wave equation, we observe that it is a product of easily differentiable (exponential) terms, each solely dependent on a single variable. This solution technique is called *separation of variables* and can also be applied to the more-dimensional case.

We therefore assume a solution of the form

$$z(x,y,t) = F(x)G(y)\mathrm{e}^{\mathrm{i}\omega t} \tag{3.15}$$

for the two-dimensional wave equation (3.2). With

$$\begin{aligned} z_{\mathrm{xx}} &= F_{\mathrm{xx}}G\mathrm{e}^{\mathrm{i}\omega t} \\ z_{\mathrm{yy}} &= G_{\mathrm{yy}}F\mathrm{e}^{\mathrm{i}\omega t} \\ z_{\mathrm{tt}} &= -\omega^2\mathrm{e}^{\mathrm{i}\omega t}FG \end{aligned} \tag{3.16}$$

the wave equation $z_{\mathrm{tt}} = c^2(z_{\mathrm{xx}} + z_{\mathrm{yy}})$ becomes

$$-\omega^2\mathrm{e}^{\mathrm{i}\omega t}FG = c^2\left(F_{\mathrm{xx}}G\mathrm{e}^{\mathrm{i}\omega t} + G_{\mathrm{yy}}F\mathrm{e}^{\mathrm{i}\omega t}\right) \tag{3.17}$$

and therefore

$$-\frac{\omega^2}{c^2} - \frac{G_{\mathrm{yy}}}{G(y)} = \frac{F_{\mathrm{xx}}}{F(x)}\,. \tag{3.18}$$

It can be seen that the left side of (3.18) only varies with y while the right side only varies with x. For any given value of x it should be possible to vary y in some way to make the equation wrong. The equation can only be correct for all possible pairs of x and y if both sides actually do not vary at all and are independent of both x and y and therefore constant.

Calling this constant $-k^2$ we have to solve

$$\begin{aligned} -k^2 &= \frac{F_{\mathrm{xx}}}{F(x)} \\ -k^2 &= -\frac{\omega^2}{c^2} - \frac{G_{\mathrm{yy}}}{G(y)}\,. \end{aligned} \tag{3.19}$$

These equations are satisfied by

$$\begin{aligned} F(x) &= \mathrm{Re}\left(A\mathrm{e}^{\mathrm{i}kx}\right) \\ G(y) &= \mathrm{Re}\left(B\mathrm{e}^{\mathrm{i}\sqrt{\frac{\omega^2}{c^2}-k^2}\,y}\right)\,. \end{aligned} \tag{3.20}$$

Considering a rectangular membrane fixed at $x = 0$ and $x = L_{\mathrm{x}}$ as well as at $y = 0$ and $y = L_{\mathrm{y}}$ we obtain the fol-

lowing system

$$\begin{aligned}
0 &= \mathrm{Re}\left(A\mathrm{e}^{\mathrm{i}k0}\right)\mathrm{Re}\left(B\mathrm{e}^{\mathrm{i}\sqrt{\frac{\omega^2}{c^2}-k^2}y}\right)\\
0 &= \mathrm{Re}\left(A\mathrm{e}^{\mathrm{i}kL_\mathrm{x}}\right)\mathrm{Re}\left(B\mathrm{e}^{\mathrm{i}\sqrt{\frac{\omega^2}{c^2}-k^2}y}\right)\\
0 &= \mathrm{Re}\left(A\mathrm{e}^{\mathrm{i}kx}\right)\mathrm{Re}\left(B\mathrm{e}^{\mathrm{i}\sqrt{\frac{\omega^2}{c^2}-k^2}0}\right)\\
0 &= \mathrm{Re}\left(A\mathrm{e}^{\mathrm{i}kx}\right)\mathrm{Re}\left(B\mathrm{e}^{\mathrm{i}\sqrt{\frac{\omega^2}{c^2}-k^2}L_y}\right). \qquad (3.21)
\end{aligned}$$

From this we obtain the conditions ($m, n \in \mathbb{N}$)

$$\begin{aligned}
\mathrm{Re}(A) &= 0\\
kL_\mathrm{x} &= m\pi\\
\mathrm{Re}(B) &= 0\\
\sqrt{\frac{\omega^2}{c^2}-k^2}L_\mathrm{y} &= n\pi\,. \qquad (3.22)
\end{aligned}$$

The complex amplitudes A and B have to be purely imaginary, which rotates the complex exponentials by $\pi/2$. Equations 3.20 become

$$F(x) = |A|(\mathrm{i}\cos(kx) - \sin(kx)) \qquad (3.23)$$

$$\begin{aligned}
G(y) = |B|\Bigg(&\mathrm{i}\cos\left(y\sqrt{\frac{\omega^2}{c^2}-k^2}\right)\\
&-\sin\left(y\sqrt{\frac{\omega^2}{c^2}-k^2}\right)\Bigg). \qquad (3.24)
\end{aligned}$$

The z-displacement of $m\times n$ normal modes of a rectangular membrane can therefore be written as

$$\begin{aligned}
z_{m,n}(x,y,t) = C\sin\left(\frac{m\pi}{L_\mathrm{x}}x\right)\sin\left(\frac{n\pi}{L_\mathrm{y}}y\right)\\
\times\sin(\omega t+\phi)\,. \qquad (3.25)
\end{aligned}$$

The integer numbers $m+1$ and $n+1$ are the numbers of nodal lines along the x- y-dimension respectively. Solving (3.22) for ω gives their corresponding angular frequencies as

$$\omega_{m,n} = c\,\pi\sqrt{\left(\frac{m}{L_\mathrm{x}}\right)^2+\left(\frac{n}{L_\mathrm{y}}\right)^2}. \qquad (3.26)$$

The physical displacement of the membrane must be any linear combination of these normal modes e.g., the sum of any number of normal modes with individual amplitude and individual phase.

Especially in the case where L_x and L_y are equal or have a common multiple, normal mode frequencies (eigenfrequencies) of different modes (e.g., $\omega_{n,m} = \omega_{m,n}$) will coincide.

If the membrane is stimulated at one of these frequencies all of the related normal modes will occur simultaneously with arbitrary phase differences between them. This can create unexpected patterns with rotating nodal lines and even shapes that only rotate but not oscillate, as shown in Fig. 3.2. They are called *degenerate modes*.

3.2.2 Circular Membrane

Now we apply the same method to the wave equation in polar coordinates given by (3.11). Separating the variables r, θ and t gives us a solution of the form

$$z(r,\theta,t) = F(r)G(\theta)\mathrm{e}^{\mathrm{i}\omega t}\,. \qquad (3.27)$$

With

$$\begin{aligned}
z_{\mathrm{rr}} &= F_{\mathrm{rr}}G\mathrm{e}^{\mathrm{i}\omega t}\\
z_\mathrm{r} &= F_\mathrm{r}G\mathrm{e}^{\mathrm{i}\omega t}\\
z_{\theta\theta} &= G_{\theta\theta}F\mathrm{e}^{\mathrm{i}\omega t}\\
z_{\mathrm{tt}} &= -\omega^2\mathrm{e}^{\mathrm{i}\omega t}FG \qquad (3.28)
\end{aligned}$$

the wave equation $z_{\mathrm{tt}} = c^2(z_{\mathrm{rr}} + z_\mathrm{r}/r + z_{\theta\theta}/r^2)$ can be reordered with the intention to let both sides depend on a single variable only. This technique, called *separation of variables*, has already been explained in Sect. 3.2.1. We obtain

$$-\frac{G_{\theta\theta}}{G} = \frac{r^2F_{\mathrm{rr}}}{F}+\frac{r^2\omega^2}{c^2}+\frac{rF_\mathrm{r}}{F}\,. \qquad (3.29)$$

This equation can only be correct for all possible pairs (r,θ) if both sides are actually constant. Giving this constant the name m^2 we obtain two equations

$$\begin{aligned}
m^2 &= -\frac{G_{\theta\theta}}{G}\\
m^2 &= \frac{r^2F_{\mathrm{rr}}}{F}+\frac{r^2\omega^2}{c^2}+\frac{rF_\mathrm{r}}{F}\,. \qquad (3.30)
\end{aligned}$$

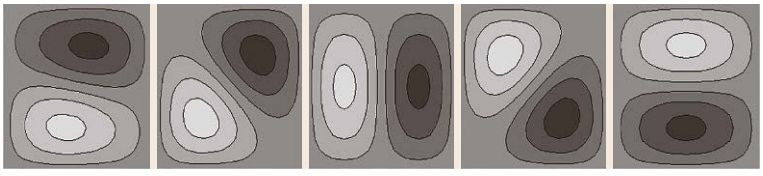

Fig. 3.2 Square membrane, degenerate mode

The first one we already know. It has the solution $G(\theta) = Ae^{\pm im\theta}$. θ is not restricted to the range $[0, 2\pi]$ and we want $G(\theta)$ to be single valued; that means $G(\theta) = G(\theta + 2\pi)$. Therefore the constant m must be an integer number. It can take the values $0, 1, 2, \ldots$ and it is related to the number of nodal diameters.

The second equation can be rearranged as

$$F_{rr} + \frac{F_r}{r} + F\left(\frac{\omega^2}{c^2} - \frac{m^2}{r^2}\right) = 0\,. \tag{3.31}$$

This is Bessel's equation and the general solutions are known as the so-called *Bessel functions* $J_m(kr)$ with $k = \omega/c$ and integer order m.

A circular membrane is fixed by the circular tensioning hoop where zero displacement is enforced. This requires $J_m(kr) = 0$ at $r = R$, R being the radius of the membrane. But Bessel functions have many zeros, so the boundary condition is satisfied for the whole ordered sequence of zeros of $J_m(kr)$.

If we take the smallest zero, the only nodal circle is the tensioning hoop. If we let the n-th zero be the one required at $r = R$, then we will get $n-1$ additional nodal circles at radii corresponding to all smaller zeros. The number n therefore designates the number of nodal circles and it is the sequential index of the corresponding zero of $J_m(kr)$.

The resonance frequency of mode (m, n) can be calculated from $\gamma_{m,n}$ being the n-th zero of the Bessel function of order m according to $f_{m,n} = c\gamma_{m,n}/2\pi R$. Figure 3.3 shows the first 15 normal modes sorted by relative frequency. It can be seen that the radial modes with a single nodal circle $(1, 1), (2, 1), (3, 1), \cdots$ are very close to a harmonic series. They are giving the timpani its audible pitch.

3.2.3 Rectangular Plate

Following the example of the rectangular membrane we assume a general solution according to (3.15) with partial derivatives as shown in (3.16). The equation of motion of a plate (3.12) is of fourth order so we also need fourth-order derivatives

$$\begin{aligned} z_{xxxx} &= F_{xxxx} G e^{i\omega t} \\ z_{yyyy} &= G_{yyyy} F e^{i\omega t} \\ z_{xxyy} &= F_{xx} G_{yy} e^{i\omega t}\,. \end{aligned} \tag{3.32}$$

Substituting these derivatives into the fourth-order differential equation for the plate yields

$$F_{xxxx} G + G_{yyyy} F + 2F_{xx} G_{yy} = \frac{\omega^2}{\Lambda} FG \tag{3.33}$$

with $\Lambda = h^2 E/(12\rho(1-\nu^2))$.

It can be seen that it is not possible to separate the variables like in (3.18) because of the mixed term z_{xxyy}. Assuming sinusoidal (or strictly speaking cosinusiodal) spatial profiles in both axial directions we can again use the ansatz $F(x) = \mathrm{Re}(Ae^{ik_x x})$ and $G(y) = \mathrm{Re}(Be^{ik_y y})$. This gives us a relation between the wave numbers k_x, k_y and the frequency ω

$$k_x^4 + k_y^4 + 2k_x^2 k_y^2 = \frac{\omega^2}{\Lambda} \tag{3.34}$$

or

$$k_x^2 + k_y^2 = k^2 = \pm\frac{\sqrt{12}\omega}{h}\sqrt{\frac{\rho(1-\nu^2)}{E}} \tag{3.35}$$

with k being the wave number in the actual direction of wave propagation. It can be seen that there are imaginary solutions for the wave number k. An imaginary

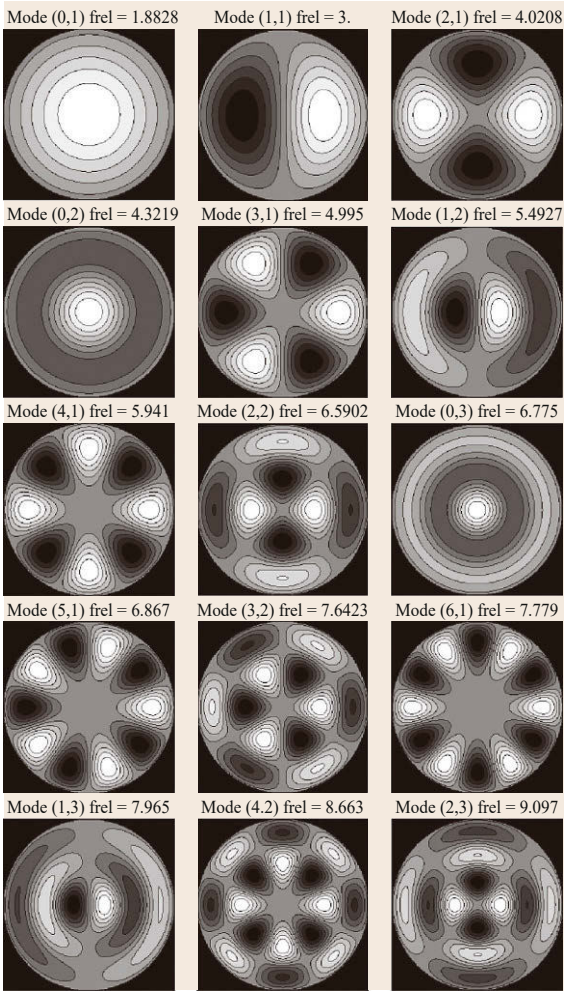

Fig. 3.3 Circular membrane normal modes

wave number causes a real but negative coefficient of the spatial variables x and y in the exponential terms for the profiles F and G. This means an exponential decay of the wave amplitude. It is said the wave is *evanescent* and does not propagate. It decays by about 55 dB per wavelength [3.4].

The phase speed c_{ph} of waves is given by ω/k. In this case it is

$$c_{\mathrm{ph}} = \sqrt{\frac{h\omega}{\sqrt{12}}\sqrt{\frac{E}{\rho(1-\nu^2)}}}\,. \tag{3.36}$$

Unlike in strings and membranes without stiffness it is not constant here but frequency dependent. This is why (3.35) is named the *dispersion relation*. The relation between frequency f and wave number k is

$$f = hk^2\frac{1}{2\pi\sqrt{12}}\sqrt{\frac{E}{\rho(1-\nu^2)}}\,. \tag{3.37}$$

It can be used to calculate resonance frequencies if the wave number k is fixed by boundary conditions.

Hagedorn calculated mode shapes and frequencies for a simply supported rectangular plate [3.2] by splitting the fourth-order differential equation into two second-order ones, one of them being identical to the wave equation of the rectangular membrane. He obtained the same modal shapes as for the rectangular membrane but at different modal frequencies

$$\omega_{m,n} = \pi^2\sqrt{\Lambda}\left(\left(\frac{m}{L_{\mathrm{x}}}\right)^2 + \left(\frac{n}{L_{\mathrm{y}}}\right)^2\right). \tag{3.38}$$

For all other boundary conditions rectangular plates have to be treated numerically.

3.2.4 Circular Disk

Let us see how the forth-order differential equation can be split into a product of second-order equations

$$(\nabla^4 - \gamma^4)Z = (\nabla^2 + \gamma^2)(\nabla^2 - \gamma^2)Z = 0\,. \tag{3.39}$$

Comparing (3.39) with (3.12) we can determine that for $z(x,y,t) = Z(x,y)\mathrm{e}^{\mathrm{i}\omega t}$ the factor γ must satisfy $\gamma^4 = \omega^2/\Lambda$. The abbreviation Λ has already been defined with (3.33).

Therefore a solution for the spatial profile $Z(x,y)$ must satisfy either $(\nabla^2 + \gamma^2)Z = 0$ or $(\nabla^2 - \gamma^2)Z = 0$. A differential equation of the first type has already been solved for the rectangular membrane as well as for the circular membrane with $\gamma = \omega/c$. Recapitulating the derivation in polar coordinates of Sect. 3.2.2 we obtain two solutions according to

$$Z_1(r,\theta) = A\mathrm{e}^{\pm\mathrm{i}m\theta}J_m(\gamma r)\,. \tag{3.40}$$

In order to solve the second equation we have to substitute γ by the imaginary factor $\mathrm{i}\gamma$. The solutions of Bessel's equation are now called hyperbolic Bessel functions $I_{\mathrm{m}}(\gamma r) = \mathrm{i}^{-m}J_{\mathrm{m}}(\mathrm{i}\gamma r)$. This gives us more solutions for Z according to

$$Z_2(r,\theta) = A\mathrm{e}^{\pm\mathrm{i}m\theta}I_m(\gamma r)\,. \tag{3.41}$$

Possible spatial profiles are therefore the linear combinations

$$Z(r,\theta) = \mathrm{e}^{\pm\mathrm{i}m\theta}(AJ_m(\gamma r) + BI_m(\gamma r))\,. \tag{3.42}$$

If the plate is clamped at a distance R from the center, boundary conditions

$$\begin{aligned} Z(R,\theta) &= 0 \\ \frac{\partial}{\partial r}Z(r,\theta) &= 0|r = R \end{aligned} \tag{3.43}$$

are enforced. This requires

$$\begin{aligned} AJ_m(\gamma R) + BI_m(\gamma R) &= 0 \\ \frac{\partial}{\partial r}(AJ_m(\gamma R) + BI_m(\gamma R)) &= 0|r = R\,. \end{aligned} \tag{3.44}$$

The first condition is satisfied by

$$B = -A\frac{J_m(\gamma R)}{I_m(\gamma R)}\,. \tag{3.45}$$

Now the second condition becomes

$$I_m(\gamma R)\frac{\partial J_m(\gamma r)}{\partial r} = J_m(\gamma R)\frac{\partial I_m(\gamma r)}{\partial r}|r = R\,. \tag{3.46}$$

The solutions for $\beta_{mn} = R\gamma_{mn}/\pi$, with m the number of nodal diameters and n the number of nodal circles, have been given by *Morse* in [3.3] as

$$\begin{aligned} \beta_{01} &= 1.015 & \beta_{11} &= 1.468 & \beta_{21} &= 1.879 \\ \beta_{02} &= 2.007 & \beta_{12} &= 2.483 & \beta_{22} &= 2.992 \\ \beta_{03} &= 3.000 & \beta_{13} &= 3.490 & \beta_{23} &= 4.000\,. \end{aligned}$$

With these solutions it is possible to determine the corresponding frequencies according to

$$f_{mn} = \frac{\pi}{2R^2}\sqrt{\frac{h^2E}{12\rho(1-\nu^2)}}\beta_{mn}^2\,. \tag{3.47}$$

3.3 Sound Waves in Space

It is straightforward to generalize (3.4) for sound propagation in three-dimensional space as

$$\frac{\partial^2 p}{\partial t^2} = c^2 \Delta p \,, \tag{3.48}$$

with Δ being the Laplace operator in three dimensions now. But first, this does not give us any relationship between the speed of sound c and basic physical quantities, and second, now might be an opportunity to demonstrate how this equation can also be systematically derived from the first principles of physics.

3.3.1 Wave Equation in Three Dimensions

The fundamental laws of fluid dynamics are the Navier–Stokes conservation laws. The first deals with conservation of mass. No mass can appear from nothingness or disappear into nothingness. The second deals with conservation of momentum mv. Actually it says that any change of a momentum $\mathrm{d}(mv)/\mathrm{d}t$ must be caused by a force. The third is about conservation of energy, but it is enough to consider the first two here.

What remains of the conservation laws for small perturbations $\hat{\rho}$, $\hat{p}$ and $\hat{\boldsymbol{v}}$ (note, that the fluid velocity v is a vector with components in all three spatial dimensions now) of a stagnant ($v_0 = 0$, $v = \hat{v}$) uniform fluid characterized by $p = \hat{p} + p_0$ and $\rho = \hat{\rho} + \rho_0$ can now be given as

$$\begin{aligned} \frac{\partial \hat{\rho}}{\partial t} + \rho_0 \nabla \cdot \hat{\boldsymbol{v}} &= 0 \\ \rho_0 \frac{\partial \hat{\boldsymbol{v}}}{\partial t} + \nabla \hat{p} &= 0 \,. \end{aligned} \tag{3.49}$$

Building the time derivative of the mass conservation law (first equation of (3.49)) and the divergence of the momentum equation (the second one)

$$\begin{aligned} \frac{\partial^2 \hat{\rho}}{\partial t^2} + \rho_0 \frac{\partial}{\partial t}(\nabla \cdot \hat{\boldsymbol{v}}) &= 0 \\ \rho_0 \frac{\partial}{\partial t}(\nabla \cdot \hat{\boldsymbol{v}}) + \Delta \hat{p} &= 0 \end{aligned} \tag{3.50}$$

we can eliminate all v-related terms by subtracting the second equation from the first one. With the proportionality between ρ and p assuming adiabatic state transitions we obtain the wave equation

$$\frac{\partial^2 \hat{p}}{\partial t^2} = c^2 \nabla^2 \hat{p} \equiv c^2 \Delta \hat{p} \,, \tag{3.51}$$

with $c = \sqrt{(c_\mathrm{p} - c_\mathrm{v})T}$. Here $\hat{p}$ is usually replaced by p, if there is no danger of mistaking linearized sound pressure and atmospheric pressure any longer.

This wave equation does not cover the cases where significant air flow, high sound pressures or other nonlinearities are present. Especially in the field of musical acoustics there are essential questions that cannot be answered based on such simplifications.

Sound propagation in brass wind instruments can easily be driven into a nonlinear region for which the wave equation is no longer valid. Wave steepening and shock wave effects are due to the high sound pressure levels generated inside the instrument. To model flow-driven instruments like flue pipes or flutes the Navier–Stokes equations in their general form have to be solved.

Modeling wave propagation does not cover all the nonlinear effects occurring in the primary oscillators of wind instruments either. Waves are propagating on the brass player's lips, the singer's vocal folds and in the air columns of all wind instruments including the singing voice, but the coupling between the vibrating reeds of clarinets, oboes or tubas to the resonator, the air column of the instrument, is highly nonlinear.

3.3.2 Rectangular Coordinates

Calculating the resonances of a simple rectangular room is a good exercise here and will have significance for room acoustics. We separate the variables for the pressure p just like in Sect. 3.2.1 on the rectangular membrane according to

$$p(x, y, z, t) = F(x)G(y)H(z)\mathrm{e}^{\mathrm{i}\omega t} \,. \tag{3.52}$$

Now we avoid complex exponentials for the space-dependent terms F, G and H because we learned in Sect. 3.2.1 that we did not gain much in using them in that place. Here we will work with the real part of the complex exponentials only. We try with

$$\begin{aligned} F(x) &= A\cos(k_1 x) \\ G(y) &= B\cos(k_2 y) \\ H(z) &= C\cos(k_3 z) \end{aligned} \tag{3.53}$$

leading to

$$\begin{aligned} p_{\mathrm{xx}} &= -k_1^2\, p(x, y, z, t) \\ p_{\mathrm{yy}} &= -k_2^2\, p(x, y, z, t) \\ p_{\mathrm{zz}} &= -k_3^2\, p(x, y, z, t) \\ p_{\mathrm{tt}} &= -\omega^2\, p(x, y, z, t) \,. \end{aligned} \tag{3.54}$$

With the three-dimensional wave equation $p_{\mathrm{tt}} = c^2(p_{\mathrm{xx}} + p_{\mathrm{yy}} + p_{\mathrm{zz}})$ we obtain a relation for the angular frequency ω of a mode when the wave numbers k_i in

the three axial directions are known

$$\omega = c\sqrt{k_1^2 + k_2^2 + k_3^2}\,. \tag{3.55}$$

We know that rigid walls represent a free boundary for the sound pressure but a fixed boundary for the velocity. While zero velocity is always enforced by rigid walls, this is not true for the sound pressure. At resonance the sound pressure will exhibit a local maximum at the wall. We can also say that rigid walls enforce a vibrational antinode of the sound pressure.

A local maximum always coincides with a zero derivative, which means a horizontal tangent. And this is how we are going to specify our boundary conditions.

The first derivative of the pressure with respect to a spatial coordinate must always be zero at the left boundary $x = 0$, $y = 0$ or $z = 0$ and at the right boundary $x = L_x$, $y = L_y$ or $z = L_z$ of a room with dimensions L_x, L_y and L_z.

As $\sin(0)$ is zero, the left boundary conditions are always met – we do not have to care about them. The remaining boundary conditions are therefore

$$\begin{aligned} 0 = p_x &\equiv -Ak_1 \sin(k_1 x) GH e^{i\omega t}|_{x=L_x} \\ 0 = p_y &\equiv -Bk_2 \sin(k_2 y) FH e^{i\omega t}|_{y=L_y} \\ 0 = p_z &\equiv -Ck_3 \sin(k_3 z) FG e^{i\omega t}|_{z=L_z}\,. \end{aligned} \tag{3.56}$$

These conditions are always and everywhere only met for

$$\begin{aligned} k_1 L_x &= n_1 \pi \\ k_2 L_y &= n_2 \pi \\ k_3 L_z &= n_3 \pi\,. \end{aligned} \tag{3.57}$$

This gives us the wave numbers of all possible normal modes of that room and with (3.55) the corresponding resonance frequencies

$$\begin{aligned} k_1 &= \frac{n_1 \pi}{L_x} \\ k_2 &= \frac{n_2 \pi}{L_y} \\ k_3 &= \frac{n_3 \pi}{L_z} \\ \omega &= c\pi \sqrt{\left(\frac{n_1}{L_x}\right)^2 + \left(\frac{n_2}{L_y}\right)^2 + \left(\frac{n_3}{L_z}\right)^2} \end{aligned} \tag{3.58}$$

with $n_i = 0, 1, 2, 3, \cdots$.

If room dimensions have common integer multiples – a room with $L_x = L_y = L_z$ being the most extreme example – then different resonances will coincide and become very strong but sparse. Rooms are said to be good for music performances if resonances are evenly spread and don't cluster.

However, resonant instrument bodies are far away from having a rectangular shape. Therefore their normal modes can only be determined numerically or experimentally.

3.3.3 Spherical Coordinates

If there is a sound source whose dimensions are small compared to the wavelengths to be studied, a point source with spherical wave propagation can be assumed. According to the symmetry of the problem a spherical coordinate system will preferably be chosen according to Fig. 3.4.

The Cartesian coordinates can be expressed in terms of radial distance r, polar angle θ and axial or azimuthal angle ψ according to

$$\begin{aligned} x &= r\cos\theta \sin\psi \\ y &= r\sin\theta \sin\psi \\ z &= r\cos\psi\,. \end{aligned} \tag{3.59}$$

The transformation of the three-dimensional Laplace operator $\Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$ into spherical coordinates would take up too much space here. It can be derived following the two-dimensional example from (3.7)–(3.10), but using the correspondences of (3.59).

Writing p for $\hat{p}$ the wave equation (3.51) now becomes

$$p_{tt} = \frac{c^2}{r^2}\left((r^2 p_r)_r + \frac{1}{\sin\theta}(p_\theta \sin\theta)_\theta + \frac{1}{\sin^2\theta} p_{\psi\psi} \right). \tag{3.60}$$

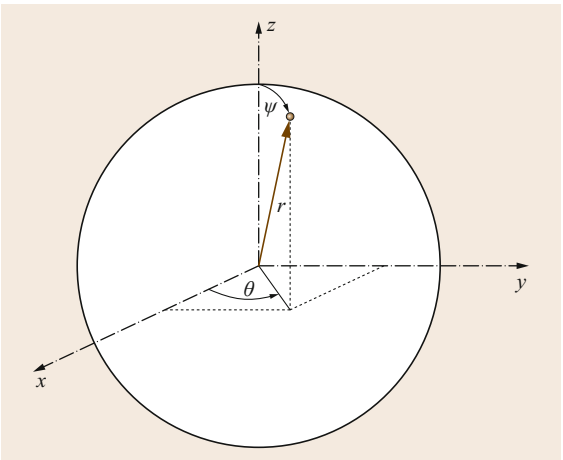

Fig. 3.4 Spherical coordinates

If the problem has a perfect spherical symmetry, like a pulsating sphere of any size in an undisturbed three-dimensional space, then all the derivatives with respect to the angles θ and ψ will become zero. The remaining wave equation is

$$p_{\mathrm{tt}} = \frac{c^2}{r^2}\left(\left(r^2 p_{\mathrm{r}}\right)_{\mathrm{r}}\right) . \tag{3.61}$$

Substituting $p \to p^* r$ and therefore $p_{\mathrm{r}} \to p^*_{\mathrm{r}}/r - p^*/r^2$ we finally obtain

$$p^*_{\mathrm{tt}} = c^2 p^*_{\mathrm{rr}} , \tag{3.62}$$

which is a one-dimensional wave equation for the spatial coordinate r and a pressure p^*, which is related to the original sound pressure p in that its relative amplitude is proportional to the distance r from the center.

The general solution for the sound pressure p is

$$p = \left(\frac{A}{r}\mathrm{e}^{-\mathrm{i}kr} + \frac{B}{r}\mathrm{e}^{\mathrm{i}kr}\right)\mathrm{e}^{\mathrm{i}\omega t} \tag{3.63}$$

Following the derivation of (3.30) with spatial variable r instead of x and with a different spatial derivative $p_{\mathrm{r}} = -\mathrm{i}kp - p/r$ we can obtain the impedance

$$Z = \frac{p}{v} = \rho c \frac{\mathrm{i}kr}{\mathrm{i}kr + 1} = -\rho c \frac{(kr)^2 + \mathrm{i}kr}{1 - (kr)^2} . \tag{3.64}$$

For $kr >> 1$ the impedance Z approaches the plane wave impedance ρc according to (2.30). On the other side if $kr << 1$ then the impedance approaches $-\rho c\mathrm{i}kr$ thus becoming purely imaginary with a phase difference between p and v of $-\pi/2$.

The sound intensity I of a single forward traveling wave ($B = 0$) with frequency ω at some distance r from the center is defined as the product of the amplitudes $\hat{p}/\sqrt{2}$ and $\hat{v}/\sqrt{2}$. As the velocity $v = p/Z$ the intensity can also be calculated according to $I = \hat{p}^2/(2Z) = \hat{p}^2 Y/2$, with Y being the reciprocal of the complex impedance Z, named *admittance*.

With the complex admittance

$$Y = \frac{1}{\rho c} - \frac{\mathrm{i}}{\rho c k r} \tag{3.65}$$

the real part of the sound intensity I becomes

$$\mathrm{Re}(I) = \hat{p}^2 \frac{\mathrm{Re}(Y)}{2} = \frac{|A|^2}{2\rho c r^2} . \tag{3.66}$$

It decreases with the square of the distance r because the total effective power $\mathrm{Re}(P)$ contained in a wavefront is spread over the surface $S = 4r^2\pi$ of a steadily growing sphere.

The imaginary part of the sound intensity I

$$\mathrm{Im}(I) = \hat{p}^2 \frac{\mathrm{Im}(Y)}{2} = -\frac{|A|^2}{2\rho c k r^3} \tag{3.67}$$

decreases with the third power of the distance r. This means that the total reactive power of a wavefront $\mathrm{Im}(P) = \mathrm{Im}(I)4r^2\pi$ is no longer constant but decreases with r. Close to the center it can become very high and even infinity for $r = 0$. This is not a violation of the law of conservation of energy because reactive power corresponds to a periodic transfer of energy between the pressure and the velocity wave and it is not dissipated.

It has to be noted that all the results obtained for spherical wave propagation in three-dimensional space are equally valid for one-dimensional wave propagation in a conical duct of any length or size. This is understandable because there is only a dependency on the distance from the center of the sphere, i. e., from the apex of the cone.

It doesn't matter whether we study spherical wavefronts as a whole or only a part of these spheres within a certain solid angle inside the boundaries of a cone. All variables are constant across the surface of any such sphere. Conical boundaries do therefore not change anything if the apex of the cone is identical to the center of the spheres. This is the reason why (2.64) is equally valid for cylindrical and conical ducts.

3.3.4 Cavities with Vents

It is well known that vented cavities like bottles exhibit acoustic resonances. These resonances can be excited by blowing air across the bottle neck or by popping it with the palm at the mouth of the bottle neck.

Helmholtz used these well-defined resonators, which later on were given his name, to detect frequency components in composite sounds [3.5]. His original drawing is shown in Fig. 3.5. Inserting the short nipple marked with the letter *b* into the ear, he could detect even faint air resonances stimulated by sound present at the open mouth labeled with the letter *a*.

This special kind of resonator is of essential importance in musical acoustics. All hollow bodies of stringed instruments, like violins, guitars, lutes and others, which are not completely closed but allow some acoustic flow through some kind of f-holes, c-holes or sound holes, act in this way.

Their cavity resonance is tuned to support the lowest register of these instruments, at frequencies that could otherwise never be radiated by normal plate resonances because the related wavelengths are usually much greater than the size of the plates.

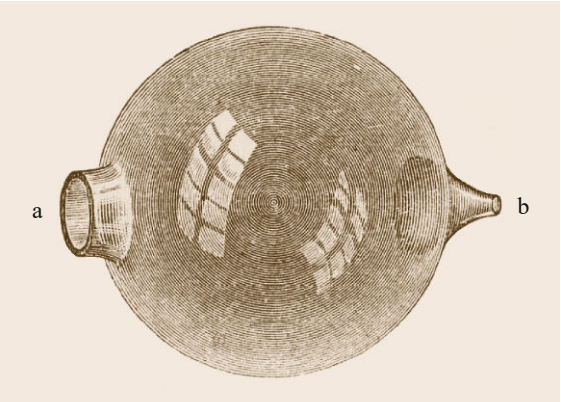

Fig. 3.5 Helmholtz resonators (after [3.5])

Although it appears as if Helmholtz resonators were three-dimensional cavities with wave propagation inside mainly closed boundaries, it is not necessary to treat them in this way. Usually their main resonance frequency is low enough so that the cavity is small compared to the wavelength at that frequency.

In that case the actual shape of the cavity no longer matters and solely its volume determines the acoustical characteristics, together with length and cross-sectional area of the vent.

The resonator can be treated as a single mass-spring system. The mass is provided by the air enclosed in the vent. It is given by $m = \rho SL$, with density of air ρ, cross-sectional area S and length L of the *bottle neck*.

In case of a very short *neck*, or no neck at all, L is an equivalent length taking a so-called *end-correction* into account. This end-correction of an open cylindrical tube lengthens the tube at each open end by a certain distance d, which was theoretically determined by *Levine* and *Schwinger* in [3.6] as $d = 0.61R$ (R being the radius of the cylindrical neck) and has later been confirmed experimentally.

In the case of sound holes we have to apply the end-correction twice (inside and outside) and get $L = T + 0.61D$ with thickness T of the top plate and diameter D of the sound hole. The open area S of the sound hole becomes $S = D^2\pi/4$.

The spring is provided by the elastic air enclosed in the cavity. A spring constant $E = F/z = \mathrm{d}F/\mathrm{d}z$ is the proportionality factor between force F and displacement z or the differential quotient if F is a function of z. The force is due to the air pressure p inside the cavity and given by $F = pS$.

For ideal gases we have $pV = nRT$. If we compress the air in our cavity (initial volume V_0, pressure p_0) by a piston of air in the neck then the reduced volume $V_0 - \mathrm{d}V$ will lead to an increased pressure $p_0 + \mathrm{d}p$.

Assuming that neither the temperature nor the amount of substance in the now reduced volume has significantly changed we can equate the products

$$\begin{aligned} p_0V_0 &= (p_0 + \mathrm{d}p)(V_0 - \mathrm{d}V) \\ &= p_0V_0 + V_0\,\mathrm{d}p - p_0\,\mathrm{d}V - \mathrm{d}p\,\mathrm{d}V\,. \end{aligned} \tag{3.68}$$

Neglecting the second-order term, substituting $\mathrm{d}V = S\,\mathrm{d}z$ and solving for $\mathrm{d}p$ we obtain

$$\mathrm{d}p = \frac{p_0}{V_0} S\,\mathrm{d}z\,. \tag{3.69}$$

For adiabatic conditions p_0 must be replaced by Kp_0 which equals to $c^2\rho$ according to (2.28).

With $\mathrm{d}F = \mathrm{d}pS$ we get the spring constant E according to

$$E = \frac{\mathrm{d}F}{\mathrm{d}z} = \frac{p_0}{V_0}S^2 = \frac{c^2\rho_0}{V_0}S^2 \tag{3.70}$$

using $Kp = c^2\rho$ derived from (2.28).

This leads to the Helmholtz resonance

$$\omega_0 = \sqrt{\frac{E}{m}} = c\sqrt{\frac{S}{V_0L}}\,. \tag{3.71}$$

Higher air modes cannot be explained by a single mass-spring model but can definitely be observed in stringed instrument bodies at frequencies where the shapes of cavity and sound holes as well as wave propagation inside the body can no longer be ignored. A full three-dimensional treatment of standing waves inside the body would be required to analyze these resonances. For such problems there are no analytical solutions and numerical methods have to be applied.

3.3.5 Solution for Long Ducts

It will now be shown how the three-dimensional wave equation can be solved for the boundary conditions given by long acoustic ducts with cylindrical or rectangular cross-section. The solution will not be restricted to cases where wavefronts can be treated as plane waves. Especially in horns with flaring bells the plane wave assumption is not at all realistic and one-dimensional approximations deviate significantly from the reality in which we encounter internal wavefronts, which are neither plane nor spherical.

In order to make use of an available axial symmetry, the wave equation is formulated in cylindrical coordinates. Just like any arbitrary displacement profile of a vibrating string at a given time point can be represented by a linear combination of all possible normal

modes (spatial superposition principle), any wavefront inside the duct, at a certain axial distance from the open end, and at a certain point in time, can also be described as a weighted sum of all possible normal modes satisfying the local boundary conditions.

If the propagation characteristics of all normal modes are known, the actual physical wavefront and its propagation in space as well as its periodic fluctuation in time can be described as a superposition of basic shapes. This method is referred to as modal decomposition.

The first normal mode is the plane wave. If we truncate after the first mode we obtain the already-derived plane-wave approximation. Higher modes are described by Bessel functions of the first kind of order zero, if the duct is straight (nodal lines must be circles). In tubes with toroidal bends [3.7] wavefronts will also contain normal modes described by higher-order Bessel functions with diameters as nodal lines.

Here we will follow the presentation of *Kemp* [3.8] for the axisymmetric case. In a similar way modal decomposition can also be applied to get a three-dimensional solution within a duct with rectangular cross-section. This is the case in certain wooden organ pipes. For this derivation please refer to [3.8].

3.3.6 Modal Decomposition

In cylindrical coordinates (r, θ, z) the Laplacian operator Δ becomes

$$\Delta = \Delta_\perp + \frac{\partial^2}{\partial z^2} = \left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial \theta^2}\right) + \left(\frac{\partial^2}{\partial z^2}\right). \quad (3.72)$$

If we express pressure p and axial velocity v_z using infinite series according to [3.9] we get the solutions

$$p(r, \theta, z, t) = \sum_i P_i(z)\Psi_i(r, \theta)\exp(\mathrm{i}\omega t) \quad (3.73)$$

and

$$v_z(r, \theta, z, t) = \frac{1}{S(z)}\sum_i U_i(z)\Psi_i(r, \theta)\exp(\mathrm{i}\omega t)\,, \quad (3.74)$$

with pressure profile P_i and velocity profile U_i of the i-th mode along the z-axis and the profile Ψ_i orthogonal to it. The complex-valued profiles contain the spatial distribution of oscillation amplitudes and their initial phases at time $t = 0$. $S(z)$ describes the geometry of the acoustical duct by specifying the cross-sectional area along the z-axis. Instrument makers are more acquainted with the so-called bore profile defining bore diameters instead of cross-sectional areas. But as ducts do not necessarily need to be perfectly cylindrical, it is better to base computations on the cross-sectional area.

We know that modal profiles along the z-axis

$$P_i(z) = \exp(\mathrm{i}k_i z), \quad U_i(z) = \exp(\mathrm{i}k_i z)\,, \quad (3.75)$$

are sinusoidal with modal wave numbers k_i. The profiles Ψ_i across the longitudinal axis are the so-called classical eigenfunctions obeying

$$\Delta_\perp \Psi_i = -{\alpha_i}^2 \Psi_i \quad (3.76)$$

with boundary condition $\partial\Psi_i/\partial r = 0$ for $r = R$, R being the radius of the cylindrical duct. The eigenvalues in the axisymmetric case are given by $\alpha_i(z) = \gamma_i/R$ with γ_i being the successive zeros of the Bessel function of order one.

Substituting p from (3.73) into the wave (3.51), resolving the differential operator Δ from (3.72), dividing by p and substituting P_i and $\Delta_\perp\Psi_i$ from (3.75) and (3.76) we can get rid of all partial derivatives and obtain the relation

$$k_i^2 = k^2 - \alpha_i^2\,, \quad (3.77)$$

with the free space wave number $k = \omega/c$ and and modal wave lengths $\lambda_i = 2\pi/k_i$ being a function of modal wave numbers k_i.

This leads us to the interpretation that the propagation of the different modes along a cylindrical piece of duct does not differ from the plane wave case, described by (2.42) and (2.30), yet each mode having got its own wave number k_i and its own characteristic impedance $Z_{c,i} = \pm k\rho c/(k_i S)$. If the wave number k_i becomes imaginary (for $k < \alpha_i$), exponential damping is observed.

Equations (2.45) and (2.46), the modal projection equations from plane 1 to plane 0, a distance d away, can therefore be rewritten for the multimodal case as

$$P_{0,i} = \cos(k_i d)P_{1,i} + \mathrm{i}\sin(k_i d)Z_{c,i}U_{1,i} \quad (3.78)$$

and

$$U_{0,i} = i\sin(k_i d)Z_{c,i}^{-1}P_{1,i} + \cos(k_i \mathrm{d})U_{1,i}\,. \quad (3.79)$$

Defining column vectors $\boldsymbol{P}$ and $\boldsymbol{U}$ containing the pressure amplitudes P_i with respect to the volume flow amplitudes U_i of all modes at any cross-sectional plane

of the duct, we can introduce a multimodal impedance matrix $\mathbf{Z}$, with

$$\boldsymbol{P} = \mathbf{Z}\boldsymbol{U}\,, \tag{3.80}$$

which describes the relationship between pressure and volume flow amplitudes of different modes at any given position inside the duct. If the matrix $\mathbf{Z}$ is diagonal then the different modes are uncoupled and no modal conversion takes place. Otherwise energy is transferred from one mode to another, an effect which is of particular interest at discontinuities of the duct.

The projection equations (3.78) and (3.79) can be rewritten in matrix notation as

$$\boldsymbol{P}_{(0)} = \mathbf{D_1}\boldsymbol{P}_{(1)} + \mathbf{D_2}\mathbf{Z}_\mathrm{c}\boldsymbol{U}_{(1)} \tag{3.81}$$

and

$$\boldsymbol{U}_{(0)} = \mathbf{D_2}\mathbf{Z}_\mathrm{c}^{-1}\boldsymbol{P}_{(1)} + \mathbf{D_1}\boldsymbol{U}_{(1)} \tag{3.82}$$

with diagonal matrices $\mathbf{D_1}(i,i) = \cos(k_i d)$, $\mathbf{D_2}(i,i) = \mathrm{i}\sin(k_i d)$ and $\mathbf{Z}_\mathrm{c}(i,i) = k\rho c/(k_i S)$.

If these equations are substituted into (3.80) we can (for the derivation refer to [3.8] obtain the projection equation for impedance matrices

$$\mathbf{Z}_{(0)} = (\mathbf{Z}_{(1)} + \mathrm{i}\mathbf{D}\mathbf{Z}_\mathrm{c})(\mathrm{i}\mathbf{D}\mathbf{Z}_\mathrm{c}^{-1}\mathbf{Z}_{(1)} + \mathbf{I})^{-1} \tag{3.83}$$

with diagonal matrix $\mathbf{D}(i,i) = \tan(k_i d)$.

Assuming axisymmetric pressure distributions only, the solution of the eigenproblem in (3.76) is

$$\Psi_i = \frac{J_0\left(\frac{\gamma_i r}{R}\right)}{J_0(\gamma_i)} \tag{3.84}$$

with J_0 being the Bessel function of the first kind of order zero.

Bruneau et al. studied a multimodal wave propagation model including viscous losses [3.10]. Starting with a lossy boundary condition he obtained complex modal wave numbers

$$k_i = \pm\sqrt{k^2 - \left(\frac{\gamma_i}{R}\right)^2 + \left(\frac{2k}{R}\right)(\mathrm{Im}\,(\epsilon_i) - \mathrm{iRe}\,(\epsilon_i))} \tag{3.85}$$

with

$$\epsilon_i = \left(\frac{1-(\gamma_i)^2}{(k^2R^2)}\right)\epsilon_\mathrm{v} + \epsilon_\mathrm{t} \tag{3.86}$$

with $\epsilon_\mathrm{v} = (1+\mathrm{i})2.03\times10^{-5}\sqrt{f}$ and $\epsilon_\mathrm{t} = (1+\mathrm{i})0.95\times10^{-5}\sqrt{f}$ (simplified, refer to [3.8, 10].

3.3.7 Modal Conversion

While different modes in a uniform duct propagate independently of each other, mode conversion takes place where the duct's cross-sectional area changes. The i-th mode after the discontinuity will be composed from a weighted sum of all modes before the discontinuity. The pressure and volume velocity mode amplitude vectors $\boldsymbol{P}$ and $\boldsymbol{U}$ at one side of the discontinuity (cross-section S_0) are related to the corresponding vectors at the other side (cross-section S_1) by

$$\boldsymbol{P_0} = \mathbf{F}\boldsymbol{P_1}, \quad \boldsymbol{U_1} = \mathbf{F}^\top\boldsymbol{U_0}, \quad S_0 < S_1 \tag{3.87}$$

and

$$\boldsymbol{P_1} = \mathbf{V}\boldsymbol{P_0}, \quad \boldsymbol{U_0} = \mathbf{V}^\top\boldsymbol{U_1}, \quad S_0 > S_1\,. \tag{3.88}$$

The matrices $\mathbf{F}$ and $\mathbf{V}$ for cylindrical and rectangular ducts have been derived by *Kemp* in [3.8]. The results for the cylindrical case are repeated here as

$$F_{n,m}(\beta) = \frac{2\beta\gamma_m J_1(\beta\gamma_m)}{(\beta^2{\gamma_m}^2 - {\gamma_n}^2)J_0(\gamma_m)}\,, \tag{3.89}$$

with $\beta = R_1/R_2$ and $F(0,0) = 1$ and $V_{n,m}(\beta) = F_{n,m}(1/\beta)$.

From the equations (3.87) and (3.88) the projection of the impedance matrix across a discontinuity can be calculated as

$$\mathbf{Z}_0 = \mathbf{F}\mathbf{Z}_1\mathbf{F}^\top, \quad S_0 < S_1\,, \tag{3.90}$$

and

$$\mathbf{Z}_0 = \mathbf{V}^{-1}\mathbf{Z}_1(\mathbf{V}^\top)^{-1}, \quad S_0 > S_1\,. \tag{3.91}$$

3.3.8 Multimodal Radiation

In [3.11], *Zorumski* published a numerically applicable multimodal solution for the radiation impedance of a cylindrical pipe terminated in an infinite flange.

Multimodal wave propagation in axisymmetric or rectangular ducts has superbly been reviewed and extended by *Kemp* in [3.8]. Important studies of multimodal wave propagation have been published by *Pagneux* [3.9] and *Amir* [3.12].

The multimodal result for the radiation impedance of a circular opening in an infinite baffle is repeated here

$$Z_{n,m} = \frac{\rho c}{S}\int_0^{\frac{\pi}{2}} \sin\phi D_n(\sin\phi)D_m(\sin\phi)\,\mathrm{d}\phi + \frac{\mathrm{i}\rho c}{S}\int_0^{\infty} \cosh\xi D_n(\cosh\xi)D_m(\cosh\xi)\,\mathrm{d}\xi\,, \tag{3.92}$$

where

$$D_i(\tau) = \frac{-\sqrt{2}\tau J_1(\tau kR)}{\left(\frac{\gamma_i}{(kR)}\right)^2 - \tau^2} \,. \tag{3.93}$$

In a study published by *Hélie* and *Rodet* in [3.13] the multimodal radiation impedance was calculated for a pulsating portion of a sphere without any solid wall or object other than the rest of the sphere, which remains motionless.

The resulting expression for the impedance Z as a function of frequency f, angle of the axis of symmetry θ and mode number n is

$$Z_n(f,\theta) = -\mathrm{i}Z_c\gamma_n\left(\frac{2\pi f r_0}{c_0}\right)\mu_n(\theta_0)\mathrm{P}_n(\cos\theta)\,, \tag{3.94}$$

where

$$\mu_n(\theta_0) = \frac{\mathrm{P}_{n-1}(\theta_0) - \mathrm{P}_{n+1}(\theta_0)}{2} \tag{3.95}$$

with r_0 being the radius of the sphere, $Z_c = \rho_0 c_0$ being the characteristic specific impedance, ρ_0 and c_0 the mass density and speed of sound, θ_0 being the maximum opening angle θ at the edge of the pulsating portion of the sphere, P_n being the Legendre polynomials and $\gamma_n(z) = h_n(z)/h'(z)$ with h_n representing the outgoing spherical Hankel functions.

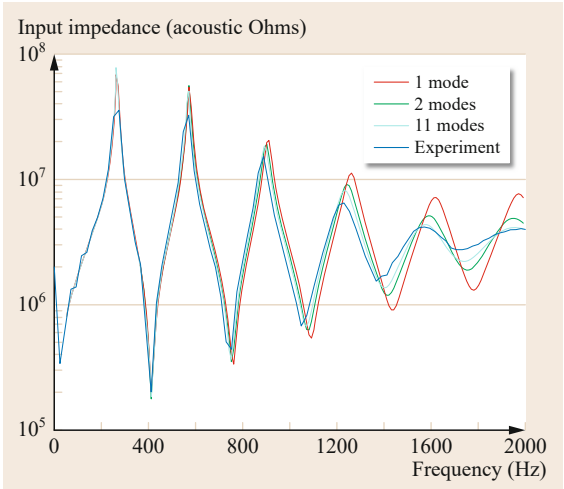

Fig. 3.6 Trumpet section input impedance as calculated by *Kemp* (after [3.8])

Taking multimodal propagation into account can improve modeling of musical instruments significantly. Even below the cutoff frequency, modal conversion makes quite a notable difference as shown in Fig. 3.6. Comparisons with numerical finite element method (FEM) simulations made by *Amir*, *Pagneux* and *Kergomard* [3.9, 12] show good agreement.

4. Construction of Wooden Musical Instruments

Chris Waltham, Shigeru Yoshikawa

This work aims to provide an overview of why and how wood is used in musical instruments, primarily strings, woodwind and percussion. The introduction is a description of the desirable properties of a musical instrument and how these relate to the physical properties of wood. A summary is given of the most important woods mentioned in this chapter, including common and Latin names. Section 4.2 discusses the physical properties of woods most relevant to musical instruments and how they relate to their biological taxonomy and also to organology. Sections 4.3 and 4.4 are devoted respectively to woods that make up the acoustically radiant parts of instruments (tonewoods), and those whose function is to transmit vibrations from one part to another, or are simply structural (framewoods). Section 4.5 deals with how the wood is selected, prepared, assembled into an instrument, and finished.

4.1 Scope

This chapter describes the construction of wooden instruments from the point of view of a physical scientist or mechanical engineer, emphasizing the role played by the material properties of wood. While the authors have tried to include in the discussion as geographically wide a variety of instruments as possible, their experience and backgrounds have naturally led them to concentrate on East Asian and Western instruments. The rich variety of string instruments from the rest of Asia, Africa and elsewhere, will have to await a future study.

4.1.1 General Physical Properties of Musical Instruments

Power Output

If we take a comfortable sound pressure level to be 60 dB and ask what isotropic acoustic power source will provide this at a distance of 10 m, the result is of the order 1 mW. This is typical of the normal range of a trained human voice [4.1, p. 622]. For brief periods, music may reasonably rise to 90 dB at 10 m, but this seldom happens with a single instrument.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_4

Section 4.3.3 shows how a typical musical *box* i. e., a guitar, can radiate 60 dB at 10 m over most of its frequency range with an application of a reasonable force of 1 N rms at the bridge. Admittance measurements show that the displacement of the bridge is of the order of 1 μm at 440 Hz, which is structurally quite acceptable for a 2.5 mm spruce plate.

Frequency and Temporal Response

The human ear can nominally respond to frequencies between 20 Hz and 20 kHz. However, in practice our sensitivity is very low at either end of the spectrum and sounds of musical importance tend to lie between about 100 Hz and 5 kHz. Many instruments have the fundamentals of lowest notes below 100 Hz, but we tend to hear only the overtones and *hear* the fundamental only by inference.

The upper limit for musical *speed*, even in electronic music where there are no restrictions on the ability of the player, is about 20 notes per second. Thirty-second notes played at $\text{♩} = 120$ implies a rate of 16 Hz, so each note lasts 60 ms. Hence the ability to define the pitch of these notes is $\Delta f \approx 16$ Hz, which is $\pm$ half a semitone at middle C (262 Hz). In other words, faster notes would have no well-defined pitch.

The *speed limit* puts a limit on the maximum Q of the completed instrument; $Q = \pi f_0 \tau$, where τ is the decay time. For τ of 0.06 s and middle C (262 Hz), $Q \lesssim 50$. For the wooden boxes of string instruments, a Q of 20 or 30 is typical and the need for resonances to be close enough together not to leave big gaps in the radiation gives a similar restriction (Sect. 4.3.3).

4.1.2 Why Wood?

In spite of all recent advances in materials science, wood remains the construction material of choice for the majority of all musical instruments worldwide. Table 4.1 lists all the material properties discussed in this chapter, and gives values for three woods common in musical instruments (a softwood, a hardwood and a monocot) and compares them to a plastic and a metal (acrylic and aluminum). Some distinguishing features of woods and metals can immediately be seen, and the reasons for and consequences of these numerical differences will be examined.

Let us briefly consider why wood is selected as the material for string instruments. Wood was certainly one of the few options available to builders in preindustrial times, but despite extensive research into alternatives in the last hundred years or so, it shows no sign of being displaced. In any case, material scientists are looking to improve secondary characteristics like durability and uniformity while reproducing the primary vibrational properties of, typically, Sitka spruce [4.4]. A look at the Table 4.1 gives some clues. The first is weight; the mass of a given plate scales as ρ/c [4.5], so a 70 g spruce violin top would have to be replaced by a 440 g acrylic top or a 400 g aluminum one, either of which would make for a very heavy instrument. The second parameter that stands out is the quality factor; acrylic is much less resonant than most woods, and aluminum much more resonant. The basic considerations outlined in Sect. 4.1 indicate the desirability of the intermediate quality factors of wood, and this is explored later in Sect. 4.3.3.

In Table 4.1 Sitka spruce (used for the top plate of the violin and guitar) and amboyna wood (used for the body and neck of the shamisen, a Japanese three-stringed instrument) are shown as representatives of tonewoods and framewoods respectively. Bamboo, particularly Japanese madake, is traditionally used for the body of the shakuhachi, nohkan (noh flute), shoh, hichiriki, and other Asian woodwind and percussion instruments.

4.1.3 Summary of Woods

The nomenclature of woods is often confusing. Table 4.2 lists all the woods discussed in this chapter, along with binomial and other common names, and examples of musical uses.

Table 4.1 Vibroacoustic properties of wood, plastic and metal bars (after [4.2, 3]). For orthotropic wood, E refers to E_L, G refers to G_{LR}, and c to c_L i. e., properties in the direction of the grain

Property	Sitka spruce	Amboyna	Bamboo	Acrylic	Aluminum
Density ρ (kg/m^3)	470	870	700	1200	2700
Young's modulus E (GPa)	12	20	15	5.3	71
Shear modulus G (GPa)	1.1	1.6	1.3	1.9	27
Elastic modulus ratio (E/G)	11	12.5	11.5	2.8	2.6
Quality factor (Q)	131	155	140	17	980
Sound speed (in bar) $c = \sqrt{E/\rho}$ (m/s)	5100	4800	4600	2100	5130
Wave resistance ρc (MPa s/m)	2.4	4.2	3.2	2.5	13.8
Vibration parameter c/ρ (m^4/kg/s)	11	5.5	6.6	1.75	1.9
Transmission parameter cQ (10^5 m/s)	6.7	7.4	6.4	0.36	50.3
Acoustic conversion efficiency cQ/ρ	1420	855	920	30	1860

Table 4.2 Summary of woods discussed and their nomenclature. H = hardwood, S = softwood, M = monocot

Common name	Type	Binomial name	Other names	Native	Musical use
Amboyna	H	*Pterocarpus indicus*	Padauk, rosewood	Southeast Asia	Shamisen body, marimba bars
Bamboo (Japanese)	M	*Phyllostachys bambusoides*	Madake	Japan	Shakuhachi etc.
Boxwood	H	*Buxus sempervirens*	Tsuge		Biwa plectrum, marimba mallet
Cypress (Japanese)	S	*Chamaecyparis obtusa*	Hinoke	Central Japan	Stage floor, Noh
Ebony	H	*Diospyros*	Kokutan	West Africa, South Asia	Clarinet
Grenadilla	H	*Dalbergia melanoxylum*	African blackwood	Africa, dry	Clarinet, oboe
Maple (Japan)	H	*Acer palmatum*	Kaede	Japan	
Maple (Norway)	H	*Acer platanoides*		Temperate zone	Violin family back, ribs
Maple (Sycamore)	H	*Acer pseudoplatanus*		Central Europe, Southwest Asia	
Magnolia (Japan)	H	*Magnolia obovata*	Hohnoki	Japan	Biwa fret
Mulberry	H	*Morus alba*	Kuwa	East Asia	Biwa body
Padauk	H	*Pterocarpus soyauxii*		Africa	Marimba bars
Paulownia	H	*Paulownia tomentosa*	Tung, kiri	China	Eastern soundboards
Pernambuco	H	*Guilandia ecbinata*		Brazil	Violin bow
Rosewood (Brazil)	H	*Dalbergia nigra*	Jacaranda	Brazil	Guitar back, ribs, marimba bars
Spruce (Norway)	S	*Picea abies*		Northern temperate, high	Western soundboards
Spruce (Sitka)	S	*Picea sitchensis*		Canada pacific coast	Western soundboards
Zelkova (Japan)	H	*Zelkova serrata*	Keyaki	E.Asia	Wa-daiko

4.2 Physical Properties of Wood

4.2.1 Stiffness, Density, Damping, and Orthotropy

Wood is an orthotropic material; its elastic and strength properties are dependent on the direction of the force with respect to the grain. The natural coordinate system is radial (R), longitudinal (L) and tangential (T). The elastic properties are defined by 12 constants, nine of which are independent: three moduli of elasticity (E_i), three shear moduli ($G_{ij}, i \neq j$), and six Poisson ratios μ_{ij} (related by $\mu_{ij}/E_i = \mu_{ji}/E_j$ for $i \neq j$) [4.6, Chap. 5-2]. Elastic moduli have been shown to be constant enough in the audio frequency range to be characterized by single numbers [4.7]; however they do vary from sample to sample and also with moisture content (and therefore age).

Wood for Western instruments is invariably quarter-sawn (in contrast to some Asian instruments, see Sect. 4.5.2) i. e., the face of the instrument is the radial plane. This gives the largest bending strength of any orientation, as E_T is usually the smallest of the elastic moduli.

Tabulations of Q for wooden bars in the L-direction exist in a venerable work by *Barducci* and *Pasqualini* [4.8] and more recently by *Bucur* [4.9]. Details of how to make a full measurement in all orientations are given by *McIntyre* and *Woodhouse* [4.10], including how to average orthonormal values for complex mode shapes involving movement in both directions. Norway Spruce is given as an example, in which case, Q in the L-direction was 140, while that in the R-direction was in the 40s.

Although often quoted to three significant figures, Q varies with sample and also with frequency. The loss factor is often assumed to be independent of frequency [4.5], but in a 1950 paper, *Fukada* [4.7] showed that woods from conifers often displayed a maximum Q at around 1 kHz, dropping off by tens of percent below 200 Hz or above 3 kHz, while some hardwoods showed a minimum value of Q in the few kHz range. The quality factor Q measures the dissipation of vibrational energy by the internal friction of material. Since cellulosic microfibril is highly crystalline in tone woods, they have high Q in general.

We will now turn to a discussion of the classification of wood by cellular structure i. e., softwood, hardwood, monocot. As it happens, these cellular distinctions mostly, but not always, coincide with the distinction between tone and frame woods. Notable exceptions are paulownia, a *soft* hardwood, widely used in Asia for string instrument soundboards, and yew, a *hard* softwood, once used for harp frames. Also included here is a brief discussion of plywoods, whose use is not confined to cheap student instruments.

4.2.2 Classification Wood by Cellular Structure

Softwoods

Softwoods come from a group of seed-producing trees called gymnosperms (which are most often, for the purposes of our discussion, conifers). They are the most primitive of woods and have the simplest cellular structure. The vast majority of cells, the tracheids, run in the longitudinal direction, with the occasional resin canal running in the radial direction [4.11, p. 14]. This structure gives softwoods a markedly anisotropic elasticity, with E_L/E_R typically 10 and E_L/E_T typically 25 [4.6, Chap. 5-2]. The quality factor in the radial direction is often very much smaller than that in the longitudinal.

Hardwoods

Hardwoods come from a group of flowering trees called angiosperms. Their longitudinal cells come in two main forms, the larger pores and smaller fibers, and radial ray cells are much more abundant than in softwoods [4.11, p. 14]. This structure gives hardwoods a less anisotropic elasticity than softwoods, with E_L/E_R typically 7 and E_L/E_T typically 20 [4.6, Chap. 5-2].

Composite Woods

The most common composite wood used in musical instruments is plywood. This layered composite consists of sheets of wood with different grain orientations and it therefore has more isotropic properties than single pieces of wood. Plywood is used for the soundboards of small harps (where strength is an issue due to the tension of the strings), some of high quality, and the backs of cheaper guzhengs.

The veneer on spruce harp soundboards may be considered as a form of *plywood* as the veneer grain runs longitudinally i. e., perpendicular to the transverse soundboard grain. This orientation is to prevent cracking of the glue joints in the multipiece soundboard. The effect is to reduce the longitudinal-radial anisotropy of the spruce by a factor of three [4.12] i. e., E_L/E_R from 12 to 4. In addition the quantity of glue used in the bonding needs to be minimized, as a typical $100\,\mathrm{g/m^2}$ layer ($Q \approx 5$) will decrease the overall Q of the soundboard by 25% [4.13].

Monocots

Monocots also come from flowering trees, and the only variety significant in musical instrument making is bamboo, which is widely used in Asia for the tubular body of woodwinds and for the vibrating plates of percussions. The bamboo culm is divided quasiperiodically by nodes, one of which forms a solid cross wall and is called the diaphragm. The internodes have a culm wall surrounding a large hollow cavity, called a lacuna. The culm consists of about 50% parenchyma, 40% fibers, and 10% conducting cells (vessels and sieve tubes) on average [4.14]. The polylamellated wall structure of the culm fibers (vascular bundle sheaths) results in an extremely high tensile strength. Bamboo culms have no cambium, and no radial cell elements (such as rays in trees) exist in the internodes. Bamboo is therefore quite different from other woods (although both natural materials have orthotropic properties) and also from isotropic materials such as metals and man-made polymers [4.14]. Similarly to wood, the longitudinal axis of bamboo is parallel to the fibers along the culm, the radial axis is perpendicular to the culm circumference, and the tangential axis is along the culm circumference.

4.2.3 Classification of Acoustic Woods

The most acoustically important properties of wood appear to be the elastic constant E_L, the density ρ, the anisotropy E_L/E_R and some measure of the damping, e.g., Q. Several ways of combining these quantities have been proposed to select acoustically useful woods, and to distinguish between woods best suited to soundboards (*tonewoods*), ribs and backs (*frame-woods*), bows, woodwinds etc.

Consider the material properties listed in Table 4.1. The longitudinal sound speed is almost the same in dry woods, bamboo, and even metals, which implies a strong correlation between E_L and ρ. *Wegst* plots E_L versus the loss coefficient and finds no clear correlation between these two quantities [4.15, Fig. 5]. However, a group of woods with high E_L (20–40 GPa) includes those favored for violin bows, and if the quality factor is high enough, woods for xylophone bars. Soundbox woods appear at lower E_L (centered around 12 GPa), with those for soundboards having low loss and those for ribs/backs higher loss. Woods favored for wind instruments are not distinguished from soundboard woods on this plot.

Several authors starting with *Schelleng* [4.5] have discussed the importance of the ratio c/ρ, variously called the *vibration parameter* [4.2], or since the vibration of a wood plate radiates sound, the *radiation ratio* [4.16, 17] and *sound radiation coefficient* [4.15]. Schelleng derived c/ρ by supposing that both the stiffness and the inertia of two plates should be the same if their vibrational properties are to be the same. The ratio c/ρ for Sitka spruce is six times higher than that for aluminum, and twice that for amboyna, which is typical of the ratio between tone and framewoods [4.15].

The low density of woods and bamboo compared to metals gives a low wave resistance ρc and a high vibration parameter. A lower wave resistance means a better coupling to the surrounding air. The low wave resistance of Sitka spruce (and its European counterparts) 2.4 MPa s/m makes it ubiquitous in the soundboards of Western string instruments. Paulownia has an even lower value [4.2] (1.4 MPa s/m) and is common in Asian instruments. The higher ρc of amboyna wood causes higher reflection of sound within the instrument body, suggesting it as a good frame material in string instruments.

The acoustic conversion efficiency (ACE) proposed by *Yankovskii* [4.25] has also been used to characterize acoustic materials [4.22, 26]. This ACE is the ratio of acoustic energy radiated from a beam to the vibration energy of the beam and is proportional to cQ/ρ. However, cQ and ρ are fairly independent of each other for a wide variety of woods, so one of the current authors (Shigeru Yoshikawa) proposed using cQ (see (4.7) in the Appendix for physical meaning) as a measure for distinguishing tone and frame woods [4.2].

In Fig. 4.1 cQ is plotted against ρ/c, the reciprocal of the vibration parameter, which may be called the *antivibration parameter*. A clear separation is seen between tonewoods (paulownia, Sitka spruce, and Norway spruce) and framewoods (Brazilian/Rio rosewood, amboyna wood, Japanese and Norway maple). Also included in Fig. 4.1 are a selection of other woods: mulberry (Japanese kuwa, Morus alba) for the best quality Japanese lutes (Satsuma biwa) [4.2, 20]; ebony [4.18] and grenadilla [4.21], which are used for the best quality clarinet bodies; pernambuco [4.15, 16, 19] for violin bows; zelkova [4.20, 27] for the shells of Japanese big drums (wa-daiko); bamboo for shakuhachi bodies [4.15, 23, 24]; and Japanese cypress [4.27] for the stage floor for Noh plays (the percussive sound of the player's stamping feet is an important element in these plays). These woods have different physical properties that cannot be explained well by the quality criteria for string instrument woods, though Japanese cypress and zelkova can be excellent substitutes for Sitka spruce and Japanese maple respectively. Mulberry, ebony and grenadilla are very heavy and hard, and show very low vibration transmission. Pernambuco is also heavy, but shows very high vibration transmission. Bamboo shows characteristics in between tonewoods and framewoods, and has been proposed for several applications to musical instruments [4.15].

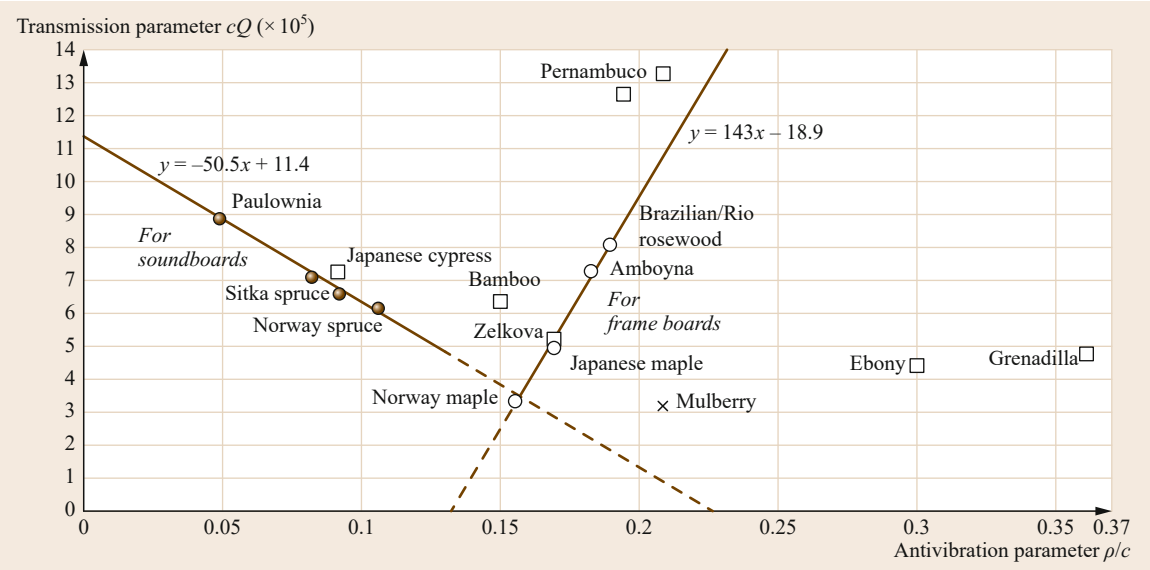

Fig. 4.1 Classification diagram of traditional woods for string instruments and for other instruments. •: tonewoods for the soundboard; ○: framewoods; ×: traditional wood for the Satsuma biwa; □: traditional woods for other instruments (after [4.2, 15, 18–24])

4.3 Tonewoods

The purpose of tonewoods is to radiate sound. In this section we will examine acoustic radiation from vibrating wooden bars, plates and boxes.

4.3.1 Bars (Idiophones)

The most straightforward uses of tonewoods are in the idiophone family. Bars of wood, not naturally harmonic, are shaped to have an overtone structure with a definite pitch [4.28]. The bars serve as their own radiator, sometimes with the assistance of sympathetically resonating tubes, as in the marimba.

Wegst's classification scheme [4.15] shows woods favored for idiophones have higher E, higher ρ and consequently higher Q than woods used for soundboards. The reason for this is partly because the input energy comes from a single impulse and is not sustained by a string, and partly because the wood has to be hard to avoid damage from the mallet. As the sound comes from weakly radiating bending modes the bars have to be struck sharply. Typical woods for the bars are rosewoods (genus *dalbergia*) and padauk, while the very hard boxwood makes for good mallets.

Bork [4.29] gives the following expression for T_{60}, the time it takes a sound to decay to a level of 60 dB below its peak

$$T_{60} = \frac{2.2}{\eta f} \,. \tag{4.1}$$

A typical loss value for a marimba bar $\eta \approx 0.005$ so a well-suspended middle-C bar will have $T_{60} \approx 2$ s.

4.3.2 Plates

Few musical instruments have simple plates as their acoustic radiators. A notable exception is the piano which has a two-dimensional soundboard that is large enough to avoid acoustic short-circuiting between the two sides. However, the behavior of plates is an important step to understanding soundboxes.

In Fig. 4.2, tap tones from sample plates of Sitka spruce, maple and aluminum are analyzed in the frequency domain in 1/3 octave bands [4.3]. The ordinate P_m indicates the maximum pressure level in each 1/3 octave band from 25 Hz to 20 kHz. Several peaks and troughs of P_m depend on the sample size. Although Sitka spruce and maple show the strongest response around 1 kHz and similar response below 1 kHz, the response of Sitka spruce is much weaker than that of maple above about 3 kHz. This weaker radiation of Sitka spruce in higher frequencies seems to be preferred as tonewood because the auditory emphasis of lower frequencies is desirable to the pitch sensation in Western music. In contrast to Sitka spruce and maple, aluminum shows much weaker response below 1 kHz and much stronger response above 3 kHz. This characteristic of metal is generally unwelcome in Asian and Western music.

A large difference of radiation characteristics between wood and metal at higher frequencies (above around 2 kHz in Fig. 4.2) is attributed to the relative strength of shear and bending deformations in flexural vibrations. As the frequency of the flexural vibration increases, the shear deformation component in the flexural deformation increases in wood, but the bending deformation component is still dominant in isotropic materials like metals. The shear effect, which is indicated by higher values of elastic modulus ratio E/G ($= E_L/G_{LR}$ in wood) in Table 4.1, causes an appreciable increase of loss factor η in higher frequencies [4.3]. Although E/G of the Sitka spruce example shown in Table 4.1 is lower than that of the amboyna wood example, Sitka spruce can often have a much higher value (> 15) than that of amboyna wood (which can be < 8) [4.3]. The stronger shear effect of Sitka spruce than in maple and aluminum seems to be relevant to sound radiation from the soundboard because its low-pass filter effect with a cutoff frequency of about 2 kHz tends to lend the radiated sound a desired softness [4.30].

Although it is difficult to determine the frequency spectrum of plate radiation, the frequency f_B (in Hz)

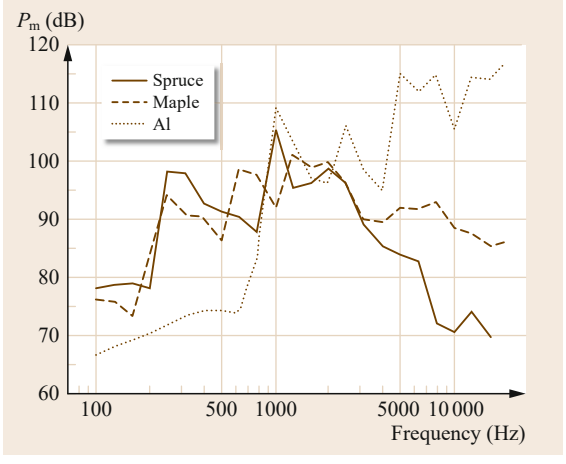

Fig. 4.2 Acoustic radiation characteristics of tap tones from the sample plates ($105 \times 105 \times 2$ mm Sitka spruce and maple) and bar ($105 \times 16 \times 2$ mm aluminum). Peak sound pressure levels are shown in 1/3-octave bands (after [4.3, Fig. 12])

of a bending wave in a thin uniform plate is given by [4.31]

$$f_B = 0.0459\, h c_L k_n^2 \tag{4.2}$$

$$c_L = \sqrt{\frac{E_L}{\rho(1-\nu^2)}}\,, \tag{4.3}$$

where h is the plate thickness, c_L is the longitudinal wave velocity in an infinite plate, ν is Poisson's ratio, and k_n is the wave number corresponding to the normal modes of vibrations that depend on the boundary conditions of the plate. Therefore, h (as well as ρ and E) is important to determine the vibrational properties of woods, particularly of tonewoods. The thinness of the top plate in the violin, cello, and guitar largely contributes to decrease their resonance frequencies [4.20]. Also, the mechanical input impedance Z_m of a thin infinite plate (the ratio of force to the normal velocity of the plate at the driving point) depends on the plate thickness as well as the characteristic impedance ρc. For bending waves in an infinite plate, Z_m is surprisingly a real, frequency-independent constant [4.32]

$$Z_m = \frac{4}{\sqrt{3(1-\nu^2)}}\rho c h^2\,. \tag{4.4}$$

Plate thickness is important to meet two conflicting requirements. Sufficient vibratory energy must be transmitted from the string to the soundboard to produce an audible tone, but at the same time, the energy should not be transmitted so rapidly that the string vibration dies down quickly producing an unmusical *thud* [4.33]. In order to achieve high sound quality, the mechanical impedances of the strings and the soundboard must be controlled very carefully in string instruments [4.15]. In the violin, a bridge stands on the top plate and forms a termination of the strings. Since the bridge is usually made of maple, its impedance is considerably higher than the top plate impedance. However, a careful design of bridge geometry (pattern, shape, and thickness) realizes a desirable impedance range of the bridge that joins the strings and the top plate to create excellent sound quality of the violin. At the same time, very subtle thickness adjustments of the top and back plates are essential to create the tonal excellence as easily inferred from (4.4).

4.3.3 Boxes (String Instruments)

Although vibrating strings are necessary to define the fundamental frequency and overtone series of an instrument, the acoustic power output of a vibrating string itself is far too low to be of any practical use. Hence string instruments need a radiator, a soundbox, which usually takes the form of a thin wooden shell with a hole or holes.

Any solid structure has resonant frequencies of its own, and a string instruments radiation is a product of the string modes and the modes of the soundbox. These modes should be spaced close enough together to allow all possible string frequencies to radiate. There are particular constraints of the quality factors of the box; the damping should be low enough that the box can resonate, but no smaller than that which would give a 3 dB bandwidth of about one semitone (the interval of which is about 6% in frequency; $Q \approx 1/0.06 = 17$). Tonewoods have natural Qs well in excess of 20, even in the radial direction (Sect. 4.2), leaving room for other wall-surface losses and, of course, radiation loss to depress the overall value. It is important to note that often the only Q-factor quoted in the literature is for bending waves traveling in the longitudinal direction of the grain, whereas the losses of two-dimensional (2-D) plates are often dominated by the Q-factor in the radial direction, which is typically a factor of four lower.

Boxes provide fairly regularly spaced modes. For a plate of area S, thickness h and sound speeds c_x and c_y in each of the orthonormal directions, the mean frequency interval Δf is as follows [4.34, p. 587]

$$\Delta f \approx \frac{\sqrt{c_x c_y h}}{1.5S}\,. \tag{4.5}$$

This equation yields values of 73 and 108 Hz for violin top and back plate dimensions respectively. For real violin plates, the bass end of the frequency spectrum is *blocked* by the curvature [4.34], which makes for a larger spacing. The bracing of a guitar top plate has the same function.

Firth [4.35] notes that for the clarsach, a small Scottish harp, the modes of the bare soundboard are about 50 Hz apart. This spacing grows to about 100 Hz with the addition of the stiffening string bar (which goes a long way to removing the effect of the anisotropy of the soundboard wood), and then to almost 200 Hz for the completed soundbox. Comparable values were found for a modern concert harp soundbox [4.36].

Mechanical Efficiency

The basic scaling laws of plate vibrations [4.5] and their radiation efficiency [4.37, p. 156] mean that for a given fundamental plate frequency the power radiated by a plate for a given input force *falls* with plate size. In his study of the guitar, Davis points out that the size of instruments is limited by how thin the plates can be made [4.38], and in the case of spruce this is about 2.5 mm.

It has been noted [4.38] that most string instruments have their two lowest resonances tuned to the fundamental frequency of the lowest string and approximately a factor of two (one octave) above that. For instruments as diverse as the guitar, violin, oud and ruan, these two resonances result from the coupling of the lowest soundboard resonance with the Helmholtz resonance of the air in the soundbox. (Although this is not true of the harp, whose lowest strings are tuned much below the principal resonances of the soundboard [4.36]).

The guitar has a particularly simple low-frequency resonant structure, which makes it a useful instrument to study as it is the low frequencies that most characterize the *voice* of an instrument. The two lowest resonances lie at around 100 and 200 Hz [4.39]. The *air* resonance at 100 Hz is almost the lowest found in Western instruments (except for the double bass, whose *air* resonance is at 60 Hz [4.40]). The structure of these modes can be understood in a simple way: for the lower mode the top plate and the air in the soundhole move in antiphase, while for the higher mode the top plate and the air move in phase (Fig. 4.3). Both modes are significant radiators and they contribute much to the character of the guitar sound. The octave gap between them is large, however, and between these modes, the soundboard admittance drops 50 dB. This would cause a detrimental gap in the radiation between the two resonances if that were the end of the story. However, there is a phase flip between the two modes that prevents total cancellation in regions between them, caused by the fact that at low frequency, if one pushes down on the top plate, air will come out of the soundhole [4.41]. The result is only a 20 dB drop in radiativity (sound pressure at a specified distance divided by input force), one which the ear can accommodate without apparent difficulty.

The other advantage to having a soundhole is that it puts the lowest radiating mode in a frequency range that would otherwise only be accessible with a very thin soundboard [4.38].

The quality factors for the two guitar modes are around 20, and the similarity is noteworthy considering that the balance of losses in the tonehole and viscoelastic losses in the wood are different for the two modes. Models and measurements show that the radiation efficiency (acoustic power radiated divided by mechanical power input at the bridge) at low frequencies is about 30% [4.39]. *Schelleng* [4.42] gives a very similar value for the violin. *Daltrop* et al. [4.36] find Q for the lowest primary modes of a concert harp to be about 20.

At higher frequencies the acoustic efficiency drops off as higher-order modes in the guitar plates cause acoustic short-circuiting that occurs when the wavelength in the plates is much smaller than the wavelength of the radiated sound. However this is not as critical as the low-frequency efficiency. For one thing, human ears work much better at high frequencies than at low. Secondly the density of soundbox resonances tends to be fairly constant in Hz across a wide frequency range – typically a few tens of Hz for a guitar. In contrast the frequency space between musical notes spreads out at high frequencies, so the chance of all the partials of a note *falling between the cracks* of soundbox radiativity is much reduced at higher frequencies.

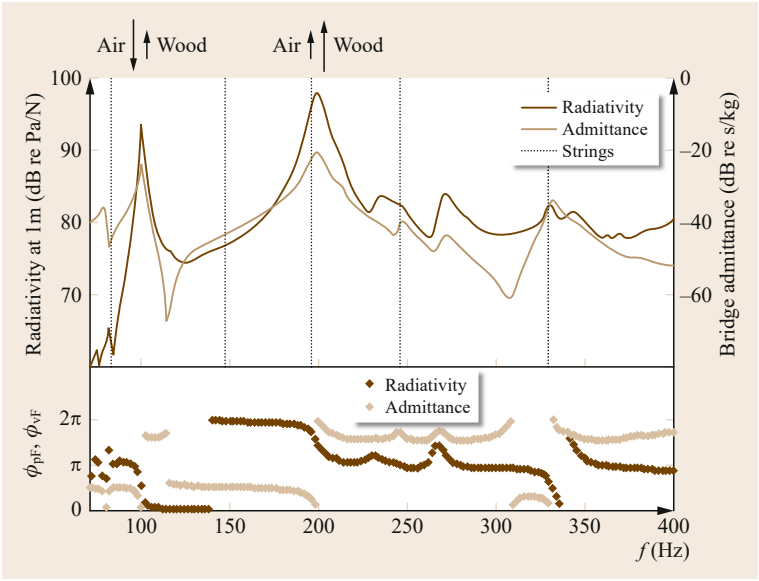

Fig. 4.3 Guitar radiativity and bridge admittance. The principal *air-mode* occurs at 100 Hz; the principal *wood-mode* occurs at 200 Hz. Higher-order plate and cavity modes above 200 Hz have relatively low radiativity compared to the bridge admittance

4.3.4 Examples of Tonewoods

Spruce (Softwood, Tonewood)

There are many different species of spruce; those of most interest musically are Norway spruce from northern Europe and high-altitude central Europe, and Sitka spruce (Fig. 4.4) from the Pacific coast of southern Alaska down to the tip of northern California. Old growth from slow-growing areas is favored for its tight, straight and even grain. Spruce selected for instruments has low density and high Q, and its large anisotropy (E_L/E_R in excess of 10) is particularly important in the low frequency breathing modes (A0, C2 and C3) of the violin family (see note on mode nomenclature in [4.43]). In fact the anisotropy is enhanced by the bass bar, which adds longitudinal stiffness while allowing transverse flexibility. In the case of modern harp soundboards, the anisotropy is less important than the other qualities, and is actually reduced by the addition of veneer and harmonic bars [4.12, 44].

Maple (Hardwood, Tonewood and Framewood)

Maple comes in many different varieties, all of the genus *Acer*. North American maple is often broadly described as *hard* and *soft*. Extreme examples listed in the Forest Products Laboratory Wood Handbook [4.6, Chap. 5-5] are the hard sugar maple (*Acer saccharum*) and the soft silver maple (whose binomial name is confusingly *Acer saccharinum*). Sugar maple has similar properties to the maples shown in Fig 4.1 and silver maple has 75% of the density and 56% of the E_L of sugar maple. Hard varieties are preferred for musical instruments, and their mechanical properties sit at the intersection between tonewoods and framewoods.

As maple sits at the intersection between tone- and framewoods, it is possible to make an entire instrument out of it e.g., a gothic harp [4.45]. However, maple is most renowned for its use in members of the violin family. The material of choice for violin backs and ribs is curly maple, variously known as tiger, flame and most obviously, fiddleback maple (Fig. 4.4). The names do not refer to a distinct species but to the rippled formation of the grain, which makes for singularly beautiful patterns when varnished, patterns that alter with light direction. *Ghemeziu* and *Beldie* [4.9] note that curly maple *Acer pseudoplatanus* has a lower density and higher E_L/E_R ratio than straight-grain *Acer pseudoplatanus*. However the reasons for its choice are aesthetic and not mechanical. It is certainly not chosen for ease of working; the constantly varying grain direction makes planing and carving problematic, as a less-than-perfectly sharp blade will scoop out chunks of wood and ruin the surface.

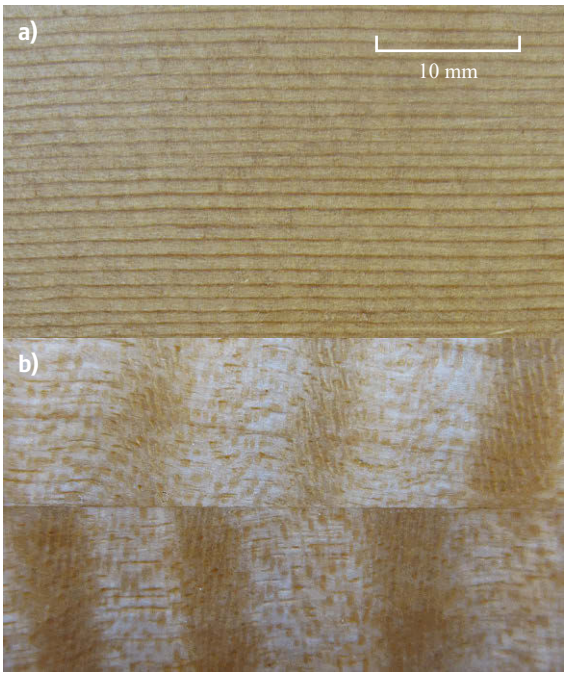

Fig. 4.4a,b Violin tonewoods. **(a)** Straight-grained Sitka spruce for top plate. **(b)** Centerline of matched two-piece curly maple back plate; note the *wavy horizontal grain*, the *vertical rays* and the alternating *light-dark pattern* along and across the *centerline*

Paulownia (Hardwood, Tonewood)

Paulownia (Japanese kiri) is a hardwood species, but it is rather lighter (around $250\,\mathrm{kg/m^3}$) than most softwoods. Its anisotropy is very high ($E_L/E_R \approx 48$, the value of $E_R = 0.134\,\mathrm{GPa}$ was measured at Tsukuba University [4.46]). However, the elastic modulus ratio $E_L/G_{LR} \approx 10{-}12$, less than that for Sitka spruce ($E_L/G_{LR} \approx 20$). A very high value of E_L/E_R may be explained as follows: In general, the E_L of a honeycomb material is proportional to its density while E_R is proportional to ρ^3 [4.47]. Consequently the E_L/E_R ratio should be proportional to ρ^{-2}. Since E_L/E_R of spruce ($\rho \approx 450\,\mathrm{kg/m^3}$) is usually 10–20, the very high E_L/E_R of paulownia becomes understandable when its low density is considered.

Paulownia is widely used in Asian string instruments e.g., the Japanese long zithers, koto and soh and the Chinese guzheng and yueqin (Fig. 4.5). In general, thinner cell wall, that is, lighter wood gives higher dimensional stability. This is because the dimensional change of wood is dominated by the swelling and shrinkage of the wood cell wall (thicker cell wall tends to cause the dimensional change). Therefore, the

Fig. 4.5 Paulownia soundboard of a yueqin

very fine cell wall of paulownia prevents the distortion and warp caused by humidity change. This makes precise and delicate workmanship possible for musical instruments as well as for furniture. In addition, paulownia consists of consecutive small and individual spaces (called the apotracheal parenchyma cells or the tylosis structure), which can yield the smallest density and the dehumidification.

Paulownia can be given a very smooth surface, which makes it suitable for the sliding of bridges (called *ji* in Japanese) on the top plates of kotos, guzhengs and the Korean gayageum when a chord change is required during the performance [4.48]. The koto strings are plucked with small plectra worn on three fingers (the thumb, index and middle) of the right hand. Because this plucking is not so strong and the koto body is very large and long, the material must support vibration well to maintain the sound. Both the highly resonant nature and high anisotropy of paulownia seem to be relevant requirements. In addition, it is observed that harmonics higher than 10 kHz usually appear in koto sounds [4.48]. This may be because small and hard plectrums made of ivory are used for the plucking instead of the player's fingernails. This type of high-frequency emphasis in the koto yields a sharp impression at the attack transient. This tonal characteristic may be supported by low E_L/G_{LR} value (about 10) of paulownia in comparison with high E_L/G_{LR} value (about 20) of Sitka spruce, which produces the high-cut filter effect above 3 kHz (Fig. 4.2). It should be also noted that paulownia is better than spruce in both vibration (radiation) and transmission properties and that paulownia is a material quite the opposite to mulberry used for the Satsuma biwa (Fig. 4.1).

Paulownia was traditionally used to make wooden chests for clothes and safe boxes for valuables. Such chests are now themselves very valuable.

4.4 Framewoods

The way framewoods are used in woodwind, string instruments and membranophones is quite different, so these cases will be considered separately.

4.4.1 Woodwind Instruments

Since the sound of woodwind instruments is produced by the resonance of the air column enclosed by the instrument body, the body wall material is not primarily important from the acoustical viewpoint. Strength, lightness and dimensional stability are obviously necessary however, and makers and players of woodwind instruments have strong preferences for certain woods. For example, bamboo has been used for longitudinal end-blown flutes, Japanese shakuhachi and Chinese xiao (Fig. 4.6), and grenadilla has been used for the clarinet and the oboe.

Bamboo (Monocot, Framewood)

As shown in Table 4.1 and Fig. 4.1, physical and acoustical properties of bamboo are between those of tonewoods and framewoods. However, the properties of bamboo significantly vary from the inside to the outside of the culm wall. For example, the density ranges from about 600 kg/m^3 at the inner regions that contain a small amount of fibers (about 15%) to about 1000–1200 kg/m^3 at the outer surface that contains large amount of fibers (about 60%) [4.15, 23]. The variation of E_L and tensile strength with position in culm wall is almost correlated with that of density. The value of E varies from about 5 GPa at the inside to about 17 GPa at the outside [4.23]. Also, the innermost and outermost surfaces of the culm wall are formed by heavily thickened and lignified parenchyma cells (called the pitch ring) and by the cortex with

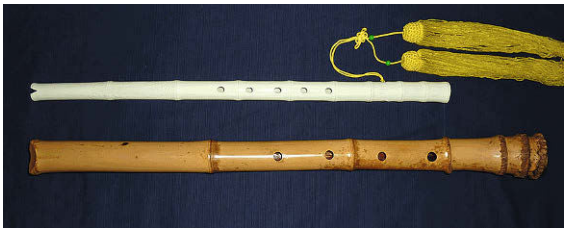

Fig. 4.6 Photos of a Chinese xiao (made of ivory-like material imitating bamboo nodes, 58.6 cm long, E♭4) and a Japanese shakuhachi (made of bamboo called madake, 69.5 cm long, B♭3, manufactured by Johzan Iso (b. 1929))

Fig. 4.7 Violin peg turned out of ebony. Ebony can be machined with a sharp edge, as can be seen in the detailing

a wax-coated layer (called the epidermis) respectively [4.15].

Bamboo is readily available in Asia, and its fully dense and fibrous outermost surface is probably suited for woodwind body and playability. In addition, the thick root end of bamboo, which is used to make the shakuhachi, strengthens the wall rigidity. On the other hand, slender dark-stained bamboo pipes are usually used for free-reed mouth organs (Chinese sheng, Korean saeng, Japanese sho, and Indonesian khaen) [4.49]. The much smaller diameter of these organ bores probably supports the wall rigidity.

Grenadilla, Ebony (Hardwood, Framewood)

The lower right-hand end of Fig. 4.1 (weak vibration generation and transmission, and high ρ/c) indicates woods suited for reed instrument bodies, which are subjected to high acoustic pressures in the bore. Hardwoods such as grenadilla and ebony have been traditionally used for the clarinet and oboe bodies. Physical properties of grenadilla ($\rho = 1280\,\mathrm{kg/m^3}$, $E_\mathrm{L} = 15.9\,\mathrm{GPa}$, and $Q = 137$) [4.21] give very low longitudinal sound speed $c = 3520\,\mathrm{m/s}$. On the other hand, grenadilla shows very high shear modulus $G_\mathrm{LR} = 3.1\,\mathrm{GPa}$ (Table 4.1). Grenadilla trees often grow in very gnarled and twisted shapes, and its grain is frequently interlocked. Such interlocked grain probably yields low sound speed and high shear modulus (low elastic modulus ratio $E_\mathrm{L}/G_\mathrm{LR}$) [4.50].

Ebony has an almost invisible grain, and is easy to machine to fine tolerances and with sharp edges, a feature crucially important for the tonehole of wind instruments. The wood can be polished to a fine finish without varnish (Fig. 4.7). Because it is a hard-wearing wood, ebony also finds use for violin pegs and fingerboards.

4.4.2 String Instruments

The purpose of framewoods in string instruments is primarily to create a box around the top plate (or both plates, where both are prominent radiators as in the case of the violin family, or the guzheng).

Mulberry (Hardwood, Framewood)

The Japanese Satsuma biwa, which is almost completely made of mulberry, is a unique string instrument judging from the position of mulberry in Fig. 4.1. Mulberry lies far off the quality criteria for Western string instruments, given by the two regression lines. It lies in between Norway maple and ebony, and has a very high value of the antivibration parameter and a very low value of the transmission parameter. However, the poor vibrational properties of mulberry seem to match the playing style of the Satsuma biwa, in which the string is strongly struck with a large triangular wooden plectrum (*bachi* in Japanese) made of hard boxwood. Striking the Satsuma biwa strings yields very characteristic impact tones because the top plate, which has low resonance, is simultaneously struck by a stroke of a large plectrum. It is very important that a mechanism has been invented to compensate for the poor resonance of the mulberry body. The mechanism, called the *sawari* (meaning *gentle touch*), allows the strings to vibrate against the neck or frets, emphasizing high frequencies [4.20, 48]. The biwa frets are very wide compared to those of the guitar and are usually made of hard magnolia (Japanese hohnoki, *Magnolia obovata*) to generate the subtle sawari effects. A few variants of this sawari are seen as *jawari* (in Hindi) on the Indian sitar and tambura, and as brays on medieval and baroque harps [4.51].

Pernambuco (Hardwood, Framewood)

Pernambuco shows values of antivibration parameter a little higher than that of Brazilian rosewood, but shows values of transmission parameter much higher than that of Brazilian rosewood. This extraordinarily high cQ suggests the property necessary to the violin bow.

4.4.3 Membranophones

Wood frames (or shells) for drums generally have negligible effects on the sound from the membranes

stretched with high tension at both sides. However, we will consider one case where the frame is tonally important, that of the Japanese drum.

Zelkova (Hardwood, Framewood)

It is well known that the most suitable shell material for a Japanese traditional wooden drum (called *wa-daiko*, where *wa* means *Japan* and *daiko* or *taiko* means *drum*) is keyaki (zelkova). Although that reason is not clear, it is said that zelkova has a kind of toughness (or viscosity). In Fig. 4.1 zelkova is plotted very closely to maple. However, Japanese maple is never applied to the wa-daiko shell. A physical or acoustical parameter should be explored to represent the above toughness of wood.

According to *Ono* et al. [4.52], a sharp peak is detected in the tap tone of the shell of a keyaki wa-daiko at 360 Hz when the membranes are stretched, but that peak is shifted to 260 Hz when the membranes are removed. This result shows that the shell of a keyaki wa-daiko is elastically deformed during the attachment of membranes with high tension. Ono explains that a material with a large E_L or c exhibits high elastic deformability. However, Norway spruce and paulownia, which are not used for drum shells, have a very large c value of about 5300 m/s, while the sound speed in zelkova is only 4180 m/s [4.2, 16, 22]. Zelkova is also used for tone plates in Japanese temples – plates that are suspended from the roof and hit with a wooden hammer to call out the time of day.

4.5 Construction

String instruments tend to be constructed out of carved plates, tuned, and glued into the form of a box. Woodwind instruments are often turned on a lathe, or make use of a biological tube, like bamboo.

4.5.1 Woodwind Instruments

The shakuhachi, a Japanese end-blown flute, is formed from the root end of a stem of bamboo. The length or the lowest pitch is determined by the top node and the root end that is precisely cut; the instrument has about seven nodes (Fig. 4.6).

The original construction method of the shakuhachi had no finish applied to the inside surface (this is called a *ground-paste-free* bore), and the culm was not divided (Fig. 4.6). The diaphragms were not completely removed and a kind of protuberance was formed along the bore near the node as shown in Fig. 4.8. The remaining portion of the diaphragm subtly affects the intonation and produces a natural tone color, which cannot be heard in a modern shakuhachis that have a ground-paste applied to the inside. Since the ground-paste-free shakuhachi made by the original method was played exclusively by a group of itinerant priests called *Komusoh*, it is called the Komusoh shakuhachi. In contrast, the ground-pasted shakuhachi is referred to as a modern shakuhachi [4.53]. The finger holes on the Komusoh shakuhachi are undercut; such an undercut is not observed in the modern instrument. The acoustical effects of the undercut should be investigated in the near future.

Finishing

Usually the inner walls of the modern shakuhachi, nohkan, ryuteki etc. are finished with a protective coating of urushi lacquer. However, its application in the shakuhachi depends on the use or otherwise of a ground paste called *ji* (meaning *ground*), a kind of paste made by mixing the polishing powder into Japanese lacquer, urushi [4.54]. The paste becomes hard enough when it is dried. In order to apply this ground paste to the inner surface of bamboo culm, all the diaphragms (solid cross walls) at the nodes are completely removed and the culm is divided near the middle (between the third and fourth finger holes). The ground paste makes it easy to adjust the intonation by modifying the bore shape and to amplify the sound volume by polishing the bore surface. The ground-pasted shakuhachi was possibly first made around the 1900s. If no ground is used, the shakuhachi is usually coated once or twice with urushi. However in the very rare but famous example, the *Rodohdoh* (shown in Fig. 4.8), the urushi coating is inferred from the thickness (over 1 mm) to have been done at least 30 times and then polished. According to a skilled professional maker [4.55], such a thick coating was probably carried out to fine-tune the intonation and tonal balance after a few years of use. The ground-pasted shakuhachi is coated at least three times because the ground paste absorbs the urushi lacquer.

Western woodwind instruments are made on a lathe. The hardwoods such as ebony and grendilla used need only to be polished (e.g., with 0000 steel wool) to produce an attractive lustrous finish. The surfaces are hard enough that a protective coating like varnish is not necessary.

4.5.2 String Instruments

Once the type of wood has been decided upon, there are two more physically significant factors involved in the choice of pieces: grain and age. There are also aesthetic

considerations, like color and the peculiar case of curly maple (Sect. 4.3.4), which will not be discussed further.

Wood Selection

Grain. Studies of wood used in classic members of the violin show [4.9] that straight grain, fine texture, and low density are favored properties. The acceptable ring width grows with instrument size: 0.8–2.5 mm limits for the violin and viola; an average 3 mm for the cello; an average 5 mm for basses. The variation in ring width within a single instrument should be such that the minimum-to-maximum ratio is larger than 0.7. In contrast, piano strings have such a wide variation in frequency that their soundboard ring widths are graded 0.7–3 mm from the treble to the bass end of a single instrument. The difference between early- and late-wood densities should be as large as possible, typically 280–900 kg/m^3, and the proportion of latewood should be no greater than 25% (more latewood increases E and internal friction).

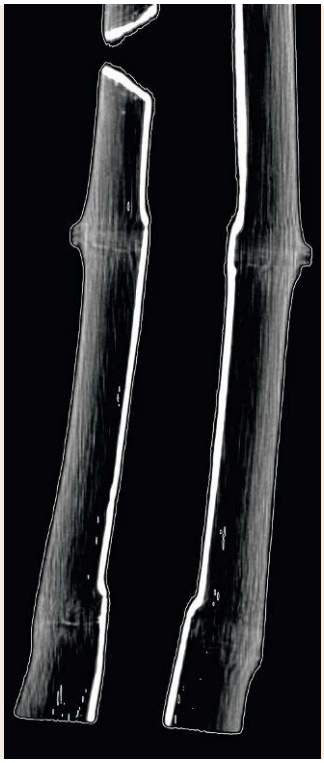

Fig. 4.8 A picture of a computed tomography-scanned old famous ground-paste-free shakuhachi (made by Shinryu Matano (1886–1936) and inscribed as *Rodohdoh*, 585 mm long, diameter 12–15 mm, in C4). Only the root side is shown. Note that the diaphragms remain a little. The bright layer indicates the urushi coating (courtesy of Hamamatsu Museum of Musical Instruments)

The Japanese long zither, koto or soh, consists of top and back plates. The top plate, about 180 cm long and about 25 cm wide, is made from a thick board of paulownia by scraping it out. The thickness of the top-plate part is about 37 mm near the middle and about 30 mm at both ends. However, the thickness at both shoulders is reduced to about 20 mm by making round grooves along the inner corners. More interestingly, the thickness of the back plate is only about 11 mm, and so acoustic radiation at high frequencies is often stronger from the back plate (with two soundholes near the ends) than from the top plate [4.56]. In contrast to the quarter-sawn wood for Western string instruments, paulownia for the koto is usually cross-grained, that is, the face of the top plate is the circumferential plane. Moreover, a high-quality koto is made of a part of the trunk close to the bark because of finer grain. The top plate is charred by a heated iron and then polished up with an steel brush and a special scrubbing brush to bring out the full beauty of the grain [4.56]. A dent or damage made on the top plate is easily restored by applying a heated iron through a wet towel. This restoring method based on the peculiarity of paulownia (although it also works with spruce) is often applied to the Chikuzen biwa whose top plate is also made of paulownia, unlike the mulberry of the Satsuma biwa [4.56].

Age. Wood is a biological material and changes continuously from the moment the tree is cut. Hence there are two significant time scales: the time between the tree cutting and the fabrication of the instrument, and the age of the instrument. For the first, dimensional stability is crucial, as green wood may be 80% water by weight and after long seasoning the moisture content may be only 10%. After several years of drying in the open air, hygroscopic equilibrium can be reached at 8–10% humidity with 60–65% environmental relative humidity. Forced drying by applied heat can, with care, speed the process up somewhat [4.57, Chaps. 6–8]. For the much longer timescales associated with old instruments, *Noguchi* et al. [4.58] studied Japanese red pine (*Pinus densiflora*) samples 8–296 yr old, and found that the sound speed increased 15% over this time span, and the loss tangent decreased 25%. The authors attributed the change to *the crystallization of cellulose, depolymerization of hemicelluloses, and cross-linking in the lignin complex*. These conclusions seem to support the widely held view that old Italian instruments are superior to modern ones. This said, recent blind comparison tests [4.59] of newly made and old Italian violins have come to the controversial conclusion that, knowing nothing of the provenance of a violin, experienced players tend to choose modern instruments.

Other string instruments are reckoned to improve with age, for example the guqin, some of which are hundreds of years old and reputed to be even better if slightly worm eaten! [4.60] (see Fig. 4.9). In contrast, harps tend not to have a long playing life, owing to the stress the strings place on the soundboard [4.44].

Western wind instruments made from hardwoods tend to be polished rather than varnished and can often be adversely affected by thermal and moisture cycling over decades. The fit and sealing of holes and keys is particularly susceptible to small dimensional changes.

Tuning Bars and Plates

The final step before gluing the parts of a soundbox together is the tuning of the plates. Tuning the wooden bars of an idiophone is a similar procedure, and is included in this section.

Bars. The first three partials of low and medium register marimba and xylophone bars are tuned to f_1, $4f_1$ and $10f_1$; higher register bars have partials tuned with smaller spacing [4.28]. *Bork* [4.29] gives detailed instructions on how to tune the partials of a bar more-or-less independently of each other. He also demonstrates how to position and tune the tubular resonators beneath the bars.

Plates. Ideally one would like to know how a soundbox is going to behave before all the constituent parts are glued together. To understand the relationship between plates and completed box from first principles is hard, and the solution lies at the edge of even early-21st-century computational physics. In the case of the violin family, the approach has been one of reverse engineering; the availability of large numbers of high quality old instruments, and the reversibility of hide glue, has made it possible to discover how to tune plates and make modern copies. Thus we have a set of aiming points for the principal modes and their frequencies. The first, second and fifth lowest modes, labeled 1, 2 and 5, (Fig. 4.10) define the plate stiffness to torsion, bending in the longitudinal direction, and bending in the transverse direction respectively. The quality of the plates remains the best indicator of the quality of the completed instrument [4.61].

Erik Jansson's practical guide to violin and guitar making describes in detail how to get from spruce and maple blocks to finished plates with the right modes [4.62]. Since this was written, the availability of software to record and analyze audio signals has made the process much more straightforward, at least for those of us who have trouble identifying the pitch of a tapped plate by ear. Free spectral analysis software can be used to find modal patterns without the need of more traditional approaches like the Chladni technique, which is hard to apply for deeply curved plates, and also very loud.

Adhesives

There are several mechanisms by which adhesives bond two wood surfaces together. The two most important are secondary forces (van der Waals, H-bonds) [4.63, p. 14] and mechanical interlocking [4.64, p. 492]. The strongest bonds are formed between two smooth clean conformal surfaces separated by a few µm of adhesive. Bonding between coarsely sanded surfaces is less strong, because of detritus on the wood surface.

Fig. 4.9 Worm holes in the soundboard (probably Paulownia) of a Ming dynasty guqin, seen through the tonehole on the underside

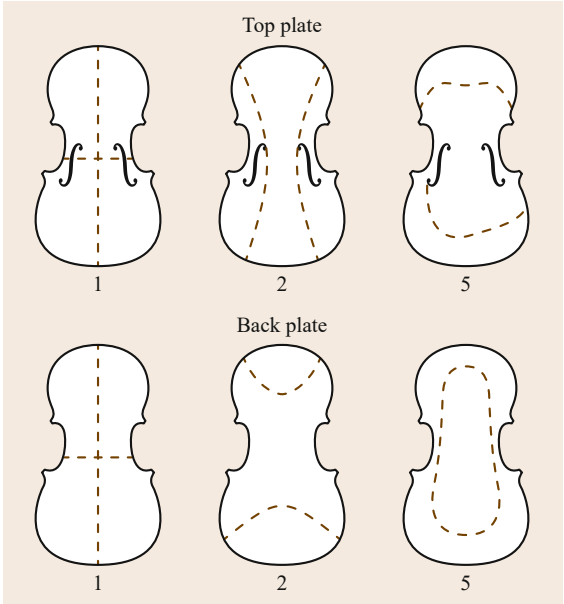

Fig. 4.10 The most important modes to get right when tuning violin plates (after [4.62])

For string instruments, one of the most important properties in an adhesive is resistance to creep. The tension in the strings causes a steady long-term stress on many wood joints. An extreme but not unusual case is that of a modern concert harp, where the combined tension of all the strings pulling on the soundboard at an angle of about 30° is of the order 10 kN.

While many modern chemical adhesives (aliphatics, polyvinyl alcohol glue, etc.) have attractive qualities, and are stronger than the wood they bond [4.64, p. 533], hide glue remains the adhesive of choice for many instrument makers.

Hide glue is made from the collagen of cattle [4.64, p. 492]. Bone glue is an alternative, but has a lower molecular weight and thus less strength. Hide glue is cheap, and comes in dry granules that can be dissolved in water at 60 °C. Care had to be taken with the temperature, as the glue degrades if overheated. When cool it forms a moderately strong bond, which gains in strength with natural drying. Hide glue is more creep resistant than common industrial glues, it does not leave marks on the wood, and joints can be undone without damage to the wood by the application of a little steam.

Hide glue properties are critical to the construction of violin family members. The front and back plate that determine the sound quality of the instruments are typically made from two pieces of wood glued along the centerline (Fig. 4.4). In order to maintain symmetry between the wood figure on either side of this line, one piece is cut down the middle, planed on one edge and folded out like opening a book. With some skill, these two edges are now correctly jointed (the technique being insensitive to small errors in the planing angle). If hide glue is applied to these two cleanly planed edges, the two halves of the plate can be bonded without clamping; the natural shrinkage of the glue being sufficient to draw the two wood surfaces together [4.65]. The great advantage of not using clamps is that there is now only minimal stress built into the glue joint, and it will survive environmental changes much better than if external clamps had been used to force the two pieces of wood together.

With hide glue it is also possible to assemble a violin family soundbox with dry glue joints, giving time to arrange the delicate clamping that is necessary to keep the two plates and ribs together while the glue sets. Glue is applied to all contact surfaces and allowed to dry until no longer sticky. Then the instrument is assembled and clamped in a calm and considered manner, and finally a jet of steam is quickly applied to the glue to soften it and complete the bonding.

Varnish

Volumes have been written about violin varnish. Let us simply quote here the view of Antoine Vidal, a friend of the great 19th century French luthier Jean-Baptiste Vuillaume (quoted in [4.66]):

> *The violin finished and not varnished has more power and mellowness in its tone; but if it remains in this virgin state, it becomes modified little by little, and, after a somewhat short time, the tone becomes poor and feeble. It must therefore be concluded that the varnish, while giving a more pleasing appearance, conserves, preserves, and that therein, above all, consists its great utility.*

Barlow and Woodhouse used electron microscopy to examine the varnish layers of old Italian and Dutch violins and celli [4.67]. The wood was first covered with a relatively thick (about 30 µm) *ground* covered by a much thinner layer of varnish. The ground layer consisted of particulate matter resembling plaster of Paris, and apparently comparable to modern Polyfilla, which, once varnished, becomes transparent. The function of this layer is certainly the sealing of the wood to prevent the colored varnish soaking in and producing a patchy finish; spruce, being more porous than maple, is more susceptible to this effect. However, the ground layers appeared to be much thicker than necessary to achieve this end, so there may have been additional reasons for its use.

Schelleng's study of the vibrational effects of varnishing [4.68] showed definitively that varnish should be hard and thin to avoid excessive damping of the plates. More recent tests show varnishing increases stiffness and mass (thus the speed of sound can go either way); in particular the modulus of elasticity and internal friction in the R direction is much increased for spruce [4.9]. In studies of harp soundboards *Gunji* et al. [4.13] found that a $400\,g/m^2$ layer of lacquer ($Q \approx 50$) will decrease the quality factor of the soundboard by 20%.

Testing

The ultimate test of a recently constructed instrument is of course the playing of it. However, many physical tests can be made on the complete instrument, of which tap tests are the most accessible to luthiers without sophisticated equipment. The principal air and wood modes of the guitar, ruan and even a concert harp [4.69] can be identified by tapping the instrument with and without light styrofoam blocks in the soundholes. Many articles have been written about identifying violin modes and describe corrective action if some are in the wrong place, e.g., [4.70].

4.6 Conclusion

In this chapter we have surveyed the relationship between wood, and how it is chosen, worked and finished, and the musical instruments from which it is made. In all cases we have worked backwards from well-established instruments, some of which reached their current state of evolution long before the age of scientific analysis. In the manufacture of wooden musical instruments, a little technical analysis is a great benefit; it will not ensure the invention or production of great instruments, but it can prevent a lot of mistakes.

4.A Appendix

The quality factor Q is a measure of the damping of a material; the higher the Q the more resonant the material is. If τ is the time it takes for a system freely vibrating at frequency f_0 to decay to $1/e$ times its original amplitude, then $Q = \pi f_0 \tau$. Alternately, in the frequency domain, if the width of a resonance at half-power is Δf, then $Q = f_0/\Delta f$. In older texts damping is referred to as the logarithmic decrement δ, and for $Q \gg 1$, $Q \approx \pi/\delta$ (or if the author is working in base-ten logarithms, $Q \approx 1.365/\delta_{10}$. Another form is the dimensionless damping ratio $\zeta = 1/(2Q)$, the loss factor η and the loss angle ψ.

$$Q = \frac{1}{\eta} = \frac{\pi}{\delta} = \frac{1}{\tan\psi} \,. \tag{4.6}$$

Another important characteristic for instrument woods is vibration transmission [4.2, 20, 48]. If the damping is relatively weak, the characteristic acoustic transmission is the reciprocal of the attenuation constant α of the longitudinal wave. The solution of the lossy wave equation gives

$$\alpha^{-1} = \frac{2Q}{k} = \frac{2cQ}{\omega} \,, \tag{4.7}$$

where k and ω are the wave number and angular frequency respectively [4.32, 48]. Since ω is not a wood property, cQ may be used instead of cQ/ω to express the transmission characteristic of the vibration excited in wood. In the text, cQ is called the transmission parameter.

5. Measurement Techniques

Thomas Moore

The measurements normally required to understand the physics of musical instruments, including the human voice, usually fall into one of three categories: measuring the airborne sound, measuring the deflection of the surface of an instrument, or measuring the input impedance. This chapter introduces the most common measurement techniques that provide information on these three physical parameters with an emphasis on the first two, which are the measurements most commonly desired by musical acousticians. The chapter begins with a discussion of airborne sound and how it is sensed. Specifically, several types of microphones are introduced followed by a discussion of some of the techniques that rely on sensing by microphones. A review of the techniques for measuring and visualizing deflection shapes is then presented. These techniques range from observing nodal lines using simple Chladni patterns to visualizing deflection shapes using electronic speckle pattern interferometry. The topic of impedance measurement is addressed next, with discussions of both measurements of the input impedance of wind instruments and the measurement of mechanical impedance. This review is not meant to be a complete analysis of each measurement technique. Instead, it is meant to serve as an introduction to the most commonly used techniques and provide references for the interested reader to pursue further study. The advent of new technologies continually changes the equipment that is available to the scientist, but the underlying physical principles remain relevant.

5.1 Measurement of Airborne Sound

The most ubiquitous measuring device in musical acoustics, as is the case with almost all other areas of acoustical study, is the microphone. Since musical sound is normally transmitted to the listener through the air, it is the sound in air that is normally of analytical interest. Therefore, the microphone is the most useful instrument for detecting the sound. Once detected, the signal from the microphone can be analyzed in various ways, but the accurate translation of the sound into an electrical signal is of paramount importance; this is the purpose of the microphone. Translating air pressure into an electrical signal can be accomplished through various means, and therefore there are several different types of microphones. Similarly, there are different types of sounds, and therefore there are microphones that are designed for different applications. This section introduces several applications and types of microphones, with an emphasis on the strengths and limitations of microphones in different applications involving the study and recording of musical instruments.

5.1.1 Types of Microphones: Form

Microphones can be classified by both form and function; form referring to how the microphones are constructed and function referring to how they are applied.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_5

There are many types of microphones in common usage but condenser microphones are by far the most commonly used in musical acoustics. Other types have specific advantages that cause them to occasionally be used by musical acousticians, therefore we will briefly review dynamic microphones and ceramic microphones as well. Detailed discussions of these and several other types of microphones can be found in [5.1, 2].

Condenser microphones utilize a change of capacitance to detect external pressure (condenser is an obsolescent term for capacitor). Electret microphones are one type of condenser microphone, however, they are usually referred to as electret microphones to distinguish them from the more common type, which does not use an electret material.

Electret microphones are made by depositing an electret film on a diaphragm and placing the diaphragm in close proximity to a plate that is connected to an amplifier. The electret film holds a charge that is permanent, therefore it forms a charged parallel-plate capacitor with the plate. As the diaphragm moves, the distance between the diaphragm and plate changes. The capacitance of a parallel plate capacitor with an air gap is given by

$$C = \frac{\varepsilon_0 A}{d} , \tag{5.1}$$

where A is the area of the plates, d is the distance between them and ε_0 is the permittivity of free space. The capacitance of a charged capacitor is given by

$$C = \frac{Q}{V} , \tag{5.2}$$

where Q is the charge on the capacitor and V is the potential difference between the plates. From these two equations it is obvious that the potential difference between the two plates is linearly proportional to the distance between them provided Q is a constant. An electret has a constant charge, and therefore the motion of the diaphragm is linearly translated into a change in the potential difference between the plates. Electret microphones do not require external power, however, they often contain an integrated preamplifier that does.

The microphone more commonly referred to as a condenser microphone works on the same principle as the electret microphone, however, the charge on the plates is the result of being connected to a power source. It is sometimes referred to as an externally biased or externally polarized microphone. The charge may come from a battery or may be delivered through a preamplifier. When the power source comes from an external preamplifier it is often supplied at 48 V and is referred to as *phantom power*. Condenser microphones, whether they involve an electret or not, have a flatter frequency response over the range of human hearing than dynamic microphones and are typically more sensitive than ceramic microphones. Both dynamic and ceramic microphones are discussed in the following paragraphs.

It is becoming common to refer to electret microphones as simply condenser microphones, so it is often unclear what type of condenser microphone is being used. Since the response is similar for both types it is rarely important when analyzing the electrical signals, but the power requirements for the two can be different. Therefore, it is important to know the type of condenser microphone in use when designing an experimental apparatus.

Dynamic microphones have the same construction as a common speaker, but rather than transforming an input electrical signal to a pressure wave in the air, a dynamic microphone produces an electric signal from the motion of a diaphragm. The diaphragm is attached to a coil that is free to move in a static magnetic field and the resulting electrical signal is a consequence of Faraday's law, i. e., the induced electromotive force in a coil moving in a magnetic field is given by

$$E = -\frac{\mathrm{d}\Phi}{\mathrm{d}t} , \tag{5.3}$$

where Φ is the magnetic flux through the coil, $\mathrm{d}t$ is the differential element of time, and the SI system of units assumed. These microphones are very robust, but have limited frequency response and local electric fields from nearby equipment (e.g., transformers) can induce current in the coil leading to noise in the signal.

Ceramic microphones have a piezoelectric element attached to a diaphragm. When the diaphragm moves in response to a pressure change it induces a strain in the piezoelectric element, which produces a potential difference between the two sides of the crystal that is linearly proportional to the stress. These microphones are extremely robust and can be used for measurements of high pressures, for example inside of brass wind instruments. The frequency response of ceramic microphones is sometimes limited in the high frequencies, so it is advisable to review the response curve before using one. Like dynamic microphones, they do not require a power supply.

5.1.2 Types of Microphones: Function

The application will determine which type of microphone to choose, but it also defines the function of the microphone. The function is usually characterized by the type of acoustic field that is being measured. The three most common acoustic fields are free, diffuse (random incidence), and pressure.

A free-field microphone is intended to be used in a situation where there is a single source and there are no reflections from nearby objects. This situation usually occurs in an anechoic chamber or outdoors. Although the acoustic field is distorted by the presence of the microphone, a free-field microphone is designed to compensate for these effects. The result is that the measurement is as if the microphone were not present. When in use, the microphone should be positioned so that the diaphragm is normal to the incoming pressure variation. That is, it should be pointed directly at the source. Free-field microphones are normally used for scientific investigations of musical instruments.

A random-incidence or diffuse-field microphone is intended to be used in situations where the sound source is not localized. That is, it is not a free field. This situation occurs naturally in enclosed spaces where the reflections from walls cause the pressure variations to be incident on the microphone from multiple directions. Sometimes referred to as an omnidirectional microphone, the diffuse-field microphone corrects for both its presence in the field and the variations caused by sound being incident from different angles. Random-incidence microphones are normally used for recording the sounds of musical instruments during performance or for testing room acoustics.

A pressure-field microphone is not normally used in musical acoustics. It is designed to measure the acoustic field as it actually exists in front of the microphone. Therefore, the presence of the microphone is not taken into account. These microphones are usually mounted into structures (e.g., walls) to determine the incident pressure field.

5.1.3 Microphone Arrays and Near-Field Acoustic Holography

Microphones are often used individually to sense discrete points in a sound field, but they are also often used in combination with other microphones. Multiple microphones have been common for recording musical performances since the advent of stereophonic recording. More recently, the common use of multiple speakers in playback of a recording (i. e., surround-sound) has resulted in a considerable body of work analyzing many of the possible arrangements. Arrays of three and four microphones are common for recording music and analyzing acoustic spaces, [5.3, 4] but spherical arrays of microphones have been used recently and can provide three-dimensional information about a sound field [5.5, 6]. However, when investigating musical instruments, microphone arrays are typically used to identify the position of the radiating areas on the instrument. Precisely locating such areas can lend insight into the motion of the instrument as well as the pattern of acoustic radiation emanating from it.

Determining the origin of the radiation of a musical instrument can often be accomplished by imaging the motion of the surface. Several processes useful for this will be discussed in Sect. 5.2. However, in many instruments the origin of the sound cannot be directly imaged, such as when the sound originates from holes in the instrument. In these cases the radiation pattern can be determined by placing an array of microphones in the acoustic near field (less than a wavelength from the source) and determining the originating source velocity through a process that has become known as near-field acoustic holography (NAH). NAH is a natural outgrowth of acoustic holography and allows one to reconstruct the pressure and particle velocity at any point between the sensing array and the radiating object, hence the holographic reference.

NAH was first described by *Williams* and *Maynard*, who noted the possible application to musical acoustics as one of the motivations for developing the process [5.7]. The process is explained in detail in [5.8] and an excellent overview of acoustical holography and NAH can be found in [5.9]. The interested reader should consult these sources for a detailed explanation, but a short introduction is sufficient to understand acoustic holography and gain an appreciation for the analytical power of the process. We begin by analyzing the situation where the radiated sound field is measured in one plane and the field at a plane further from the source is calculated from this information (conventional acoustic holography). We then make the logical transition to NAH.

Conventional Acoustic Holography

If the acoustic pressure is known at any plane some distance from a radiating source, then it is possible to calculate the pressure and particle velocity at any other plane in free space. From these two quantities the acoustic intensity can be calculated. Since this is true at any plane, it is possible to construct a three-dimensional image of the sound field analytically. Although this process, known as acoustic holography, is theoretically similar to that of the more familiar optical holographic process, in practice it is much different. The differences are discussed in detail in [5.9].

Although there are more complete and rigorous ways to describe the process, it is sufficient to understand the process of acoustic holography by noting that any solution to the wave equation for a pressure in free space can be written as a sum of a complete set of plane waves. These plane waves are defined by their angular frequency ω, amplitude P and wave vector $\boldsymbol{k}$. In what follows we assume a single angular frequency is of in-

terest, keeping in mind that in any given situation there may be many frequencies that must be analyzed separately.

For simplicity we proceed from here by assuming a Cartesian coordinate system, realizing that any orthogonal coordinate system can be used if it better suits the physical system under investigation.

We may represent each plane wave in space in the normal way as an amplitude P with a spatially oscillating part that is dependent upon the direction, speed and frequency of the wave. These plane waves are represented by

$$p_{\boldsymbol{k}}(\boldsymbol{r}) = P_{\boldsymbol{k}} \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} \,, \tag{5.4}$$

where $P_{\boldsymbol{k}}$ is the wave amplitude, $\boldsymbol{k}$ is the wave vector defined in the Cartesian coordinate system as $\boldsymbol{k} = k_x\hat{i} + k_y\hat{j} + k_z\hat{k}$ with a magnitude of ω/c, $\boldsymbol{r}$ is the spatial coordinate (x, y, z), and c is the speed of sound in the medium. Since a single frequency is assumed we have suppressed the time-dependent nature of (5.4).

On any plane of constant z the field can be represented by a summation of plane waves in the x–y plane. The amplitude of each plane wave, which is dependent upon the wave vector, can be determined by projecting the pressure wave onto the basis set of plane waves in the x–y plane. Therefore

$$P(k_x, k_y, z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} p(x, y, z) \times \mathrm{e}^{-i(k_x x + k_y y)} \,\mathrm{d}x\mathrm{d}y \,, \tag{5.5}$$

and any solution to the free space wave equation can be written as

$$p(x, y, z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} P(k_x, k_y, z) \times \mathrm{e}^{\mathrm{i}(k_x x + k_y y)} \mathrm{d}k_x \mathrm{d}k_y \,. \tag{5.6}$$

Note that (5.5) and (5.6) form a Fourier transform pair and therefore can be written as

$$\mathcal{F}\{p(x, y, z)\} = P(k_x, k_y, z) \tag{5.7}$$

and

$$\mathcal{F}^{-1}\{P(k_x, k_y, z)\} = p(x, y, z) \,. \tag{5.8}$$

$P(k_x, k_y, z)$ is usually referred to as the angular spectrum.

Let us assume the situation shown in Fig. 5.1, where a radiating planar source is present on the plane $z = 0$. If the pressure is known on the (x', y') plane, which is

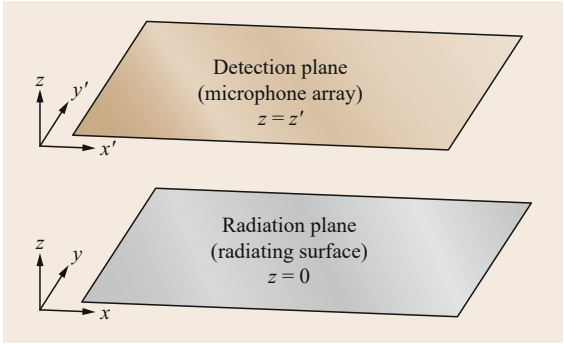

Fig. 5.1 Coordinate system for analyzing acoustic holography. The instrument under study is located at coordinates $(x, y, 0)$ and the microphones are located at coordinates (x', y', z')

parallel to the radiating surface and located some distance z' away, the pressure can be found on any other parallel plane by calculating the angular spectrum at z', propagating it to the new plane at z, and projecting the spectrum onto all possible plane waves in the x–y plane. The propagator function (i. e., Green's function) is

$$\mathrm{e}^{\mathrm{i}k_z(z-z')} \,, \tag{5.9}$$

and therefore

$$p(x, y, z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} P(k_x, k_y, z') \times \mathrm{e}^{\mathrm{i}(k_x(x-x') + k_y(y-y') + k_z(z-z'))} \mathrm{d}k_x \,\mathrm{d}k_y \,. \tag{5.10}$$

Or put more simply,

$$p(x, y, z) = \mathcal{F}^{-1}\left\{P\left(k_x, k_y, z'\right) \mathrm{e}^{\mathrm{i}k_z(z-z')}\right\} \,, \tag{5.11}$$

where x and y in (5.5) and (5.6) are replaced with $(x - x')$ and $(y - y')$. In this way the pressure at any point in space can be determined simply by measuring the pressure on the plane defined by $z = z'$.

It is important to remember that k_z is not independent of k_x and k_y since

$$k = \frac{\omega}{c} = \sqrt{k_x^2 + k_y^2 + k_z^2} \,,$$

and conventional acoustic holography demands that k_z be real. That is, $k^2 - k_x^2 - k_y^2 > 0$. Physically this restriction means that only freely propagating waves are considered since waves in which $k^2 - k_x^2 - k_y^2 < 0$ are evanescent. More will be said about this in the next section.

The challenge of acoustic holography is to determine the pressure field on the z' plane. Normally, an

array of closely spaced microphones is used and the precision of the measurement is determined by the wavelength and the sampling spatial frequency. Although pressure measurements occur at discrete points, if the plane is adequately sampled the far-field pressure can be calculated quite accurately by summing the pressure resulting from each point on (x', y').

To determine the acoustic intensity it is necessary to know the particle velocity in addition to the pressure. The particle velocity associated with the calculated pressure field can be derived using Euler's equation

$$\boldsymbol{v}(\boldsymbol{r}) = \frac{-i}{\omega\rho_0}\nabla p(\boldsymbol{r})\,, \tag{5.12}$$

where ρ_0 is the density of air. In Cartesian coordinates this can be written as

$$\boldsymbol{v}(\boldsymbol{r}) = \frac{1}{\rho_0 ck}\mathcal{F}^{-1}\left\{\left(\hat{\imath}k_x + \hat{\jmath}k_y + \hat{k}k_z\right) \times P\left(k_x, k_y, z'\right)\mathrm{e}^{\mathrm{i}k_z(z-z')}\right\}, \tag{5.13}$$

where as usual $k = \sqrt{k_x^2 + k_y^2 + k_z^2}$.

Near-Field Acoustic Holography

Determining the pressure and vector velocity at a point where $z > z'$ is known as a forward problem. In this way one may determine the acoustic intensity at any point in the direction of travel of the disturbance. However, in the study of musical instruments it is often more useful to determine the pressure and velocity fields that created the disturbance. That is, we are normally interested in the surface of the instrument. To investigate the radiation from the surface of an instrument one must calculate the desired quantities at a plane where $z < z'$. This is known as an inverse problem. Typically the measurement is made in the far field and for obvious reasons the resolution is limited to the acoustic wavelength. However, this resolution limit can be overcome by placing the recording microphones in the near field of the radiator, which is defined as being significantly less than a wavelength distant from the source. In practice the distance will normally be less than approximately $1/8$ wavelength. Solving the inverse problem using measurements made in the near field is referred to as near-field acoustic holography (NAH).

The requirement for making the measurements in the near field stems from the necessity to detect evanescent waves. These waves are generated by subsonic bending waves in the object, for example the top plate of a guitar, which have shorter wavelengths than the acoustic wavelength of the sound in the air. This forces the bending waves to move at a slower speed than sound waves of the same frequency do in air, and the shorter wavelengths provide increased precision of the measurement. These evanescent waves decay exponentially as they propagate away from the surface; therefore the microphones must be close to the surface to detect them. Assuming that the surrounding air stays in contact with the surface, the surface velocity of the source can be determined by calculating the velocity of the air at the surface of the object. This can be calculated from the pressure field measured at some plane a distance z' from the surface.

Theoretically, one can solve the inverse problem in a manner similar to the method one uses to solve the forward problem. That is, measure the pressure at some plane a distance z' from the surface located at $z = 0$, and then compute the angular spectrum by calculating the Fourier transform (5.6), multiply by an inverse propagator to propagate the field from z' to $z = 0$ and then perform an inverse Fourier transform to determine the real quantity. Normally the measured quantity is the pressure in the z'-plane and the calculated quantity is the velocity at $z = 0$.

There are several subtleties in this process that are beyond the scope of this review and the interested reader should consult [5.8, 9]. However, it is important to note two points. First, the velocity at the surface of the radiator can be calculated using (5.13), so that the velocity normal to the surface is given by

$$v_z(x, y, 0) = \frac{k_z}{\rho_0 ck}\mathcal{F}^{-1}\left\{P\left(k_x, k_y, z'\right)\mathrm{e}^{-\mathrm{i}k_z z'}\right\}. \tag{5.14}$$

As usual, $k_z = \sqrt{k^2 - k_x^2 - k_y^2}$, but in the case of evanescent waves k_z is purely imaginary because $k_x + k_y > k$. Therefore, the exponent is real and the wave decays exponentially with increasing z. The second point to note is that the measuring process is discrete in nature and introduces high spatial frequencies that are not present in the sound. These must be eliminated by applying a low-pass filter during the calculation. Other issues also complicate the measurement, including microphone spacing and noise; these are all addressed in general in [5.8] with some of the more practical aspects of applying NAH being addressed in [5.10]. Naturally, there is no reason to assume that a Cartesian coordinate system is the logical choice in every instance, but the theory is independent of the coordinate system used and implementation in spherical and cylindrical systems is also common.

An example of the intensity field around a tenor steel pan derived by NAH is shown in Fig. 5.2 [5.11].

A similar example of the sound field around a violin can be found in [5.12].

While we have addressed the physics of NAH and microphones in general, once the signal has been detected there is a significant amount of signal processing that can be applied. In addition to NAH, microphone arrays can be used for enhancing directivity, differential detection, localization and echo reduction, among many other things. The signal processing involved in these applications has been addressed in several places and a good overview can be found in [5.13, 14].

Equivalent Sources Calculations

As noted above, the sound field radiated by a musical instrument can be reconstructed using measurements made with microphone arrays by NAH, but these same measurements can be used in a different manner to achieve the same goal [5.15]. One example is an equivalent sources calculation, sometimes referred to as the source simulation technique, which is a procedure that represents the radiating surface as a collection of individual sources. These virtual sources are arranged such that the linear superposition of the radiation from all of them creates a field that is equivalent to the measured pressure field. Once this is accomplished, the field at the surface of the radiating body (or any other point in space) can be calculated by superimposing the field resulting from each source in the plane of interest. While the technique of equivalent sources was first proposed and demonstrated in 1989 [5.16], new techniques for solving the inverse problem are still being published.

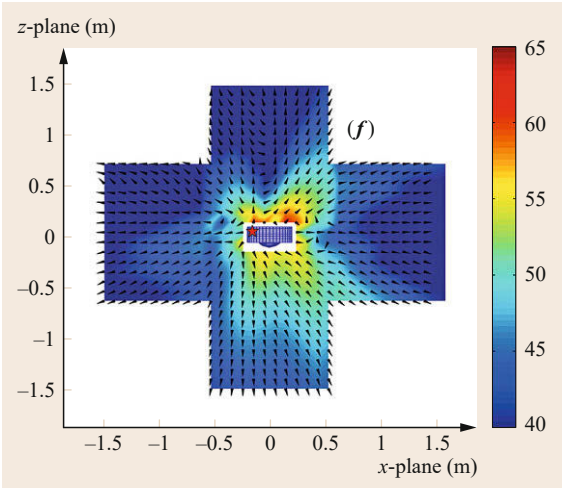

Fig. 5.2 Active acoustic intensity near a tenor steel pan derived from NAH measurements (after [5.11]). The active intensity indicates the magnitude and direction of the acoustic energy that propagates to the far field

Although the implementation of equivalent source methods can sometimes be tricky, the theory is straightforward. One merely posits a series of radiators on or behind the surface of the object and adjusts the phases and amplitudes so that the pressure recorded in the plane of the array matches the calculated pressure field. The radiators can be a series of monopoles, dipoles, or radiators with complex shapes. The correct choice of the virtual radiators is often critical to ensuring that the algorithm converges to a solution.

Assuming that all possible fields created by the real source can be represented by some collection of virtual sources on or behind the surface of interest, if the amplitudes of each of the sources is known then the pressure at any point in space can be calculated through (5.11). The problem is that the pressure is measured at some plane z' and not at the position of the virtual sources. That is, an inverse problem must be solved before (5.11) can be applied. This inverse problem is significantly different than the one that must be solved when performing NAH.

In an equivalent source calculation, rather than back propagating the measured acoustic field using (5.14), the geometry of the virtual radiators is assumed and the amplitudes are adjusted to match the measured field at the position of the microphone array. Assuming that there are N virtual monopole radiators at some point behind the surface of the actual radiator, then the pressure at each point in the plane of the virtual radiators can be designated as $p_n(x, y, 0)$. In the plane of the microphone array containing M microphones, the pressure at each microphone is $p_m(x', y', z')$. Then the problem is to ensure that

$$p_m(x', y', z') = \mathcal{F}^{-1}\left\{\mathcal{F}\left\{\sum_{n=1}^{N} p_n(x, y, 0)\right\} \times e^{ik_z(z-z')}\right\} \quad (5.15)$$

when all that is known is $p_m(x', y', z')$ for all M microphones. The ease with which this inverse problem can be solved depends upon the choice of sources as well as the method of solution and can be quite difficult. Furthermore, since there will be noise in the measurements the problem is ill posed and regularization is necessary. However, there are several algorithms available for solving these problems and multiple source methods can be very useful in the context of musical acoustics [5.17].

If the virtual sources are not assumed to be behind the radiating surface one must still solve the inverse problem, however, a simple application of some variation of (5.15) is not the most accurate or efficient procedure. When assuming that the sources are on the

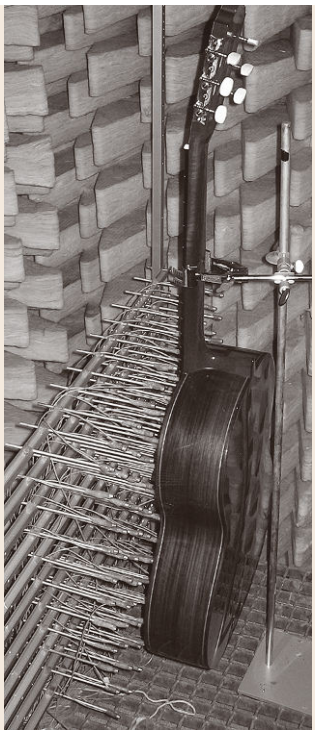

Fig. 5.3 Experimental arrangement of a near-field microphone array used to measure the radiation pattern of a guitar (after [5.18]). The array is positioned approximately 3 cm from the top plate of the guitar

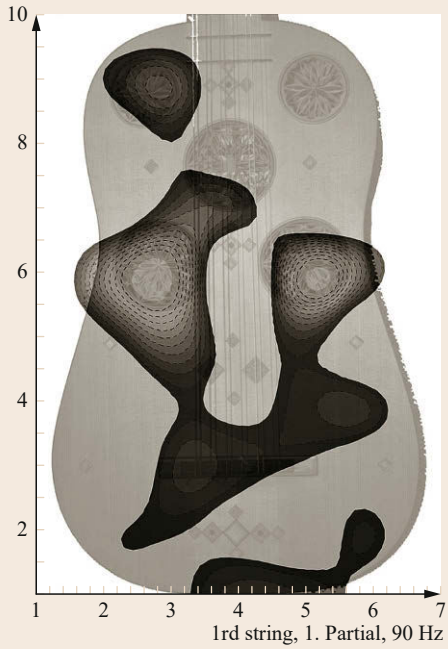

Fig. 5.4 Example of a radiation pattern calculated for a Yaish vihuela using the minimum energy method (after [5.18]). The experimental arrangement is shown in Fig. 5.3

radiating surface, one can assume the radiation is represented by an array of monopoles that are arranged so that one is under each microphone of the array. The array is placed in the near field of the radiation to achieve subwavelength resolution. The radiation pattern can then be calculated using minimum-energy methods to determine the amplitude of the monopole radiators [5.19]. An example of a typical experimental arrangement for recording the near-field radiation is shown in Fig. 5.3 and the reconstruction of the radiation pattern of a Yaish vihuela using this technique is shown in Fig. 5.4 [5.18].

5.2 Measurement of Deflection

Many musical instruments produce sound by vibration of some portion of the instrument itself. Percussion instruments are the most easily recognizable instruments that fall into this category, however, the strings of all acoustic stringed instruments are connected to some type of moving membrane or plate that efficiently transfers the energy from the string to the air. Examples include piano soundboards, violin and guitar top plates and backs, and the membrane head of the banjo. When investigating these instruments it is important to understand the motion of the individual parts and therefore visualizing the deflection shape is often necessary. Several methods for visualizing deflection shapes are addressed below.

5.2.1 Chladni Patterns

The most simple method of investigating the deflection shape of a vibrating object is to sprinkle sand on it while it is in motion. This method was pioneered by Ernst Chladni over 200 years ago and it still makes an impressive demonstration [5.20]. These so-called *Chladni patterns* do not make the deflection visible, but because the sand migrates to the nodal regions it makes the nodes visible. When the pattern of the motion is simple, observing the Chladni pattern is an effective method of determining the deflection shape. Indeed, if one can be sure that the motion represents a modal pattern, this technique is often adequate to determine

which mode is being excited if the mode shapes are known from theoretical considerations. Several examples of Chladni patterns can be found in a classic book by *Waller* [5.21]. An example of a Chladni pattern showing one of the modal patterns of a square flat plate is shown in Fig. 5.5 [5.22]. Note that it is also possible to use powder instead of sand to create the pattern, but in so doing the antinodes become visible because the powder is attracted to them instead of the nodal regions [5.23].

Although Chladni patterns have not been commonly used in the investigation of musical instruments since the advent of more precise optical methods, there are examples in the literature of the technique being used effectively. For example, the first few deflection shapes of a piano soundboard are shown using Chladni patterns in [5.24], and investigations of violin top plates and mode shapes in drum heads can also be found in the literature [5.25, 26]. However, there are limitations to using Chladni patterns for analysis of musical instruments.

The most obvious limitation of using Chladni patterns for scientific investigations is that the part of the instrument being investigated must be flat and horizontal. This means that, for example, only unstrung piano soundboards and violin top plates that are not mounted to an actual instrument can be investigated. Furthermore, if the instrument can be damaged by the sand it is not an economically efficient technique. Finally, there is no indication of the relative displacement of nonnodal regions. Chladni patterns only indicate the position of nodal regions, which is often not enough information to be useful. For these reasons Chladni patterns are seldom used for scientific investigation, although they are often used for demonstration purposes. Usually, more sophisticated techniques are employed, such as those discussed below.

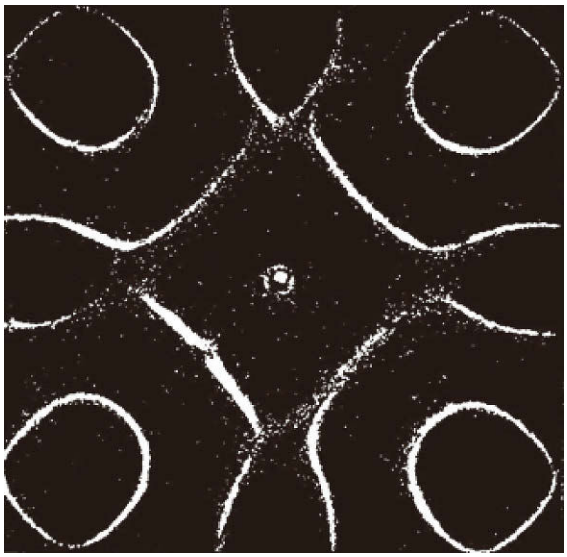

Fig. 5.5 Photograph of a Chladni pattern of one mode of a vibrating flat plate. The white sand has migrated to the nodal lines making them visible

5.2.2 Holographic Methods

With the invention of the laser in the mid-twentieth century several optical methods became available that are of use to musical acousticians. Most of these have been refined over the past 50 years and are now commonly used and easily implemented, but probably the most useful techniques that are of specific interest to musical acousticians are the processes involving optical interferometry. Although interferometry is possible without using lasers, the high coherence, directionality and power afforded by using a laser has made it the only source used for interferometry in modern research.

Interferometers rely on the principle of superposition to glean information from an optical signal. Somewhere in every interferometer two optical waves are combined and the interference between them is used to determine some aspect of the object under study. If the object under study is not transparent, one of the optical signals must be reflected from the object, which is the usual case for a musical instrument. In this case, the information that can be derived from the interferometer is the magnitude of the displacement or velocity of a point on the object.

There are numerous types of interferometers that can be applied to the study of musical instruments, but the most useful are those that provide a two-dimensional image of the surface vibration. In this section we discuss holographic interferometry, an interferometric method that can be used to produce such images. Two other interferometric techniques, electronic speckle pattern interferometry (ESPI) and laser Doppler vibrometry (LDV), will be discussed in following sections.

Holographic interferometry is used to determine the part of an object that is moving as well as the amplitude of the motion. It produces a two-dimensional image of the motion and has a sensitivity that is on the order of a fraction of the wavelength of the light being used. Therefore, amplitudes exceeding 0.01 mm are normally difficult to image using holographic techniques.

Because of the sensitivity, holographic interferometry is of little use in analyzing the motion of a musical instrument while being played because the amplitude of vibration typically exceeds the maximum resolvable displacement. Additionally, the act of playing the instrument produces whole-body motion that normally

exceeds the limitation of the resolution. Therefore, holographic methods are typically used under controlled circumstances with the instrument mounted securely and vibrations driven by some mechanism that produces very small amplitudes of the motion. For example, it is common to use the sound from a loudspeaker or a small piezoelectric element to drive the oscillations. Several different methods of holographic interferometry are addressed below.

Holographic Interferometry

Holographic interferometry has been used extensively to image the deflection shapes of many musical instruments, including bells [5.27], drums [5.28], guitars [5.29], clarinet reeds [5.30] and even wine glasses [5.31]. The process relies on the fact that when a holographic image of an object is superimposed on an image of the object being illuminated by light from the same laser, the final image is a superposition of the two images. Because the light from both images is coherent, any variation in position of the object that occurred after the creation of the hologram will result in an interference pattern. The lines of interference represent contours of equal displacement. The basic principles of holographic interferometry are described below, however, an extensive review of the physics involved can be found in [5.32].

The process of holographic interferometry begins with making a hologram of the object of interest. A typical arrangement for making a hologram is shown in Fig. 5.6. Light from a laser is split into two beams, which we refer to as the illuminating beam and the reference beam. The illuminating beam is directed toward the object of interest and the light reflected from the object falls on a photographic plate. We will refer to this reflected light as the object beam.

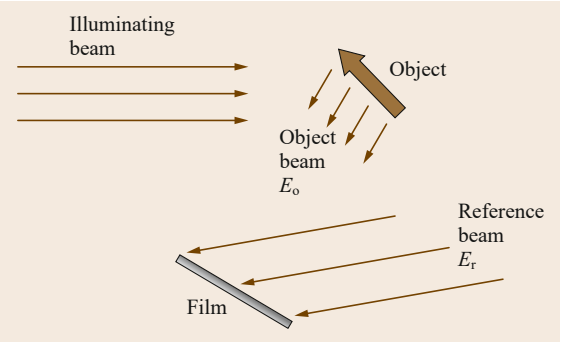

Fig. 5.6 Schematic diagram of the arrangement for making a hologram. The illuminating beam and the reference beam interfere on the film to produce a diffraction pattern, which can later be used to reconstruct an image of the object. Both beams originate from the same laser

The reference beam is also directed toward the film, where the two coherent beams interfere. The interference pattern is recorded on the film, which when developed results in a series of closely spaced dark fringes. These fringes form a diffraction pattern that when illuminated by the original laser produces a holographic image of the object. If the film is replaced in the same position in which it was originally illuminated, then the holographic image appears at the position of the original object. Therefore, imaging the object through the hologram results in the formation of two superimposed images of the object. Since the light forming the two images is coherent, a steady-state interference pattern occurs that can be photographed as a real image. If the object has not moved and the film is replaced in exactly the same place then there will be no visible fringes, however, any movement of the object will result in fringes representing contours of equal displacement.

To understand the process in more detail consider the formation of the hologram on the photographic plate. Assuming that the reference beam is of uniform intensity and linearly polarized, light from the reference beam falling on the photographic plate can be represented by the electric field

$$E_r = A_r e^{i(\boldsymbol{k}_r \cdot \boldsymbol{r})} , \tag{5.16}$$

where $\boldsymbol{k}_r$ is the wave vector of the light, $\boldsymbol{r}$ is the spatial coordinate, A_r is the amplitude, and the time-varying optical frequency has been suppressed because all of the light is coherent and assumed to have the same frequency. The electric field of the light reflected from the object and incident on the same position on the film can be written as

$$E_o(\xi) = A_o(\xi) e^{i(\boldsymbol{k}_o \cdot \boldsymbol{r} + \phi(\xi))} , \tag{5.17}$$

where ξ is the spatial coordinate of a point on the film, $\phi(\xi)$ represents the phase shift due to the different path lengths from the object to the plate, A_o is the amplitude, and $|\boldsymbol{k}_o| = |\boldsymbol{k}_r|$. Since these two fields are incident on the plate at the same position they interfere and produce an intensity pattern that is recorded by the photographic emulsion. Once the latent image is developed the plate has a transmission function given by

$$T = \beta \left| A_r + A_o(\xi) e^{i\phi(\xi)} \right|^2 , \tag{5.18}$$

where β is a constant determined by the response of the photographic emulsion to the light. The plate is a diffraction grating with the grating spacing determined by the relative phases of the two incident beams at the position of the film.

By replacing the plate with the interference pattern into its original position the intensity of the diffraction grating is imposed on the reference beam forming a field given by

$$E_{\mathrm{d}}(\xi) = A_{\mathrm{r}} \mathrm{e}^{\mathrm{i}(\boldsymbol{k}_{\mathrm{r}} \cdot \boldsymbol{r})}(1 - T) \,, \tag{5.19}$$

which can be written as

$$E_{\mathrm{d}}(\xi) = A_{\mathrm{r}} \mathrm{e}^{\mathrm{i}(\boldsymbol{k}_{\mathrm{r}} \cdot \boldsymbol{r})} \left\{ 1 - \beta \left[A_{\mathrm{r}}^2 + A_{\mathrm{o}}^2(\xi) + A_{\mathrm{r}} A_{\mathrm{o}}(\xi) \mathrm{e}^{\mathrm{i}([\boldsymbol{k}_{\mathrm{r}} - \boldsymbol{k}_{\mathrm{o}}] \cdot \boldsymbol{r} - \phi(\xi))} + A_{\mathrm{r}} A_{\mathrm{o}}(\xi) \mathrm{e}^{-\mathrm{i}([\boldsymbol{k}_{\mathrm{r}} - \boldsymbol{k}_{\mathrm{o}}] \cdot \boldsymbol{r} - \phi(\xi))} \right] \right\} . \tag{5.20}$$

When (5.20) is expanded it becomes obvious that the fifth term is

$$E_{\mathrm{h}}(\boldsymbol{\xi}) = \beta A_{\mathrm{r}}^2 A_{\mathrm{o}}(\boldsymbol{\xi}) \mathrm{e}^{\mathrm{i}(\boldsymbol{k}_{\mathrm{o}} \cdot \boldsymbol{r} + \phi(\xi))} \,, \tag{5.21}$$

which is a replica of the image of the object multiplied by a constant. This is the holographic image. The other terms represent light with different wave vectors and therefore the light attributable to these terms is traveling in other directions and these beams are easily distinguished from the hologram.

If the original object has not been moved, the light from the object and the light diffracted from the hologram produce two identical superimposed images of the object. However, any displacement of the object results in a change in phase of the object beam, which can be represented by a phase shift at the film plane with spatial dependence, $\varphi(\boldsymbol{\xi})$. The object beam can then be written as

$$E'_{\mathrm{o}}(\boldsymbol{\xi}) = E_{\mathrm{o}}(\boldsymbol{\xi}) \mathrm{e}^{\mathrm{i}(\boldsymbol{k}_{\mathrm{o}} \cdot \boldsymbol{r} + \phi(\xi) + \varphi(\boldsymbol{\xi}))} \,. \tag{5.22}$$

The resulting image can be determined by the superposition of this wave with the holographic image E_{h}, which results in an intensity pattern showing interference fringes given by

$$I_{\mathrm{i}}(\boldsymbol{\xi}) = \eta\{1 + \cos(\varphi(\xi))\} \,, \tag{5.23}$$

where η is a constant.

By imaging the object and its holographic image simultaneously, the phase difference between the two can be related to the displacement of the object and the two-dimensional coordinate ξ can be mapped onto the surface of the object. The phase difference is then a function of the displacement of the object and $\varphi(\xi)$ is given by

$$\varphi(x, y) = |\boldsymbol{k}_{\mathbf{o}}| \Delta(x, y)[\cos(\theta_{\mathrm{i}}) + \cos(\theta_{\mathrm{r}})] \,, \tag{5.24}$$

where $\Delta(x, y)$ is the amplitude of the displacement from the original position at the point (x, y) on the surface of the object and θ_{i} and θ_{r} are the angles of incidence and reflection from the object respectively. Contour lines represent subsequent displacements of

$$\Delta_{\mathrm{c}} = \frac{\lambda_{\mathrm{L}}}{\cos(\theta_{\mathrm{i}}) + \cos(\theta_{\mathrm{r}})} \,, \tag{5.25}$$

where λ_{L} is the wavelength of the light.

It is important to note that replacement of the holographic plate into its original position is critical, and rather difficult. Similarly, the entire arrangement must be isolated from ambient motion such that the magnitude of any motion of the object or film is significantly less than the wavelength of the light. This normally requires active isolation of the entire system. Thermal stability is also important or expansion and contraction of the object will create carrier fringes that make it difficult or impossible to determine the motion of interest. However, with the proper equipment and patience holographic interferometry produces high-quality interferograms that unambiguously indicate minute motion of the object of interest.

From the derivation above it is clear that small displacements of the object will be represented by fringes of equal displacement on the final image, however, the static displacement of an object is rarely important when investigating musical instruments. Instead, identifying the deflection shape of a vibrating object is usually of interest. Therefore, we must consider the case of an object vibrating with an angular frequency of ω and period $T = 2\pi/\omega$. These vibrations are typically driven externally by a mechanical component connected to a signal generator so that the point of excitation can be unambiguously determined. However, acoustical excitation by sound from a loudspeaker is useful if it is desirable not to have single-point excitation; excitation at a single point will not excite modes with nodes at the point of contact. To investigate the harmonic motion of musical instruments there are three holographic methods that are commonly used to image the harmonic displacement of an object: double-pulsed, time-averaged, and real-time.

Double-Pulsed Holographic Interferometry

The method of double-pulsed holographic interferometry is relatively easy to understand. When using this technique a hologram is recorded using a pulsed laser with a pulse length that is short compared to the period of oscillation of the object. At some later time, typically $T/2$, another laser pulse records a second latent image on the film. When the hologram is developed and reconstructed, two superimposed images appear. The two images interfere producing fringes representing the displacement of the object that occurred between the

two laser pulses. The contour lines are separated by a distance given by (5.25).

The primary advantage of double-pulsed holographic interferometry is that it is not necessary to replace the developed film back into the same position that it was when the hologram was constructed. Also, the requirements for isolation from ambient vibrations are significantly reduced since the object only needs to be stable in the time period between the two pulses. Finally, once the image is recorded and developed it can be analyzed at a later time and in a different location. Any continuous-wave laser having the same wavelength as the recording laser will produce the interferogram that can be used for analysis.

Unfortunately, the disadvantages of double-pulsed holography for the experimentalist are significant. Pulsed lasers are typically much more expensive than continuous-wave lasers, the timing and triggering mechanisms can be complicated, and having a continuous-wave laser of the same wavelength is convenient for viewing the interferogram. For these reasons it is more common to use time-averaged or real-time holographic interferometry to investigate musical instruments.

Real-Time Holographic Interferometry

Real-time holographic interferometry uses the arrangement shown in Fig. 5.6, with the interferogram being produced by the superposition of an image of the object and the hologram that results from placing the film plate back in its original position. This is similar to the arrangement of the more common holographic interferometer described above. However, once the holographic plate has been placed back into its original position the object is made to undergo harmonic motion with angular frequency ω. This produces an oscillating interference pattern with a period T as the object executes the motion. Obviously nodal areas undergo no such motion and the magnitude of the displacement will vary with position. The method of inducing the oscillation can be either mechanical or acoustical stimulation depending on the information desired.

Once the object is oscillating, the phase of the object beam given by (5.24) becomes time dependent and the phase difference between the holographic image and the real-time image of the object is given by

$$\varphi(\xi, t) = \varphi(\xi)\sin(\omega t)\,. \tag{5.26}$$

Under this condition, (5.22) becomes

$$E_o'(\xi, t) = E_o(\xi)e^{i(\boldsymbol{k}_o\cdot\boldsymbol{r}+\phi(\xi)+\varphi(\xi)\sin(\omega t))} \tag{5.27}$$

and the electric field is given by the superposition of E_h and E_o', where E_h is still given by (5.21). The image created by this superposition is then viewed by eye, or recorded by either film or a charge-coupled device (CCD) array.

The intensity pattern created by the superposition of the two fields, which is recorded by either the eye or other means is given by

$$I(\xi, t) = \eta\left\{|E_o(\xi)|^2 + |E_h(\xi)|^2 + E_o(\xi)E_h(\xi)\cos[\varphi(\xi)\sin(\omega t)]\right\}. \tag{5.28}$$

To perform real-time holographic interferometry it is necessary that the recording medium has an integration time that exceeds several periods of vibration. This is easily achieved since the recording medium is usually either the eye, a CCD array, or film and the oscillations of interest typically exceed 100 Hz. The resulting irradiance that will produce the visible pattern that will be the final image is then given by

$$\langle I_i(\xi)\rangle = I_o(\xi) + I_h(\xi) + \sqrt{I_o(\xi)I_h(\xi)} \times \frac{1}{T}\int_0^T \cos[\varphi(\xi)\sin(\omega t)]\mathrm{d}t\,, \tag{5.29}$$

where $\langle I_i(\xi)\rangle$ represents the time-average irradiance of the image.

The integral in (5.29) is one method of calculating the zero-order Bessel function of the first kind, therefore, the time-averaged image can be written as

$$\langle I_i(\xi)\rangle = I_o(\xi) + I_h(\xi) + \sqrt{I_o(\xi)I_h(\xi)}J_0(\varphi(\xi))\,, \tag{5.30}$$

where $\varphi(\xi)$ is given by (5.24). Maximum contrast occurs when $I_r = I_o$, in which case the intensity of the interferogram is given by

$$I_i = 2I_o(\xi)[1 + J_0(\varphi(\xi))]\,. \tag{5.31}$$

As with static holographic interferometry, it is necessary to replace the hologram precisely in the position it was in when the hologram was recorded. This is a difficult process. However, the advantage to real-time holographic interferometry is that the frequency of oscillation of the object, ω, can be changed while the interferogram is being observed. Therefore, one can view the deflection shape of the object vibrating at different frequencies. If information at only a single frequency is of interest, and that frequency is known, it is not necessary to go to the trouble of repositioning the holographic plate. Instead, the process known as time-averaged holographic interferometry is useful.

Time-Averaged Holographic Interferometry

Time-averaged holographic interferometry uses the same arrangement as double-pulsed interferometry; that

is, the hologram is recorded and processed and available for viewing at any later time. However, instead of using two pulses to record the holographic image at two different displacements, the image is recorded while the object is undergoing harmonic motion. That is, the object is set into harmonic motion and the hologram is recorded over a time that is long compared to the period of oscillation of the object. Using the same procedure described above for deriving (5.30), it is straightforward to show that under these conditions (5.31) becomes

$$I_{\mathrm{i}} = I_{\mathrm{o}}(\xi)[J_0(\varphi(\xi))]^2 \,. \tag{5.32}$$

The primary disadvantage of time-averaged holographic interferometry is that you must know the frequency of interest before recording the hologram. It is also important that the amplitude of vibration be small enough such that the fringes of equal displacement are visible. In real-time holographic interferometry the frequency and amplitude of vibration can be adjusted while viewing the interferogram. However, there are significant advantages to time-averaged holographic interferometry. These include the ease of reconstruction, which does not require precise replacement of the recording medium, and the improved contrast. After the displacement of the object exceeds the distance necessary to produce the first fringe, the contrast of the real-time interferogram is reduced significantly. Only the intensity between the fringes is reduced in time-averaged interferometry. Because the intensity of the dark fringes in the time-averaged case is always zero, the contrast between light and dark fringes remains high. An example of a holographic interferogram showing one deflection shape of a vibrating guitar body can be seen in Fig. 5.7 [5.33] .

The advantages of holographic interferometry were identified quite early by acousticians [5.34]. However, as noted above, the process is tedious, time consuming, and requires excellent stability and extensive optical equipment. For standard and real-time holographic interferometry it also requires proper alignment of the holographic plate back into its original position. For these reasons holographic interferometry has not been as prevalent in the study of musical instruments as one might think. However, there is another technique that produces similar results and requires less time, expense and effort. We address this technique in the next section.

5.2.3 Electronic Speckle Pattern Interferometry (ESPI)

Electronic speckle pattern interferometry (ESPI) is a technique that produces results similar to real-time holographic interferometry, but circumvents many of the problems. Of particular importance is the elimination of the necessity of producing and replacing the holographic plate.

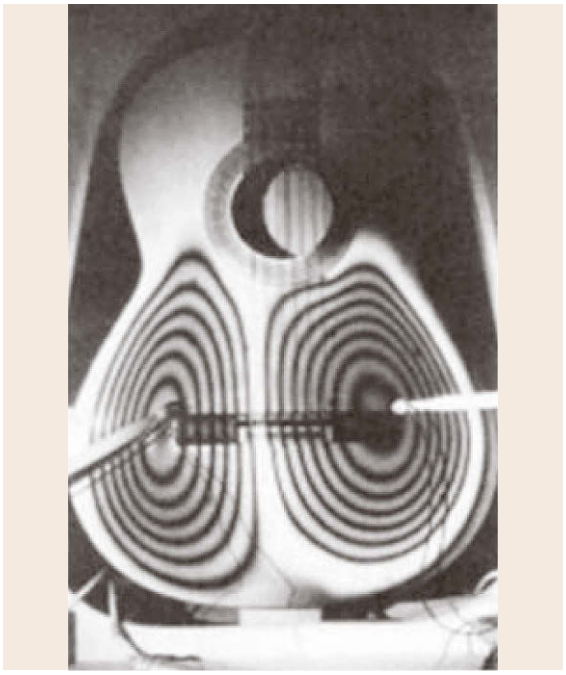

Fig. 5.7 Time-averaged holographic interferogram of a vibrating guitar body (after [5.33]). The fringes indicate contours of equal displacement. The vibrations are driven by a coil placed near a small magnet attached to the guitar

An electronic speckle pattern interferogram of a vibrating guitar body produced using ESPI is shown in Fig. 5.8. The similarity of the images, which is evident by comparing Figs. 5.7 and 5.8, causes the process of ESPI to be incorrectly referred to by the name *TV holography*. However, although the image appears similar to one produced by real-time or time-averaged holographic interferometry, and it can be viewed on a television monitor or computer screen, ESPI does not involve the production of a diffraction grating (i. e., a hologram). Therefore, the process is fundamentally different from holography.

Although holographic interferometry is still used for analysis in some laboratories, it has largely been replaced in the study of musical instruments by ESPI. The process of speckle pattern interferometry was first developed using film as the recording mechanism, but since the process involves subtracting images, film was quickly replaced by analog and then digital video. Currently, almost all ESPI is performed using a digital CCD array to capture the images, with image subtraction performed digitally in a computer. Electronic speckle pattern interferograms have been used to study

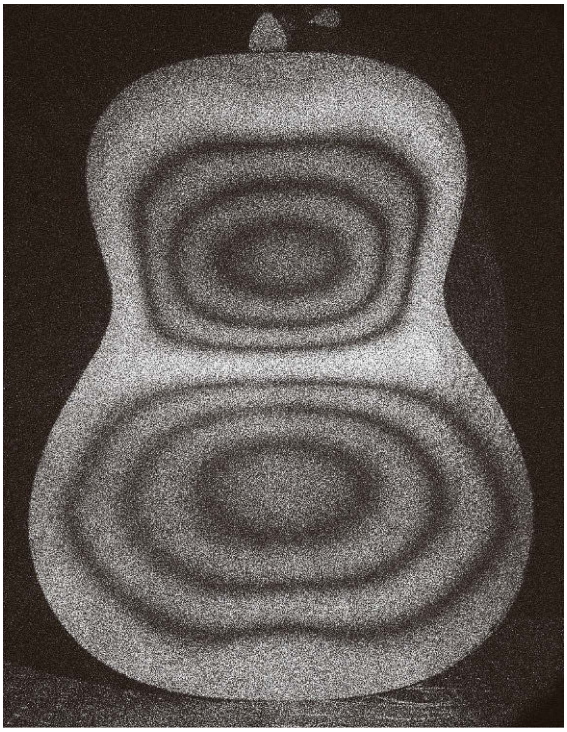

Fig. 5.8 Electronic speckle pattern interferogram of a vibrating guitar body showing fringes of equal displacement. The vibrations are driven by a speaker located approximately 1 m from the guitar

steel pans [5.35], banjos [5.36], trumpets [5.37], several percussion instruments [5.38–41], and even piano soundboards [5.42].

There are several different ways to construct an ESPI system, with each variation having distinct advantages and disadvantages. However, an understanding of the process can be gained by considering one of the simplest arrangements, a schematic diagram of which is shown in Fig. 5.9. Light from a laser is divided into two beams using a beam splitter, which is normally a semisilvered mirror that reflects a portion of the light while transmitting the rest. One of the beams is directed toward the object of interest off of which it reflects, and the other is directed toward a diffusing screen. As with holographic interferometry, the beam reflected from the object is usually referred to as the object beam and the latter as the reference beam. An image of the object is captured by a digital camera by viewing it through a second semisilvered mirror in such a way that the image of the object is superimposed on the image from the diffusing screen. The signal from the camera is then sent to a computer for processing.

Because the light used to illuminate the object and screen is highly coherent, the image projected onto the

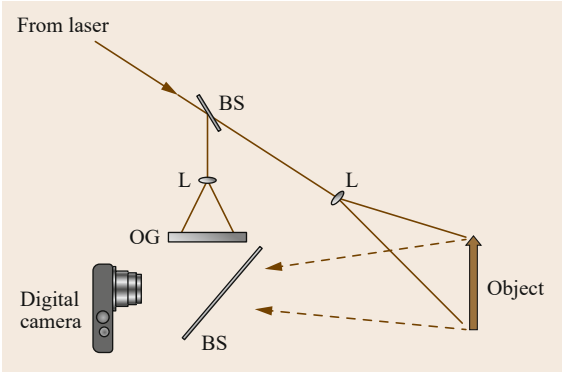

Fig. 5.9 Schematic of a simple arrangement for electronic speckle pattern interferometry with components: L = lens, BS = beam splitter, OG = opal glass. The lens on the camera is focused on the object; the opal glass plate provides the necessary reference beam, which reaches the camera by reflection from the beam splitter

recording array is speckled due to the diffraction from the edges of the aperture of the lens. The variation of this *objective speckle pattern* is complex, but the mean diameter of the speckle is approximately given by

$$d \approx (1 + M)\lambda_{\mathrm{L}} F \,, \tag{5.33}$$

where λ_{L} is the wavelength of the light from the laser, M is the magnification of the image and F is the aperture ratio of the lens (i. e., the f-number). It is normally advantageous to ensure that the mean diameter of the speckle is approximately the same size as the pixels that make up the recording array. For a thorough review of speckle within the context of ESPI, see [5.43].

To understand ESPI it is useful to consider only one pixel on the recording array, on which light from the reference beam with irradiance I_{r} interferes with light reflected from the object with irradiance I_{o}. The irradiance of the light on the pixel is then given by the usual form for interference between two coherent beams, i. e.,

$$I_1 = I_{\mathrm{r}} + I_{\mathrm{o}} + 2\sqrt{I_{\mathrm{r}} I_{\mathrm{o}}}\cos(\phi) \,, \tag{5.34}$$

where the phase angle ϕ is due to the differing optical path lengths of the two beams from the laser to the image plane. This image is recorded and digitally stored.

At some later time, after the portion of the object that is imaged onto the pixel has been translated a distance Δ, the irradiance on the image plane is given by

$$I_2 = I_{\mathrm{r}} + I_{\mathrm{o}} + 2\sqrt{I_{\mathrm{r}} I_{\mathrm{o}}}\cos(\phi + \varphi) \,, \tag{5.35}$$

where φ is given by

$$\varphi = 2\Delta|\boldsymbol{k}_{\mathbf{o}}| \,. \tag{5.36}$$

This image is also then digitally stored.

The ESPI process involves digitally subtracting the two images represented by (5.34) and (5.35) and taking the absolute value. The resulting image can then be displayed on a computer monitor. After subtraction the displayed pixel intensity is given by

$$I_{1,2} = \eta|\cos(\phi+\varphi)-\cos(\phi)|\,, \tag{5.37}$$

where η is a constant determined by the relative intensities of the two beams and the display parameters of the monitor. It is obvious from (5.37) that when $\varphi = 2n\pi$, where n is an integer, then the displayed intensity of the pixel will be zero. Similarly, when $\varphi = (2n+1)\pi$ the displayed intensity will be maximum. Therefore, the displacement of the object at the point imaged onto the pixel can be determined. Unfortunately, an image of the entire object is comprised of many pixels, all with a different value of ϕ. That is, because the value of ϕ varies from pixel to pixel in a random manner it is not obvious that the entire image will result in a meaningful interferogram. However, it can be shown that if ϕ is a random variable, on average the maximum irradiance will occur when $\varphi = 2n\pi$ and the minimum will occur when $\varphi = (2n+1)\pi$. A proof can be found in Appendix E of [5.32].

Due to the high calculation speed of modern computers it is possible to perform the image subtraction in almost real time. Therefore, it is possible to record an image of the object and then subtract subsequent images in real time and observe interferograms of the changing motion. If the displacement of the object occurs on a timescale that is long compared to the integration time of the camera, then this is a useful technique for determining displacements on the order of the wavelength of the light. Typically excellent interferograms can be achieved for motions ranging from $\approx 0.25{-}5\,\mu\text{m}$ if the light from the laser is in the visible portion of the electromagnetic spectrum.

If after storing an image of the static object the object begins oscillating with a period that is small compared to the integration time of the detector, as is common when studying musical instruments, then the second recorded image is the result of the time average over several oscillations. The process of determining the irradiance on the pixel in this case is similar to that outlined in Sect. 5.2.2, *Real-Time Holographic Interferometry*. By integrating the oscillating image over a large number of periods the displayed intensity of the subtracted images is given by

$$I_{1,2} = \eta[1-J_0(\varphi)]\,. \tag{5.38}$$

This response is similar to the response of real-time holographic interferometry with the exception that nodal areas show as black instead of white.

As with holographic interferometry, the stability requirements for ESPI are stringent. The object and all optical components must be stable to within a fraction of the wavelength of the light or the two speckled images become uncorrelated and the interference fringes are not visible. This normally requires active isolation of the object and the optical system, or it requires that the images be captured and stored within a time that is short compared to the timescale of the ambient motion.

Although this method of ESPI has been used in the past to study musical instruments, and it is useful to explain the basic principles of ESPI, there are better arrangements for acoustical studies. It is important to note one arrangement that is of particular interest to musical acousticians because it affords the possibility of imaging large objects that are typically not stable enough to analyze using either ESPI or holographic interferometry. This method, known as *decorrelated electronic speckle pattern interferometry* (DESPI), requires a linear phase shift of one beam during the process of recording the image. The phase shift can be caused by whole-body motion of the object that is linear on the timescale of the integration of the detector, effectively inducing a linear phase shift on the illuminating beam. Alternatively, the motion can be imposed on one beam by the linear motion of a mirror that reflects either the reference or illumination beam, or by introducing an electrical or mechanical phase-shifting device in one beam. When using DESPI it is not necessary to store an image of the object prior to the onset of vibration. Instead, two images of the object that were captured during vibration are subtracted. This significantly relaxes the restriction on the magnitude of the ambient motion and often eliminates the need for active isolation of the system. An analysis of decorrelated ESPI can be found in [5.44].

The contrast of the interferogram obtained using DESPI is dependent upon how rapidly the phase of the beam is changing, either due to motion of the object or an imposed path length difference on one beam, and the integration time of the detector. But there is a wide tolerance for motion and the imposition of this motion can enhance both the contrast and the precision of the interferogram. A comparison of two images of a vibrating plate is shown in Fig. 5.10, where the image obtained through the ESPI system described above is shown in Fig. 5.10a and the same plate imaged using DESPI is shown in Fig. 5.10b [5.44].

In the example shown in Fig. 5.10b the linear motion was imposed on one of the beams of the interferometer and was carefully controlled to produce maximum contrast. However, in many cases ambient motion can produce the same result. Indeed, the ambient motion that normally limits the usefulness of ESPI

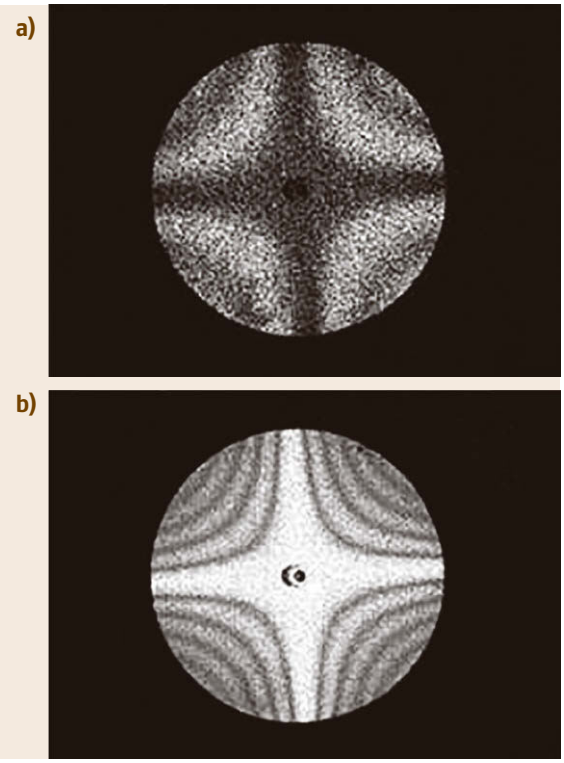

Fig. 5.10a,b Interferograms of a vibrating circular plate using (a) a simple ESPI system and (b) the same plate using DESPI (after [5.44]). Both plates have the same amplitude and frequency of vibration

for large objects can be used to produce excellent interferograms using DESPI. In such cases the integration time of the detector can be used to ensure that the magnitude of the ambient motion is sufficient to decorrelate the illuminating and reference beams. An example is shown in Fig. 5.11, where the deflection shape of a vibrating piano soundboard is made visible using DESPI. A similar image using ESPI would be extremely difficult to produce.

The contrast of interferograms produced by ESPI and DESPI is not as high as those produced by holographic interferometry. The speckle nature of the image is also more pronounced. However, usually the quality of the image is sufficient to obtain the same information that can be obtained from a time-averaged holographic interferogram. For example, compare the image of a vibrating guitar obtained by DESPI shown in Fig. 5.8 with a similar one obtained through time-averaged holographic interferometry shown in Fig. 5.7.

While ESPI is becoming more common in the analysis of musical instruments, the cost of a commercial ESPI system is significant. However, the system shown in Fig. 5.9 is not difficult to construct if one has experience with optical experimental techniques, and the cost of the components can be as little as one-tenth that of a commercially available system. Those wishing to build a simple ESPI system at relatively low cost should consult [5.45, 46]. An even more simple and inexpensive variation is described in [5.22], but this arrangement produces inferior results and is primarily intended for educational use.

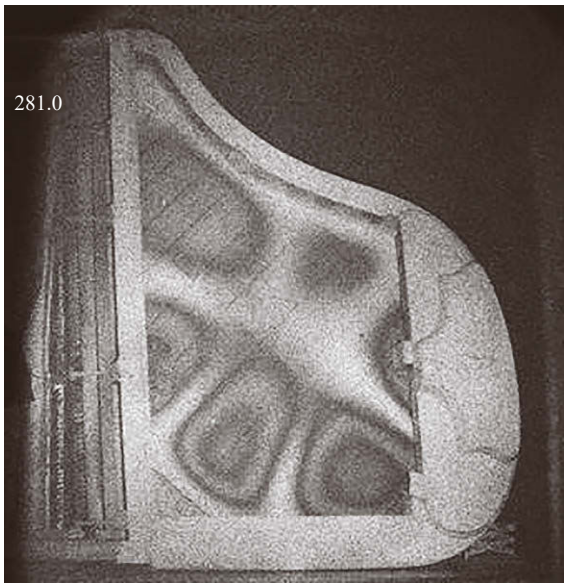

Fig. 5.11 DESPI interferogram of a piano soundboard excited acoustically by a distant speaker. The ambient motion of the piano was sufficient to decorrelate the illuminating and reference beams without imposing a controlled phase shift as part of the experimental arrangement

Note that the recording mechanism for speckle pattern interferometry does not necessarily need to be electronic. It can be accomplished using film rather than an electronic camera as the recording mechanism. Unfortunately, the effort required to use film is similar to that necessary for holographic interferometry and significantly greater than what is required when using an electronic recording mechanism. The prevalence of low-cost electronic cameras and computers has rendered film-based speckle pattern interferometry largely obsolete.

5.2.4 Laser Doppler Vibrometry

Another optical technique that is not normally classified as interferometry, but in detail relies on the physics of interfering optical waves, is laser Doppler vibrometry (LDV). LDV utilizes the frequency shift of light reflected from a moving source to determine the velocity of a vibrating surface. Although the Doppler effect

is most often associated with sound, electromagnetic waves can also experience Doppler shifts.

LDV uses light from a laser that is reflected from the point of interest on a moving object. This reflected light is mixed with the original light to produce a moving interference pattern. The speed of the fringe motion is proportional to the velocity of the object from which the beam is reflected. The laser is usually colocated with the receiver and the associated electronics are sealed with the optics into a case.

Laser Doppler vibrometry is a logical extension of laser Doppler velocimetry, which was in use as early as 1964 [5.47]. Laser Doppler velocimetry relies on the Doppler shift of a moving surface or particles in a fluid to determine the velocity of the body or fluid. Laser Doppler vibrometry relies on the same effect, but the object of interest is a harmonically vibrating solid surface and Fourier techniques can be used to isolate the vibrations within a given frequency band. LDV has been used in studying percussion instruments, [5.39, 48] the bodies of stringed instruments, [5.49] vibrations of the bells of brass instruments [5.50], and the motion of organ pipes [5.51].

To understand the operation of a laser Doppler vibrometer one must begin with the realization that the light from a laser has a narrow linewidth. Due to the narrow linewidth it is acceptable to assume that the laser has a frequency of ν_L and a wavelength of λ_L. In reality all lasers have a finite linewidth, which limits the coherence of the light and hence the distance between the object and the laser. The limitations associated with the finite coherence length can be found elsewhere and is a detail that is not necessary to understand the operation of a LDV system [5.52].

In a LDV system the light from a laser is divided into two beams by a semisurfaced mirror. One beam is directed toward the object of interest. The second beam is directed toward a second beam splitter where it is mixed with the light reflected from the object. The resulting interference pattern is imaged onto a detector. If the object is moving toward the laser then the reflected beam will have a shorter wavelength than the incident object beam because each successive phase front must travel a shorter distance than the last one.

Let the period of the electromagnetic wave incident on the object be given by $T = 1/\nu_\mathrm{L}$. A wavefront from the laser will move a distance $\lambda_\mathrm{L} = c_0 T$ during one period, where c_0 is the speed of light in air. However, during the time T an object moving at velocity $\boldsymbol{v}$ toward the laser will have moved a distance of $|\boldsymbol{v}|T$ and therefore the distance between two successive wavefronts of light reflected off of the moving object will be

$$\lambda' = c_0 T - 2|\boldsymbol{v}|T\,, \tag{5.39}$$

and the frequency of that light will be Doppler shifted to

$$\nu' = \frac{c_0}{\lambda'}\,. \tag{5.40}$$

Combining equations (5.39) and (5.40) yields

$$\nu' = \frac{\nu_\mathrm{L}}{1 - \frac{|\boldsymbol{v}|}{c_0}}\,. \tag{5.41}$$

The velocities of interest for the musical acoustician are normally on the order of 1 m/s or less. Therefore, the task becomes determining a shift in frequency of approximately one in 10^8. To do this the reflected light is mixed with the reference beam at the second beam splitter. When combined at the second beam splitter, the reference beam of frequency ν_0 and the reflected beam at frequency ν' create a changing interference pattern with a frequency of $\Delta\nu = \nu - \nu'$, or

$$\Delta\nu = \frac{-2|\boldsymbol{v}|}{\lambda_\mathrm{L}}\,. \tag{5.42}$$

If the laser is in the near-infrared region, as many are, it will have a wavelength of approximately 1 μm and therefore a typical difference frequency may be on the order of a few megahertz, which is easily detected by a photodiode.

The simplified description above is adequate to understand how a LDV system works, however, there is one other aspect that deserves mention. It is clear from (5.42) that in the situation described there is no way to determine if the object is moving toward or away from the laser. In either case the difference frequency would be the same. To solve this problem, and to increase the signal-to-noise ratio, one of the beams is usually frequency modulated by a Bragg cell so that there is a fixed carrier frequency from which $\Delta\nu$ can be added or subtracted.

As described above, this system can be used to measure the velocity of any object and hence describes laser Doppler velocimetry. However, since the motion of musical instruments is almost always periodic, the analysis can be extended to assume that the displacement of the point of interest is given by

$$x = \Delta_x \sin(\omega t)\,, \tag{5.43}$$

where Δ_x is the amplitude of the motion and ω is the acoustic angular frequency. The velocity is then given by

$$v(t) = \frac{\mathrm{d}x}{\mathrm{d}t} = \Delta_x \omega \cos(\omega t)\,, \tag{5.44}$$

and the Doppler shift is given by

$$\Delta\nu(t) = \frac{-2\Delta_x\omega}{\lambda_L}\cos(\omega t)\,. \tag{5.45}$$

A fast Fourier transform algorithm can then be used to determine the velocity as a function of frequency of vibration, in which case the process is termed laser Doppler vibrometry (LDV). Dividing the result by ω yields the amplitude of the displacement as a function of vibrational frequency.

Unlike Chladni patterns, holographic interferometry or ESPI, LDV provides the amplitude of the vibration at only a single a point on the object of interest. If it is desirable to measure the motion over a large area the laser must be scanned across the object in a grid pattern, stopping at each point for a period of time determined by the desired precision of the measurement. The motion at each point is analyzed individually and then the motion of the entire body is reconstructed using a computer algorithm. Scanning is normally achieved by a pair of actuated mirrors within the system.

5.2.5 Accelerometers

Deflection measurements using accelerometers has become common in the field of musical acoustics. These devices are inexpensive and robust, and they can provide real-time information about the motion of an object in three dimensions. Although an accelerometer only provides a voltage that is proportional to the acceleration, the velocity and position can be determined by numerical integration of the signal.

Types of Accelerometers

There are several types of accelerometers, including piezoelectric, piezoresistive, capacitive and ones using strain gages. All accelerometers produce an output that is proportional to the acceleration of the device and can be obtained in configurations that are sensitive to changes in velocity in one, two or three dimensions. Regardless of the sensing mechanism, accelerometers consist of a mass attached to a sensor. An applied force on the accelerometer produces an acceleration of the mass, which results a change in the electrical characteristics of the sensor.

A piezoelectric crystal will produce a charge proportional to the stress, a capacitive sensor will produce a change in capacitance due to a varying distance between two plates, and a piezoresistive element and strain gages typically produce an output voltage through the change in resistance of a Wheatstone bridge arrangement. There are also accelerometers that use the Hall effect and magnetic induction. Although the resistive accelerometers provide excellent sub-sonic response, in most applications associated with musical acoustics it is the response at audible frequencies that is of interest. Therefore piezoelectric and micro-electric mechanical system (MEMS) capacitive accelerometers appear to be more common. We will briefly describe how these work before addressing their application.

A simplified diagram of a piezoelectric accelerometer is shown in Fig. 5.12. As with the piezoelectric microphone described in Sect. 5.1.1, the operation of a piezoelectric accelerometer depends on the fact that piezoelectric crystals produce a polarizing charge when they are under stress. This charge results in a potential difference across the crystal that is proportional to the stress. Inside the accelerometer housing the crystal is placed between a surface attached to the housing and a movable mass m. When it is subjected to a force F in the direction that the mass can move, a potential difference of V is produced. This potential is proportional to F/m, which according to Newton's second law is the acceleration.

As with electret microphones, capacitive accelerometers rely on the fact that the capacitance of a parallel plate capacitor is given by (5.1). Typically, a MEMS accelerometer will have several *fingers* on a movable structure that produce a capacitance as shown in Fig. 5.13. The movable beams between the static plates can be modeled as a mass m on a spring with spring constant k. For the simple case of a mass on a spring the restoring force of the spring is given by

$$F_s = -kx\,, \tag{5.46}$$

where x is the displacement of the mass from its equilibrium position. The distance between the plates on either side of the central conductor (i. e., the finger) is then

$$\Delta = d_0 \pm x\,, \tag{5.47}$$

where d_0 is the equilibrium distance between the plates when the accelerometer is not undergoing acceleration.

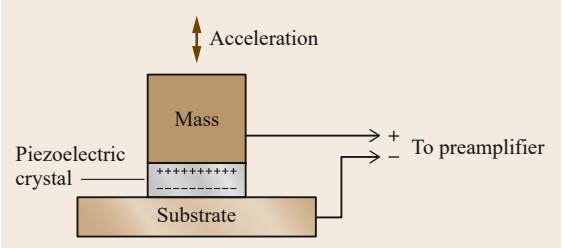

Fig. 5.12 Simplified diagram of a piezoelectric accelerometer. The piezoelectric crystal produces a potential difference that is proportional to the strain produced by the acceleration of the inertial mass

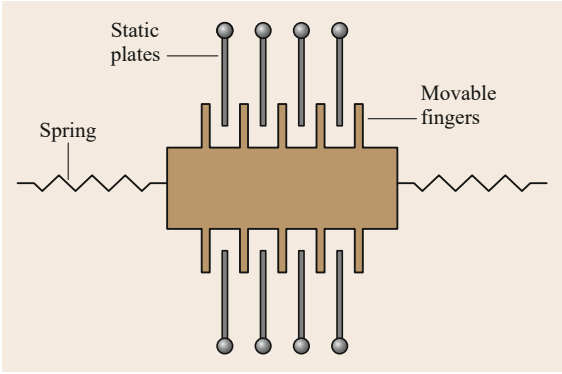

Fig. 5.13 Schematic diagram of a MEMS accelerometer. The acceleration is determined by measuring the change in capacitance that results from the fingers moving away from the equilibrium position

Detection is typically accomplished by measuring the difference in the capacitance between the plates closest to the movable finger and those further away [5.53]. When the device experiences an acceleration, the applied force results in the fingers moving closer to one set of plates than the other. Since the capacitors are all identical and wired in parallel, the capacitance is given by (5.1) multiplied by the number of capacitors N, assuming that one can ignore the edge effects and that the central fingers extend the length of the two plates. Substituting (5.47) into (5.1) and subtracting the two capacitances results in the difference between the capacitances when the accelerometer is subjected to a force. This results in an equation that indicates that the difference in capacitance is nonlinearly related to the displacement of the mass

$$\Delta C = 2N\varepsilon_0 A \frac{x}{d_0^2 - x^2} \,. \tag{5.48}$$

The nonlinearity is, however, negligible if $x \ll d_0$.

Rearranging (5.48) and ignoring the term quadratic in x reveals that the difference in capacitance is linearly related to the displacement of the fingers

$$\Delta C \approx x\left(\frac{2N\varepsilon_0 A}{d_0^2}\right) \tag{5.49}$$

and the acceleration is given by

$$a \approx \frac{-kd_0}{2N}\frac{\Delta C}{C_0} \,, \tag{5.50}$$

where C_0 is the capacitance when the sensor is experiencing no acceleration.

The sensitivity of an accelerometer is measured in units of volts per unit of acceleration. The normal unit of acceleration is equivalent to the acceleration due to the Earth's gravity, therefore the sensitivity is usually quoted in mV/g, where $g = 9.8\,\mathrm{m/s^2}$.

Measurements with Accelerometers

In the study of musical acoustics accelerometers can be used in a variety of ways, but they are typically used for determining the modal structure and the mechanical impedance (or admittance) of musical instruments [5.54–57]. Modal analysis will be briefly addressed here; measurements of the mechanical impedance are addressed in the following section.

Knowing the acceleration of a structure at the point where an accelerometer is attached is typically valuable only if something is known about the exciting force. Therefore, accelerometers are usually used in conjunction with a force sensor. There are two methods of determining the modal structure of an object using accelerometers: using multiple accelerometers placed at several points on the object, and using a single accelerometer while exciting the vibrations at different points serially. In each case it is the frequency response function (FRF) between the point of excitation and the accelerometer position that is measured. These measurements can be used to reconstruct the deflection shape of the object.

When multiple accelerometers are available and the object is small enough such that the distance between them is less than the distance between modal antinodes, it is convenient to drive the object either by impulse or steady-state excitation and record the motion at several different points. The accelerometers must be sensitive to the direction of displacement and are usually mounted so that the acceleration normal to the surface of the object produces a signal. The displacement is found by integrating the acceleration twice with respect to time.

To determine the mode shapes the position of each accelerometer must be known. To facilitate the analysis they are often placed symmetrically on the object. The multiple signals from the accelerometers can then be aggregated in a computer and used to determine the deflection and mode shapes. This technique was used in [5.56] to determine the mode shapes of a Himalayan singing bowl, but this work also demonstrated one of the limitations of this technique; the mass of the accelerometers altered the resonance frequencies of the instrument.

For modal analysis it is the displacement as a function of frequency that is of interest. If the driving mechanism is steady state and narrow band, the frequency may be swept as a function of time and the individual measurements aggregated at the frequencies of interest. If the excitation mechanism is broad band,

as when the body is excited by an impulse, the Fourier transform is calculated prior to analysis.

Multiple accelerometers can also be used to determine the whole-body motion and eliminate the effects of any modal vibrations if the body has simple symmetry, such as the bell of a brass instrument [5.50]. To do this, multiple accelerometers are attached to the structure in a symmetric pattern and vibrations are driven over a broad band, either acoustically or by contact with a shaker. The phase and amplitude of the accelerometer signals are recorded and then averaged in the complex plane. In this way the vibrations due to modal resonances are eliminated due to the fact that the antinodes are symmetric and adjacent ones are π out of phase. The resulting signal contains only the effects of whole-body and asymmetric motions.

For large instruments, such as pianos, it is more common to attach a single accelerometer to some point and excite the vibrations at points on the instrument in a grid pattern. The signal from the accelerometer and the exciting instrument, often a force hammer, can then be used to determine the mode shapes of the structure. An example of the result of this type of measurement can be found in [5.54].

The theory is the same in either case, therefore here we will only consider the case where a single accelerometer is affixed at a point (x_0, y_0) and N points at (x_n, y_n) are excited by a broad-band strike from a force hammer. It is assumed that after the strike the motion can be described by a set of damped orthogonal harmonic modes and that nonlinear coupling between the modes is negligible.

The FRF between the position of the accelerometer (x_0, y_0) and the exciting strike at (x_n, y_n) is determined by the mode amplitude at each point and the frequency-dependent modal damping γ_m, which determines the quality factor of the resonance. Denoting the mode shapes as $\Phi_\mathrm{m}(x, y)$, the FRF is given by

$$H_{0,n}(\omega) = \sum_{m=1}^{\infty} \frac{\Phi_m(x_0, y_0)\Phi_m(x_n, y_n)}{(\omega_m^2 - \omega^2) + 2i\gamma_m\omega\omega_m} , \qquad (5.51)$$

where ω_m is the resonant frequency of the m-th mode. Typically, only a limited number of modes are of interest and m is truncated such that the angular frequency does not exceed some predetermined maximum.

The mode shapes can be determined from the measurement of $H(\omega)$ by averaging measurements from several different points. Assuming that only M modes are of interest and measurements are made at N unique positions, then

$$H_{0,N}(\omega) = \sum_{m=1}^{M} \frac{\sum_{n=1}^{N} \Phi_m(x_0, y_0)\Phi_m(x_n, y_n)}{(\omega_m^2 - \omega^2) + 2i\gamma_m\omega\omega_m} . \qquad (5.52)$$

An optimization algorithm is then used to determine the mode shapes Φ_m by comparing the computed value of $H_{0,N}$ with the value derived from measurements.

When performing modal analysis in this manner it is important to ensure that the frequency spectrum of the exciting impact contains the frequencies of interest and that the accelerometer is not placed on a node of the mode of interest. It is also important to ensure that the excitation mechanism is similar at each point and, in the case of impact excitation, that there are not multiple strikes. There are several methods available to ensure that the structure is excited in an appropriate manner [5.58].

5.3 Measurement of Impedance

All musical instruments consist of one or more oscillators and one or more resonators. The final sound is largely determined by the spectrum of the oscillator and the input impedance of the resonators. Therefore, much effort goes into measuring the input impedance of musical instruments.

The input impedance of wind instruments is defined as the input pressure divided by the volume flow. In other instruments it is the mechanical impedance at the driving point that is important, which is defined as the applied force divided by the velocity. In either case, the impedance determines the efficiency of the system and it is a function of frequency. Some of the methods that can be used to measure both types of impedance are discussed here. In each case measurements are made either by using a swept sine function or a random noise generator to produce a signal. If a random noise generator is used, the Fourier transform of the signal is first calculated before determining the impedance to provide frequency discrimination.

5.3.1 Mechanical Impedance

The impedance that is of interest for many instruments, such as percussion and stringed instruments, is the impedance at the point of energy transfer from the string or striking mechanism to the resonating body. Some instruments have multiple interactions that are of

interest and therefore there is not one impedance measurement that characterizes the response. The sound generated by a piano, for example, depends on the impedance of the string during the interaction with the hammer as well as the impedance of the bridge where it meets the string. Both impedances are mechanical impedances.

The mechanical impedance at the point of excitation, referred to as the driving point impedance, is normally measured by applying a force at the same point that the acceleration is measured. To determine the mechanical impedance, the signal from an accelerometer is integrated to provide the velocity v in the direction of the exciting force. The impedance is defined by

$$Z = \frac{F}{v}\,, \tag{5.53}$$

where F is the applied force. Since the force and velocity are not generally in phase, Z is normally a complex value. Often the admittance, which is the reciprocal of the impedance, is used for analysis rather than the impedance.

The force sensor is usually made from a piezoelectric crystal that is placed between the driving mechanism and the object of interest. Compression of the crystal produces a potential difference proportional to the stress, as described in Sect. 5.2.5. The difference between an accelerometer and a force sensor is that an accelerometer has the crystal attached to an inertial mass that is free to move while in the force sensor the crystal is placed directly in line between the driving element and the object of interest.

An impedance head consists of a driving mechanism called a shaker, which is usually driven electromagnetically by a coil and magnet arrangement, similar to the arrangement found in a common speaker. The shaker may be driven by a swept harmonic signal or by a noise signal containing all of the frequencies of interest. An accelerometer is placed between the driving mechanism and the force sensor, and the force sensor is placed as close to the object as is possible. This placement of the force sensor is important because the measured impedance is affected by any mass m that exists between the force sensor and the object. When there is a mass between the force sensor and the object, the measured impedance Z_m is related to the actual impedance Z by

$$Z_m = Z + i\omega m\,, \tag{5.54}$$

and therefore it is important to minimize m to obtain an accurate measurement.

The mechanical impedance can also be measured by impacting the surface of the object with a hammer containing an integrated sensor rather than driving it with a shaker. As is the case when a shaker is driven by a noise signal, when an impact is used to excite the motion it is necessary to Fourier transform the force and acceleration signals. If the driver is a shaker driven by a harmonic signal that is swept through the frequencies of interest over time, the appropriate frequency dependence can be directly substituted for the time dependence. In each case the velocity can be determined at each frequency by dividing the acceleration by $i\omega$. A direct application of (5.53) will then yield the impedance spectrum.

The velocity at the point of excitation can also be measured by other means. LDV can be used and is very convenient, but by necessity the measurement of the velocity cannot be exactly at the point of excitation since the driver must be located there. However, if the surface of interest is thin and can be accessed from both sides, such as is possible with a piano soundboard, the measurement of velocity can be made on the opposite side of the structure. Any measurement of the displacement can also be used to determine the velocity.

5.3.2 Impedance of Wind Instruments

Measuring the mechanical impedance is relatively straightforward, however, measuring the input impedance of a wind instrument is more complicated. The input impedance of a wind instrument is a complex value defined as the ratio of the pressure p and the volume flow u at the point of input

$$Z = \frac{p}{u}\,. \tag{5.55}$$

In wind instruments the input is usually defined as the point where the oscillator meets the resonator, i. e., the mouthpiece.

While it is relatively easy to measure both the force and velocity of a point on a mechanical system, the simultaneous measurement of the pressure and volume flow at the input of a wind instrument can be quite difficult. Rather than measuring the flow, often a known flow is imposed on the system by a membrane with very high impedance. The high impedance ensures that the input impedance of the instrument under test negligibly affects the flow. In practice a piezoelectric disk works well for this purpose [5.59]. However, it is also possible to couple a low impedance driver, such as a speaker, through a small capillary tube. This arrangement can provide a close approximation to a high impedance driver and it was the first known method for making direct measurements of the input impedance of brass

instruments [5.60]. Later developments provided corrections [5.61] and this method is currently used in the commercially available brass instrument analysis system (BIAS) [5.62]. An example of the impedance of a B-flat trumpet as a function of frequency measured using the BIAS system is shown in Fig. 5.14.

Provided the driving mechanism is unaffected by the presence of the attached instrument, the input impedance can be determined simply by measuring the pressure at the input, which can be accomplished using a small microphone. The problem with this arrangement is that the microphone and the driving diaphragm must be at the same place. Any displacement of the microphone from the driving point results in an error, which can sometimes be significant, but these errors can usually be accounted for theoretically [5.59].

Methods exist for measuring the flow directly, for example a hot-wire anemometer can be use [5.63], but normally the volume flow is determined by inducing a known flow or by deducing it from a pressure gradient determined using two or more microphones [5.64, 65]. This method has been extensively improved upon since the first report of its use [5.66–68] and is in common use for measuring the input impedance of wind instruments.

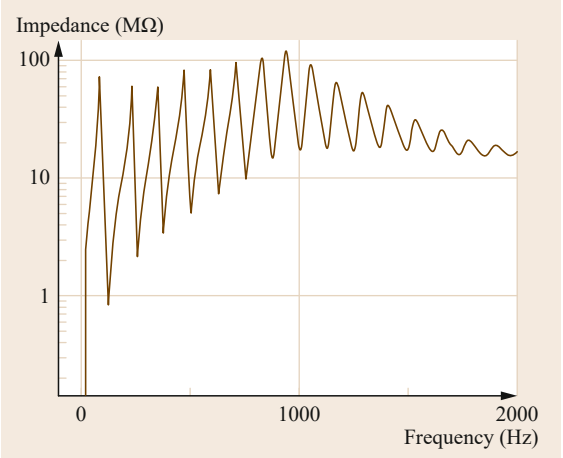

Fig. 5.14 Input impedance of a B-flat trumpet with all of the valves open measured using the BIAS impedance head. Playable notes occur where the impedance is a maximum

5.4 Conclusions

While the measurement techniques discussed here encompass many of the measurement techniques important to musical acousticians, it is by no means an exhaustive treatment of the subject. This chapter is intended only as an overview of some of the more common experimental techniques and should form the basis for further investigation.

It is likely that the technology available for measuring the physical parameters of musical instruments will continue to rapidly advance. Therefore, as new systems and techniques become commercially available in the future many of the techniques discussed here will be easier to implement than they currently are. Musical acousticians would be wise to keep pace with these developments.

6. Some Observations on the Physics of Stringed Instruments

Nicholas Giordano

We provide a general introduction to stringed instruments, focusing on the piano, guitar, and violin. These are representative of instruments in which the strings are excited by striking (the piano), plucking (the guitar), and bowing (the violin). We begin by discussing, in a general way, the strings and soundboards, and how these couple to the surrounding air to generate sound. Important features specific to these instruments are then discussed, with particular attention to the different ways the strings are set into motion, key differences in the way the soundboards vibrate, and the effects of these differences on the resulting musical tones.

6.1 Three Classes of Stringed Instruments

A very wide variety of musical instruments employ strings as the central vibrating element; that is, as the vibrating element that determines the component frequencies of the musical tone produced by the instrument. It is indeed a challenge to describe all of the important aspects of all stringed instruments and we will not attempt such an ambitious task in this chapter. (The references given throughout this chapter should provide the interested reader with an entryway to more extensive information, as do a number of excellent books [6.1–7]). Our goal instead will be to give an overview of the important features common to all stringed instruments and then highlight the key differences between the three main classes of stringed instruments. These three classes are:

1. Instruments in which the strings are struck, such as the piano
2. Instruments in which the strings are plucked, such as the guitar
3. Instruments in which the strings are bowed, such as the violin.

Our goal will be to understand how and why the tones produced by these instruments differ.

6.2 Common Components and Issues

A generic stringed instrument is composed of strings connected to a soundboard or top plate (we will use these two terms interchangeably). A string is set into motion by either striking with a hammer, plucking, or bowing. As they vibrate, the strings produce a time-varying force that sets the soundboard into motion. Because of their very small surface area, the strings themselves produce a negligible amount of sound. It is instead the motion of the soundboard that dominates sound production. When considering the soundboard motion, we may also need to take into account the way the soundboard couples to the surrounding air. For a piano, it is a good approximation to treat the soundboard as simply a vibrating surface driven by only the strings.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_6

In contrast, guitars and violins have an enclosure coupled to the outside through a hole, forming a Helmholtz resonator and we must consider the coupled modes of this resonator (and the air inside it) and the soundboard itself.

6.2.1 Strings

As a rough approximation, musical instrument strings can be treated as ideal flexible strings described by the familiar wave equation

$$\frac{\partial^2 y}{\partial t^2} = v_s^2 \frac{\partial^2 y}{\partial x^2} \,, \tag{6.1}$$

where x is position measured along the string, $v_s = \sqrt{T/\rho}$ is the speed of a transverse wave on the string with mass per unit length ρ and tension T, and y is the transverse displacement of the string. (The origin and properties of the solutions of this equation are reviewed in this volume by *Kausel* in Chap. 2). There are, of course, two transverse directions and we will consider both of them in due course. For now we will only be concerned with one of the transverse directions. In a typical musical instrument one end of the string is held rigidly while the other is attached to a bridge that attaches to the soundboard. The bridge moves with the soundboard, so that end of the string is not stationary, but this motion is sufficiently small that we can, to a first approximation, consider the string to be fixed at both ends. (It is not hard to include the effect of soundboard motion on the string and this is done in some of the piano models referenced in this chapter.) The vibrational modes of an ideal string held in this way are the usual standing waves, with frequencies that form a harmonic series $f_n = nf_1$ with n an integer and the fundamental frequency $f_1 = v_s/(2L)$ for a string of length L.

This picture of an ideal flexible string described by (6.1) with its perfectly harmonic modes is very familiar, but it does not give an adequate description of musical instrument strings. Two key features of real strings are missing from (6.1): damping and stiffness. Both of these effects are included in the more realistic wave equation [6.2, 7–10]

$$\frac{\partial^2 y}{\partial t^2} = v_s^2 \left[\frac{\partial^2 y}{\partial x^2} - \epsilon \frac{\partial^4 y}{\partial x^4} \right] - \alpha_1 \frac{\partial y}{\partial t} + \alpha_2 \frac{\partial^3 y}{\partial t^3} \,. \tag{6.2}$$

String stiffness is proportional to the Young's modulus E_s of the string material, with $\epsilon = r_s^2 \sqrt{E_s/\rho}/v_s^2$ for a string of radius r_s; this result can be derived from Newton's second law [6.2]. Damping is not as straightforward to characterize and can be described in several different ways. In (6.2) damping is accounted for with two terms. One of these terms gives the usual damping proportional to the string velocity while the other involves a higher time derivative of y. The second term is necessary for describing the frequency-dependent damping found in real strings. Such frequency-dependent damping can also be described mathematically in other ways [6.11]. As a final note concerning (6.2), this relation does not explicitly contain the force of the hammer on the string (that term would appear on the right in (6.2)) nor does it account explicitly for the motion of the end of the string attached to the bridge.

Roughly speaking, damping has a small yet discernable effect on the tonal properties, but the tonal decay is usually dominated by other sources of energy loss (often to the soundboard) rather than to the internal damping of the string.

String stiffness can be very important in instruments such as pianos, where the strings are relatively thick and are made of steel. For pianos, string stiffness affects the standing wave frequencies, shifting them above the values found for an ideal string, with

$$f_n \approx nf_1(1 + \beta n^2) \,, \tag{6.3}$$

where β is proportional to ϵ in (6.2) [6.9]. The deviations from a harmonic spectrum in (6.3) have an important affect on piano tones and on the way a piano is tuned, as we will explain below. Stiffness is much less important with the relatively thin strings found in acoustic guitars and violins, especially when these strings are composed of nylon or a similar material. Since the vibrational modes of a piano string are not harmonically related, they are usually referred to as *partials* instead of *harmonics*.

6.2.2 Soundboards

The soundboards in pianos, guitars, and violins are generally made from spruce. This choice is generally justified by noting that its ratio of Young's modulus (for the *strongest* direction, along the grain) to density is extremely large. As with most woods, the elastic constants of spruce depend strongly on direction and in the general case a total of 27 different constants are required to completely describe its elastic behavior. The pieces of spruce used in musical instruments are *quarter cut* sections [6.6], which allows a description with a much smaller number of Young's moduli, Poisson ratios, and shear moduli. Because soundboards are thin compared to the vibration amplitudes of interest, they can be modeled as *thin*

plates [6.12] (Chap. 2), although a more general treatment is sometimes used [6.11]. The equation of motion for a thin plate has the form [6.13]

$$\rho_b h_b \frac{\partial^2 u_b}{\partial t^2} = -D_x \frac{\partial^4 u_b}{\partial x^4} - (D_x \nu_y + D_y \nu_x + 4D_{xy}) \frac{\partial^4 u_b}{\partial x^2 \partial y^2} - D_y \frac{\partial^4 u_b}{\partial y^4} - \beta \frac{\partial u_b}{\partial t} , \quad (6.4)$$

where ρ_b is the density of the soundboard and u_b is the displacement of the soundboard in the perpendicular (z) direction. The rigidity factors D_x, D_y, etc. in (6.4) depend on the Young's moduli (E), Poisson ratios (ν), shear moduli (G), and plate thickness (h_b), with

$$D_x = \frac{h_b^3 E_x}{12(1-\nu_x \nu_y)} ,$$
$$D_y = \frac{h_b^3 E_y}{12(1-\nu_x \nu_y)} ,$$
$$D_{xy} = \frac{h_b^3 G_{xy}}{12} . \quad (6.5)$$

Equation (6.4) also contains a damping term (proportional to β). The form of the damping term is largely heuristic and is intended to describe the internal damping in the soundboard (other forms for this term can and have been used).

The equation of motion (6.4) is a simplified description of a full instrument, as it ignores the forces exerted by the strings on the soundboard. These would contribute an extra term on the right in (6.4), as would the force resulting from the pressure in the surrounding air. (The force of the air on a piano soundboard is only a small effect and to the best of our knowledge has not been included in any piano modeling. This force is much more important for the thinner soundboards found in violins and guitars.) Equation (6.4) also omits the effect of the soundboard crown. This is an important effect which is complicated to model and is included in only the more recent modeling work [6.14–16].

The modeling of soundboard vibrations is made challenging by several facts. First, the term proportional to the fourth derivative in (6.4) makes soundboards highly dispersive which complicates numerical solutions. Second, the rigidity factors in (6.4) are functions of position, due to the presence of soundboard ribs (narrow strips of wood glued to the underside of the soundboard and which generally run perpendicular to the grain) and one or more bridges, along with the fact that the thickness of the soundboard usually varies with position, being thinner at the edges of the board. A full discussion of these complications is beyond the scope of this chapter; we refer the reader to the literature for a full discussion [6.12, 13, 17]. For our purposes in this chapter (6.4) is useful for describing the vibrational properties of a soundboard in general terms. Such a description involves two quantities: the mechanical admittance as a function of frequency and the modal deflection shapes. The mechanical admittance is the ratio of the soundboard velocity to the magnitude of an applied force, with the force (and resulting velocity) being harmonic. Modal deflection shapes are the deflection pattern of the soundboard at a particular frequency, typically the frequency of one of the normal modes. We will give examples of these when we discuss specific instruments. A third complication has to do with the soundboard crown. This crown requires a nonlinear description (note that while (6.4) is highly dispersive, it is still linear). These nonlinear effects are now being understood [6.14–16], but more work needs to be done in this area. In particular, to the best of our knowledge, the effect of the soundboard crown on soundboard damping remains to be understood.

6.2.3 Sound Generation

Stringed instruments generate sound by virtue of the air displaced due to soundboard vibrations. In normal situations, these vibrations are small enough that the behavior is described by the relations of linear acoustics. For our purposes it is convenient to express these relations as [6.18]

$$\rho_a \frac{\partial v_x}{\partial t} = -\frac{\partial p}{\partial x} , \quad (6.6)$$
$$\rho_a \frac{\partial v_y}{\partial t} = -\frac{\partial p}{\partial y} ,$$
$$\rho_a \frac{\partial v_z}{\partial t} = -\frac{\partial p}{\partial z} ,$$
$$\frac{\partial p}{\partial t} = \rho_a c_a^2 \left[-\frac{\partial v_x}{\partial x} - \frac{\partial v_y}{\partial y} - \frac{\partial v_z}{\partial z} \right] , \quad (6.7)$$

where p is the pressure, the velocity components (of the air) are v_x, v_y and v_z, ρ_a is the density, and c_a is the speed of sound in air.

The solution of these equations is numerically straightforward, as discussed in numerous places [6.19–21]. A crucial part of the problem that does not appear explicitly in (6.6) is the source of the sound excitation. This excitation enters through the boundary conditions, which are connected with the motion of the body of the instrument. For the piano, the motion of the soundboard imposes a boundary condition on the air ve-

locity on the surface of the soundboard. For the guitar and violin, the motion of the air produces a significant force on the soundboard which must be included in the equations of motion of the soundboard, (6.4). This will be discussed further in the following sections.

6.3 The Story of Three Instruments

We will now describe how the general ideas from the previous section – in which a stringed instrument is viewed (or modeled) as a combination of string(s), soundboard, and air – apply to three specific instruments. Limitations of space will prevent us from going into great depth in many important areas; we encourage the interested reader to use the references to explore the instruments in much greater detail. For excellent general references we recommend for pianos the papers by *Conklin* [6.22–24], along with [6.6, 11], for guitars we recommend [6.3, 14, 25], and for the violin we suggest [6.1]. For general introductions to all three instruments we recommend [6.2, 7].

6.3.1 Piano

Piano Hammers and Strings

Modern pianos have 88 notes. Notes in the midrange and treble employ three steel strings, while bass notes involve (typically) two or one string(s) which are composed of a copper string wound around a steel core [6.24]. This design increases the string mass without adding excessively to the string stiffness, thus keeping the inharmonicity in (6.3) to an acceptably low level.

Piano strings are set into motion by the blow from a hammer. A modern piano hammer is a felt-covered mallet with a mass of typically 3−10 g, with the heavier hammers used for the bass strings. Felt is one of the most complex (and difficult to model) materials used in any stringed instrument and our understanding of the force–compression properties of piano hammers is purely empirical. The interaction of a piano hammer with a string is described by a force–compression function $f_h(z_h)$ where f_h is the hammer string force and z_h is the amount the felt is compressed during the hammer–string collision. There have been a great many studies of piano hammers (see [6.9, 10, 26–35] for a partial list!). The experiments have shown that $f_h(z_h)$ is an extremely nonlinear function and can have significant hysteresis. The nonlinearity is illustrated in Fig. 6.1, which shows the force–compression function for a typical hammer from the middle range of a piano measured with the hammer striking a rigidly held string. The force–compression function is described approximately by a power law $f_h \approx z_h^{\alpha}$, with an exponent value α typically between 2.5 and 5. These exponent values are distinctly larger than the value $\alpha = 1$ expected for an object that follows Hooke's law and the value $\alpha = 3/2$ based on the Hertz solution for the contact force involving elastic bodies. This nonlinearity means that the hammer becomes effectively stiffer when the compression is increased and has an important effect on the tone color for the following reason. When a note is played softly, the hammer has a relatively low velocity just prior to its collision with the string; the felt compression during the collision is then small and the hammer is effectively soft. A collision involving a soft object results in a spectrum dominated by the lowest frequencies with little weight at high frequencies (i. e., at the higher partials of the string). Conversely, when a note is played loudly the hammer velocity is high, resulting in a much larger compression and an effectively stiffer hammer. The collision with this stiffer hammer produces a sound with much more weight in the high partials as compared to the behavior with a soft hammer. In this way, the hammer nonlinearity in Fig. 6.1 gives a change in tone color along with the change in loudness of a piano tone. This is a key to the expressiveness of the instrument.

Another important contribution to the tone color involves the string stiffness. As mentioned above in connection with (6.3), string stiffness causes a string's

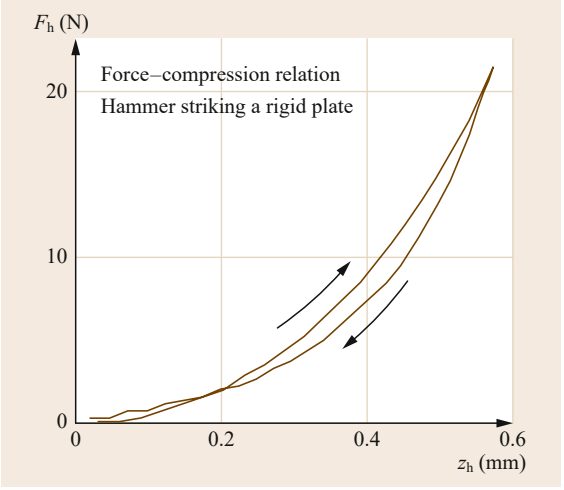

Fig. 6.1 Force–compression characteristic for a piano hammer from the middle range of a piano. Here z is the amount that the hammer felt is compressed as it collides with a rigidly held string (after [6.35])

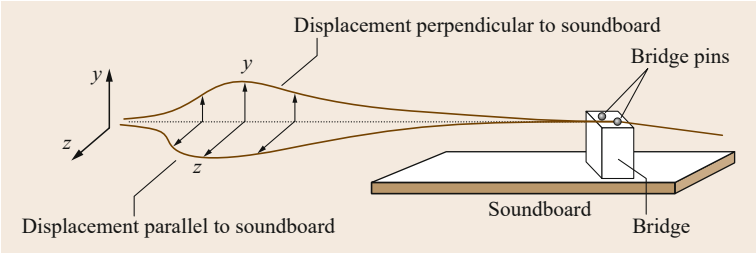

Fig. 6.2 A piano string can undergo transverse vibrations in two directions: perpendicular to the soundboard (along y) and parallel to the plane of the soundboard (along z). These two motions are coupled through the motion of the soundboard and bridge (after [6.6])

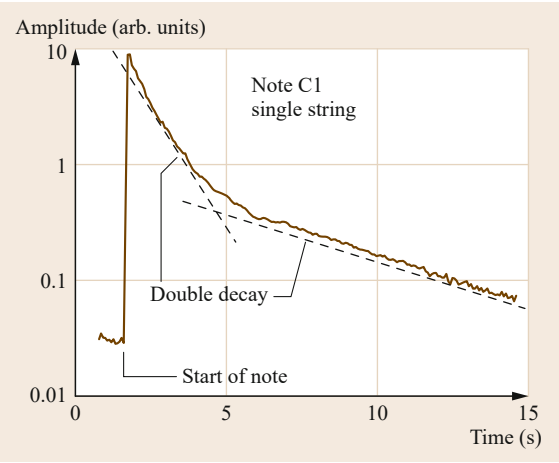

Fig. 6.3 Decay of the sound for the note C1 on a grand piano. This is the lowest C on the piano and involves the motion of a single string (after [6.6])

vibrational frequencies to deviate from a purely harmonic spectrum. One might have thought that the *best* piano tones would be ones in which the deviations from harmonicity are smallest. However, listening tests show that human listeners seem to prefer a small inharmonicity [6.36]. (See also [6.37] for a study of inharmonicity in historical instruments.) The reason for this is not clear and involves the perception of musical tones, a topic that we will not attempt to explore here. The existence of inharmonicity has important implications for the tuning of a piano. Consider two notes that are nominally an octave apart; that is, two notes that would be an octave apart on an ideal musical scale, which we can denote as notes C1 and C2. In the ideal case, the frequency of the second harmonic of C1 would be exactly twice the frequency of the fundamental of C1 and would equal the frequency of the fundamental of C2. For a real string with inharmonicity, we have according to (6.3) that the frequency of the second partial of C1 is slightly greater than twice the fundamental frequency of C1. In order for C1 and C2 to *sound good* when played together, the second partial of C1 should coincide with the fundamental of C2 and this means that the separation between these two notes must be slightly greater than the ideal factor-of-two separation. This is called a stretched octave and the presence of string stiffness means that all octaves on a well-tuned piano must be stretched.

This is a problem that was explored systematically some years ago and led to a surprising result. In a survey of the tunings produced by a collection of skilled piano tuners, it was found that all arrived at approximately the same stretched tuning; i. e., the same deviations from an ideal tuning [6.38–40]. This tuning is now called the Railsback stretch and it seems to be the tuning that *sounds best* to a typical listener [6.40]. The precise form for the preferred stretch tuning appears to be connected with (and explained by) our perceptual judgment of consonance and dissonance [6.41].

In our discussion of string motion we characterized that motion in terms of a single variable $y(x,t)$ in (6.2) where y is the displacement of the string in the direction perpendicular to the soundboard and parallel to the force exerted by the hammer (Fig. 6.2). String motion in the direction parallel to the soundboard and perpendicular to the axis of the string (the z-direction in Fig. 6.2) is also possible. Since the hammer force is along y, one might think that motion parallel to the soundboard will be negligible. That is not the case, however, because motion of the end of the string connected to the soundboard (through the bridge) couples the motions in these two perpendicular directions due to rocking motion of the bridge. This leads to an interesting time dependence for the decay of the string vibration and of the sound, as first discussed by *Weinreich* [6.42]. The *double decay* that Weinreich described is illustrated in Fig. 6.3, which shows the decay of the sound from the note C1 (the lowest C on the piano). The initial decay is dominated by the decay of vibrational motion that is initially along y. This decay is rapid because the soundboard is most compliant to forces in this direction. Eventually the vibration along z grows (because of the coupling of energy from the motion along y) and the z-vibration comes to dominate. The decay of this z-vibration is slower than that of the initial (y) vibration because the soundboard is less compliant in that direction, reducing the rate of energy loss from the string. This double decay effect gives the long persistence of a piano tone. The note considered in Fig. 6.3 is produced by a sin-

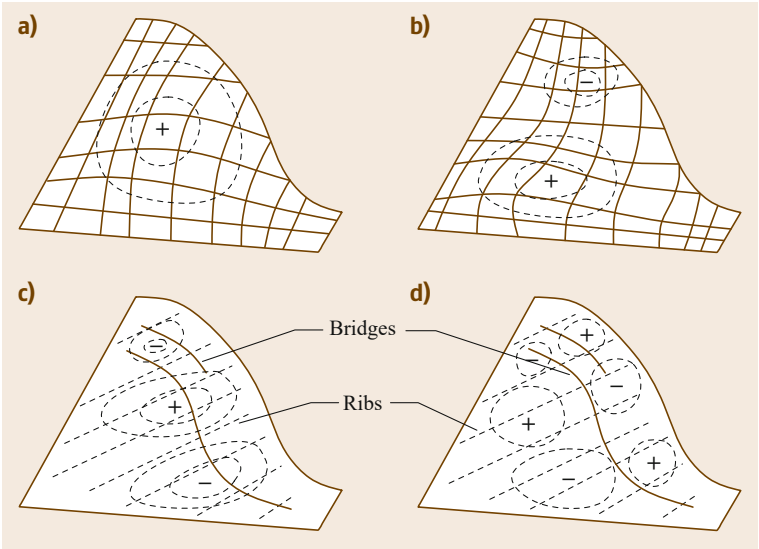

Fig. 6.4 **(a)** The lowest frequency mode of a piano soundboard is a breathing mode, which has its maximum amplitude near the center of the board. For this mode the soundboard undergoes a simple up and down motion with no nodal lines. **(b)** The second soundboard mode is one in which two parts of the board move out of phase, with a nodal line between the two regions. **(c)** The ribs and bridges affect the locations of the nodal lines. This is the third soundboard mode and has two nodal lines. **(d)** Mode with five nodal lines (after [6.6])

gle string. In notes that involve two or three strings one observes a more complicated decay, as the strings beat against each other in addition to the vibrations along y and z. This beating produces a sort of vibrato [6.6, 42], which is apparently a pleasing effect for most listeners.

Piano Soundboards and Sound Generation

Roughly speaking, one can view a piano soundboard as a large speaker as it moves in response to forces from the strings, and to understand the efficiency with which this speaker generates sound one must understand its vibrational modes. In this article we will refer to these as modes of the *soundboard* and early soundboard models [6.12] considered the motion of the soundboard alone. A more accurate description (and more recent modeling) must include the effect of the strings and thus describe the modes of the coupled soundboard–string system. At the level of our discussion here, the strings make a relatively small contribution, but the most sophisticated piano models do now include this effect.

At low frequencies, below a few hundred Hz, it is useful to think about the individual soundboard modes. The lowest is a breathing mode, illustrated in Fig. 6.4a, in which the soundboard moves uniformly up and down, with the largest amplitude near the center. The frequency of this mode for a typical piano is around 50–100 Hz (with larger pianos having a lower frequency for this mode). At higher frequencies one finds modes with two or more antinodes separated by nodal lines; the second mode (with one nodal line) is shown schematically in Fig. 6.4b. As mentioned above in connection with the equation of motion for a soundboard (6.4), soundboards contain ribs and bridges which make the rigidity nonuniform. This affects the deflection shapes and the positions of nodal lines and antinodes. In general and especially at high frequencies, the antinodes will tend to be found between the ribs and somewhat off the bridges (Fig. 6.4c,d). Deflection shapes measured using the Chladni method for grand piano soundboards have been reported by *Conklin* [6.23].

Another way to characterize the soundboard motion is in terms of the mechanical impedance $Z(f)$ which is the ratio of the force applied to the soundboard at a particular frequency to the soundboard velocity at that frequency, or equivalently, the mechanical admittance which is the reciprocal of $Z(f)$. In these measurements, the force and velocity are usually applied and measured at a point on the bridge. Typical results for $Z(f)$ are shown in Fig. 6.5 for the soundboard of an upright piano. The large dip near 100 Hz indicates the fundamental mode, since there is a strong response (a large soundboard velocity) at that frequency. The other large dips in $Z(f)$ indicate additional modes. As the frequency is increased, the average separation between modes approaches a constant that is approximately equal to the fundamental frequency, leading to an approximately constant $Z(f)$ until high frequencies where effects due to ribs and bridges can cause a decrease in the impedance.

At the lowest frequencies (well below the fundamental mode) the impedance increases monotonically and the soundboard vibration is small, resulting in a weak tone. In addition, the efficiency of sound production becomes very small at low frequency, as the sound wavelength becomes much greater than the size of the soundboard. These two effects lead to a phenomenon known as the *missing fundamental*. This effect is illustrated in Fig. 6.6, which shows the spectrum for

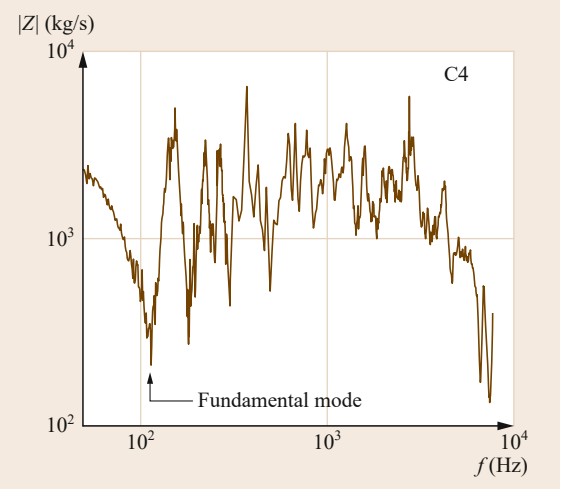

Fig. 6.5 Mechanical impedance of the piano soundboard from an upright piano. The force was applied at the bridge at the point where the strings for middle C are connected and the soundboard velocity was measured at the same location (after [6.43])

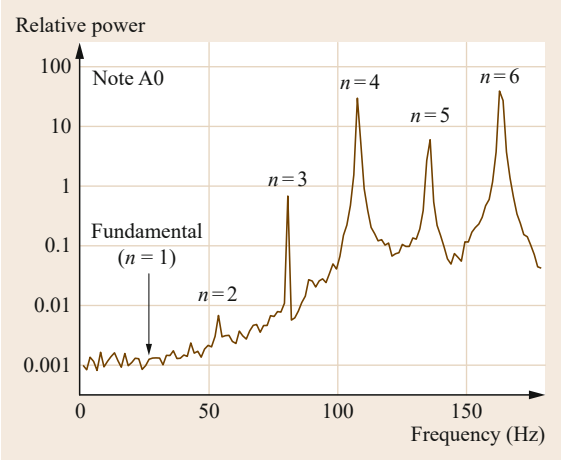

Fig. 6.6 Spectrum of the note A0 for a grand piano. (This is the lowest note on the piano). A number of partials are indicated; the sound power at the fundamental (the first partial) is negligible (after [6.6])

the lowest note on a piano (fundamental frequency 27.5 Hz). A number of partials are indicated and it is seen that the power at the fundamental is extremely small, with the strongest partials found for partial numbers of order 6 or even higher. An interesting point here is that the tone in Fig. 6.6 is perceived to have a pitch corresponding to a fundamental frequency of 27.5 Hz, even though there is negligible sound power at that frequency. One explanation for this phenomenon is that the human nervous system is somehow sensitive to the periodicity of the signal rather than the spectral content [6.44], but it does not appear that this hypothesis can explain fully how our nervous system reacts to tones with missing fundamental components [6.45].

6.3.2 Guitar

Figure 6.7 shows a schematic diagram of an acoustic guitar. In a very general way this is similar to the structure of a piano, with strings that are held rigidly at one end (at the nut, near the tuning pins at the top) and which are connected at their other ends to a bridge which rests on the soundboard (here called the body). The soundboard is typically made of spruce with the sides and back made of a hardwood, usually maple. The strings are often nylon (for a classical guitar) but can be steel. In the bass the strings often have a wire core wrapped with nylon or a thinner wire, to increase the mass without substantially increasing the string stiffness. There are several ways that the bridge can be held in place. In some cases it is glued to the top plate

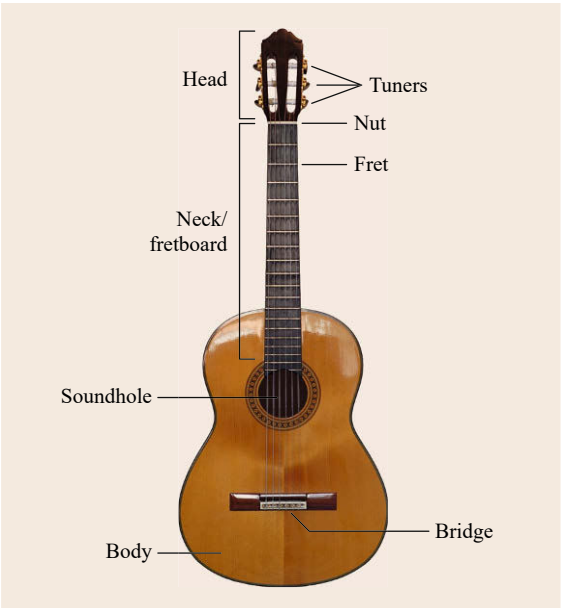

Fig. 6.7 Sketch of a guitar showing its principal components

and the strings are fastened to the bridge. This produces a torque on the bridge which can distort the top plate. Another arrangement, which reduces this torque, has the ends of the strings fastened to the bottom edge of the guitar. With this arrangement it is also possible for the bridge to be held in place by the tension of the strings [6.25].

Vibrations of the strings produce a force on the bridge that sets the soundboard into motion. An impor-

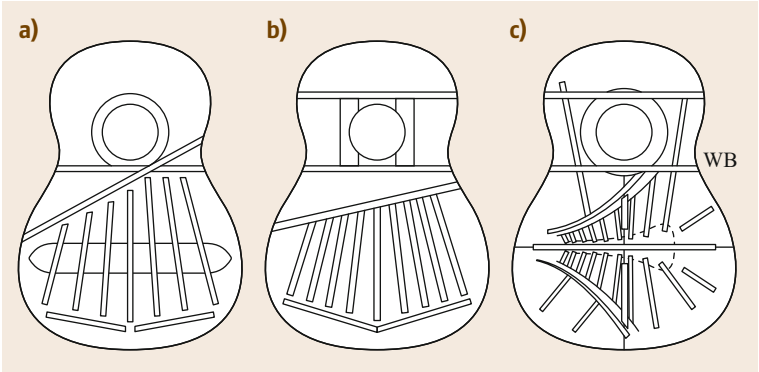

Fig. 6.8a–c Bracing patterns for several classical guitars: **(a)** Ramirez (Spanish), **(b)** Fleta (Spanish), **(c)** Eban (Unites States) (after [6.5])

tant difference between the guitar and the piano is that the soundboard forms one surface of an air cavity and air in this cavity is set into motion by the soundboard. Because of the soundhole, this forms a Helmholtz resonator [6.2] and a number of the important modes of the guitar body are combination modes of this Helmholtz resonator together with vibrations of the soundboard, sides and back. The underside of the top plate is reinforced with ribs adding strength, especially in the across-the-grain direction (perpendicular to the neck). Unlike the case of the piano, for which the arrangement of ribs is fairly standard, many different rib patterns are employed by different guitar makers, a few of which are shown in Fig. 6.8. Other common patterns are described by *French* [6.4].

Plucked Strings – Spectra and More

To understand the spectrum of a guitar tone one must first consider the motion of a plucked string [6.46]. Figure 6.9 shows the behavior for two cases, a string plucked at its center and a string plucked very close to one end. Here we assume for simplicity that the string is perfectly flexible and that the plucking force is applied to an extremely narrow portion of the string. (More realistic situations can be treated but do not change our basic picture; see the references for a discussion of such cases.) With these assumptions the string has a sharp kink at the plucking point. After the string is released this kink splits into two separate kinks that propagate in opposite directions and these travel back and forth along the string as they reflect from the ends. The resulting force from the string on the bridge as a function of time is also shown in Fig. 6.9. This force is equal to the string tension multiplied by the sine of the angle (at the bridge) that the string makes with the axis of the undisplaced string. The kinks maintain their shape as they propagate, and as can be seen from Fig. 6.9 the kink angle is constant for long periods, changing sign when the kinks reflect, leading to a square wave time dependence for the force on the bridge. When the string is plucked at its center the two portions of the square wave are of equal length (Fig. 6.9a), while if the string is plucked near one end the relative times spent in the high and low portions vary according to the location of the plucking point relative to the end of the string (Fig. 6.9c).

As very rough approximations, the velocity of the guitar top plate is proportional to the applied force and the sound produced by the vibrating top plate is proportional to its velocity. As a result, the spectrum of the resulting tone is roughly the same as the spectrum of the force on the bridge. The spectra of the two force–time square waves in Fig. 6.9 are also shown in the figure. In general, for a string plucked $1/n$ of the way from an end, the n-th harmonic and its overtones (frequencies $m \times n$ where m is an integer) are absent. In addition, for n large and for a string plucked very near one end, the amplitudes of the harmonics with orders less than n decrease slowly with n. The timbre of a guitar tone thus depends strongly on the plucking point and plucking near the end of the string enhances the high harmonics.

To this point we have not specified the direction in which the string is plucked. Unlike the piano, for which the string is excited in the direction perpendicular to the soundboard, a guitar player can control the direction of the pluck. In general, a pluck perpendicular to the soundboard will initially excite strong soundboard motion and produce a fast initial decay. Rocking motion of the bridge will then lead to string motion parallel to the soundboard and string motion in that direction will decay more slowly, producing a double decay like that found with the piano. It is also possible for a player to pluck a string in the parallel direction leading to a slower overall decay of the sound. In addition to affecting the time dependence of a tone, these different string motions will excite the soundboard modes differently, thus affecting the timbre. In this way, the player has significant control over several important aspects of the guitar tone.

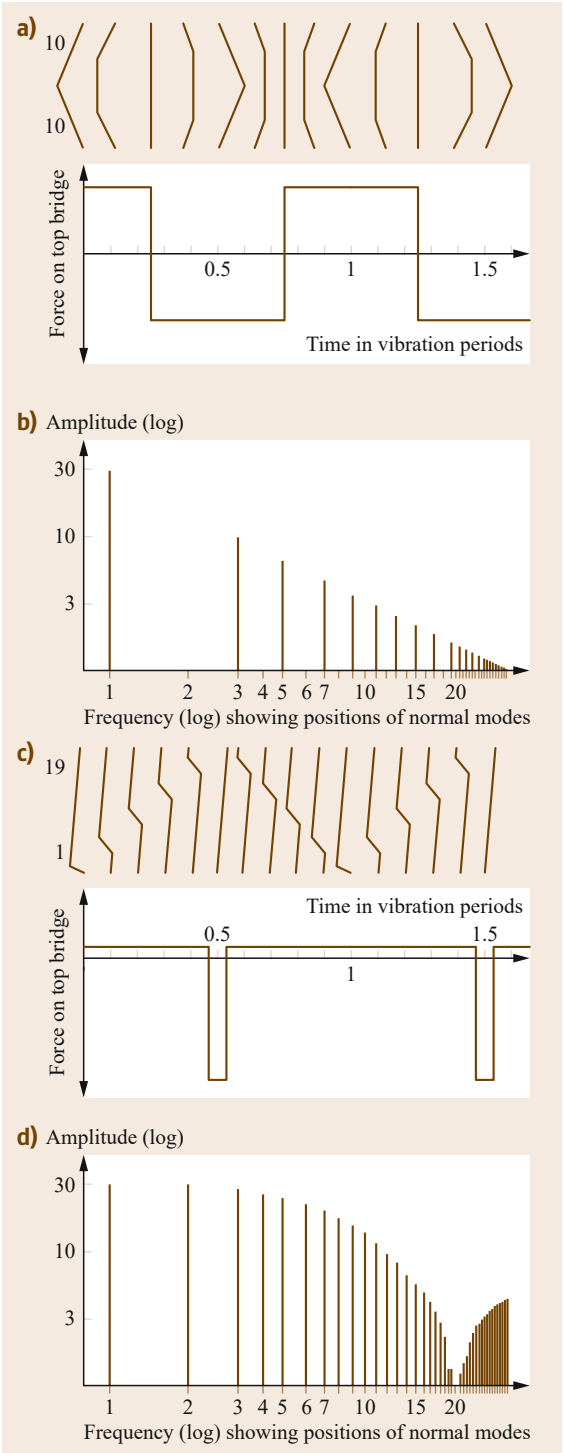

Fig. 6.9 **(a)** Motion of a string plucked at its center. The string profile is shown at the *top*, at various times during the course of its motion, with the axis of the string aligned vertically. **(b)** Spectrum of the force exerted by the plucked string in **(a)** on the support at one end. **(c)** Same as **(a)** but for a string plucked 1/20 of the way from one end. **(d)** Spectrum for the string plucked 1/20 of the way from one end (after [6.46]) ►

While we are concerned in this article mainly with the acoustic guitar, we should mention that the decay and timbre for an electric guitar behave somewhat differently. First, the time decay is very slow, since the bridge of an electric guitar is essentially rigid. Indeed, the desire for a very slow decay was a major motivation for the invention of the electric guitar. Second, the pickup of an electric guitar couples differently to the string motion than do the bridge and soundboard of an acoustic guitar. Third, the timbre is strongly shaped by the characteristics of the amplifier used to convert the signal from the electric guitar pickup coils into sound.

Vibrational Motion of the Top Plate

The response of the guitar body to the force produced by a plucked string depends on the vibrational modes of the body. Figure 6.10 shows the deflection shapes for several modes of an acoustic guitar measured using holographic techniques [6.47]. These deflection patterns show the locations of the antinodes and nodal lines for several of the lowest frequency modes and were measured by driving the top plate at the indicated frequencies. The lowest (fundamental) mode has a single antinode (Fig. 6.10a) and the number of antinodes increases as one progresses to higher modes, a few of which are shown here. Typically the lowest top plate mode has a frequency near or just above 100 Hz, which is above the fundamental frequency of the lowest bass string (82.5 Hz). While we have referred to the modes in Fig. 6.10 as being the modes of the *body* they are actually the modes of the combination of body and the air inside [6.14, 48, 49]. At low frequencies the body and air form a Helmholtz resonator while at higher frequencies one must take account of the nodes and antinodes of the air motion inside the body. In any event, the fact that the lowest mode of the body/air is not far from the frequency of the lowest bass string means that there is a strong response and hence strong sound generation even for the lowest notes, unlike the case with the piano.

These results for the deflection shapes illustrate several important points:

1. Most of the top plate motion is in the region below the soundhole, near the bridge. This is expected, since the string forces act at the bridge.
2. The deflection shapes are often close to being symmetric with respect to the axis defined by the strings and neck, but do exhibit distinct asymmetries. These

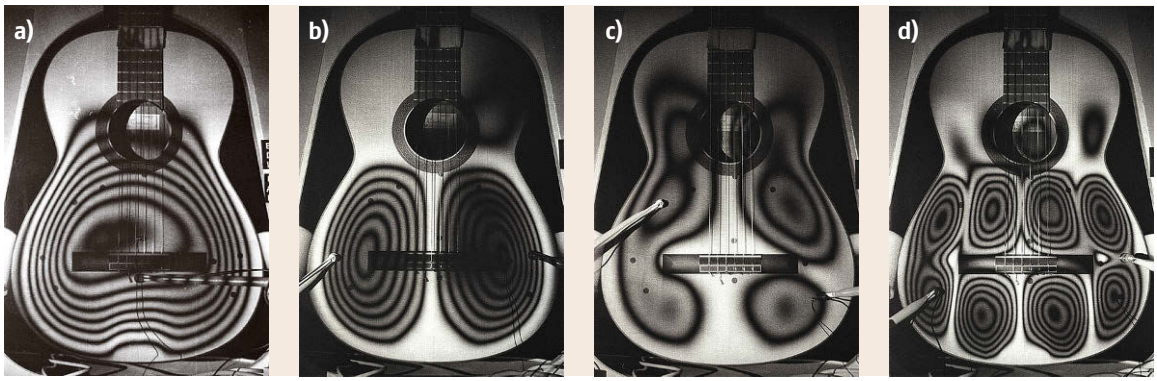

Fig. 6.10a–d Modal deflection shapes showing the top plate motion for several modes of an acoustic guitar. **(a)** The lowest mode, frequency 103 Hz. **(b)** 268 Hz, **(c)** 628 Hz, **(d)** 1010 Hz (after [6.47])

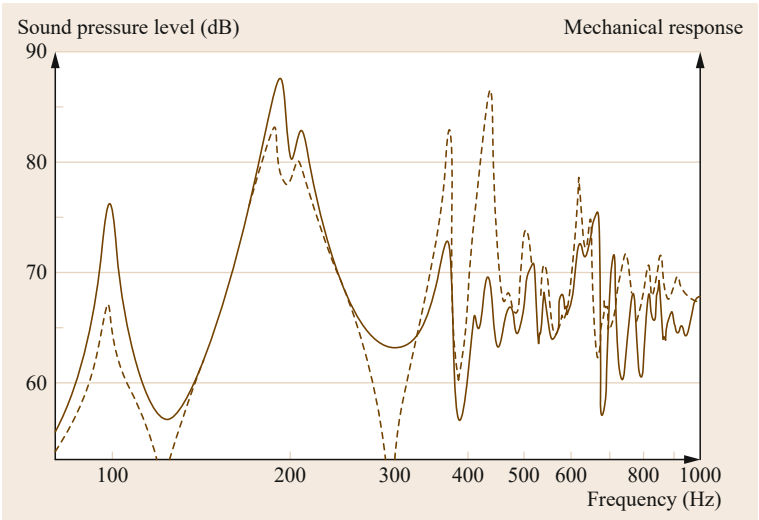

Fig. 6.11 Sound pressure level (*solid curve*) and bridge acceleration (*dashed curve*) as functions of frequency for a harmonic (single frequency) force applied to the bridge, for a Martin D-28 guitar. The force had an amplitude of 0.15 N and the sound was measured 1 m in front of the guitar (after [6.5])

asymmetries are generally caused by an asymmetric rib pattern (Fig. 6.8). Indeed, different rib patterns are presumably designed to emphasize (strengthen) or de-emphasize the sound of particular frequencies and strings, through their effect on the vibrational modes of the soundboard.

3. To understand the contribution of a particular mode to the sound production one must take account of the nature of the driving force.

For example, if a string is plucked in the direction parallel to the top plate, the force from the bridge may give what is effectively a torque on the soundboard, preferentially exciting certain modes.

Sound Generation

The deflection shapes in Fig. 6.10 give insight into the motion of the different soundboard modes, but to get a full picture of the sound generation it is useful to also examine the sound pressure as a function of frequency while driving the bridge at different frequencies [6.5]. Figure 6.11 shows results for both the sound pressure level (solid curve) and the mechanical response of the bridge (dashed curve) as a function of frequency. One would expect the two curves to be similar, as one would expect to find strong sound production at frequencies that produce large soundboard motion. The peaks of the two curves do correspond fairly well at the lower frequencies. However, we do not expect the correspondence to be perfect, since there will be modes at which the bridge motion is small (perhaps dominated by rocking motion) yet the sound production is large. In addition, the radiativity can be very different for different modes. Both of these effects should increase in importance as the frequency is increased and this is probably why the two curves in Fig. 6.11 do not agree as well at higher frequencies.

We should add that measurements like those in Fig. 6.11 have been carried out with different gases in the guitar cavity to determine which modes have significant contributions from Helmholtz resonances of the cavity. Those experiments along with detailed modal calculations have shown that some modes (typically those at the lowest frequencies) contain strong mixtures of the Helmholtz and body (structural) modes [6.48].

6.3.3 Modeling

Models of essentially all components of the guitar have been developed [6.3, 49] and a rather complete picture of all aspects of guitar function is now available. One current focus of modeling is to study how different bracing patterns, different bridge configurations, top plate thicknesses, etc. affect the tone, with the goal of helping guitar makers achieve specific tonal objectives.

6.3.4 Violin

Figure 6.12a gives a sketch of the basic structure of a violin. As with the guitar, the top plate is generally made from spruce while the sides and back are maple. The f-holes allow air to flow into and out of the body as the top plate vibrates, forming a Helmholtz resonator and (as with the guitar) vibrations of the top plate can couple strongly to the Helmholtz resonances. One difference between guitars and violins concerns the structure inside the cavity (Fig. 6.12b). Unlike the guitar, there is no system of ribs on the top plate. Instead, there is a soundpost that connects the top plate with the back and which is held in place by the overall rigidity of the two plates. There is also a single *brace* called the bass bar, that is glued to the underside of the top plate and runs beneath the bass side of the bridge parallel to the strings. We note that the bridge is not glued to the top plate, but is held in place by string tension.

The Bowed String

An understanding of the motion of a bowed string was first given by Helmholtz, who showed how the stick–slip frictional interaction of a bow with a string can give rise to periodic motion, with the period of a freely vibrating string. It is indeed amazing that a bowed string can vibrate at the frequency of a free string, even while the string is in constant contact with the heavy bow. The nature of this Helmholtz motion is explained in Fig. 6.13. As the bow moves with an approximately constant speed, the string spends a portion of each period sticking to the bow and they move together with a common speed (panels c–h on the left in Fig. 6.13). Eventually sticking cannot be maintained as the required force exceeds the maximum force of static friction and the string slips back rapidly (panels a–c) whereupon the string is *recaptured* by the bow and another interval of sticking occurs. The corresponding string motion is shown in the right panels in Fig. 6.13 which shows how a sharp kink travels back and forth along the string. The force of the string on the bridge is proportional to the sine of the angle that the string makes with its axis and thus varies in a sawtooth manner with time. Note that the force on the bridge is parallel to the plane of the top plate, so the bridge undergoes a rocking motion as the string is bowed.

While the stick–slip motion in Fig. 6.13 yields periodic motion with the desired frequency, this is not the only result that can be obtained with a bowed string. Indeed, anyone who has listened to a beginning player knows that pleasing periodic motion can be quite diffi-

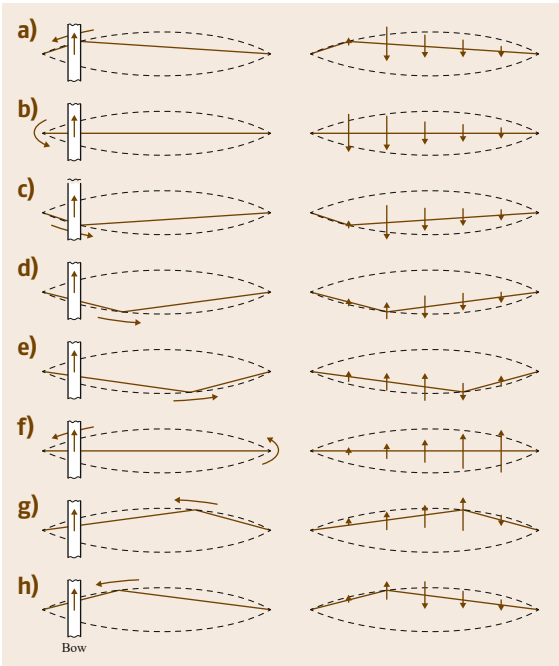

Fig. 6.13a–h The stick–slip frictional interaction of a violin bow (shown on the *left* as a *rectangle* with an *upward arrow* denoting its upward motion) with a violin string. This interaction produces an excitation in which two straight sections of the string meet at a kink, with the kink traveling back and forth on the string (after [6.5])

cult to produce, with creaks and squeals being a much more common result for a beginner. This problem was explored in a famous work by *Schelleng* [6.50] who showed that *good* Helmholtz motion, that is, periodic stick-slip motion with a period equal to the period of the freely vibrating string, is obtained only for a limited range in the parameter space defined by the bow force and the position of the bow as sketched in Fig. 6.14. Here the bow force is the downward force of the bow on the string and the bow position is measured as a fraction of the string length from the bridge.

The Schelleng diagram in Fig. 6.14 is one key to understanding why a violin can be difficult to play, and to a (possible) strategy for making a violin as *playable* as possible – e.g., by making the *desirable* region in Fig. 6.14 as large as possible. But there is another important aspect to the playability of a violin, namely, how quickly Helmholtz motion is established. It has been shown that expert violinists can establish perfect Helmholtz motion within the first few periods or so of the initiation of bowing and that listeners judge tones to be poor if the pre-Helmholtz phase of the tone lasts longer than about 50–90 ms (depending on the precise nature of the tone during that phase [6.51]); this cor-

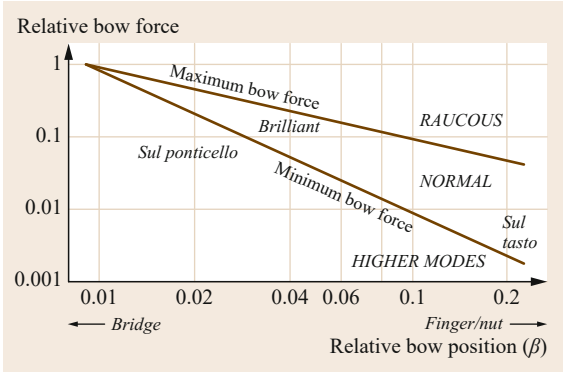

Fig. 6.14 *Schelleng diagram* showing the combination of bow force and bow position that produce Helmholtz motion (the region labeled *normal* and *brilliant*). Outside these regions other vibrational motion of the string is produced (after [6.5])

responds to between 10 and 18 periods of the ideal Helmholtz motion. This result leads naturally to the question of what combination of bowing parameters enables a player to establish perfect Helmholtz motion as quickly as possible, *when starting with the string at rest*. This problem has been studied by *Guettler* who considered the behavior starting from realistic initial conditions with realistic bowing gestures [6.52]. He showed that certain combinations of bow force and bow acceleration (Fig. 6.15) yield the quickest path to the Helmholtz motion when the bow starts from rest. This work has yielded new ways to think about the playability of an instrument.

Modes of the Violin Body and What Makes a Good Violin

The motion of the violin body has been studied using holography and other similar methods to obtain pictures of the deflection shapes of the top plate modes, like those discussed above for the guitar [6.53–55]. As with the guitar, it has been found that several of the lowest modes are mixtures of body modes and resonances of the air in the cavity [6.56]. Studies of these modes have been used to address several of the central questions in violin acoustics, including *what properties make a good violin?* and *what can I measure to tell if I have a good violin?* Let us take the second question first. Figure 6.16 shows the mobility of a violin bridge as a function of frequency. This quantity can be measured by applying a harmonic force to the bridge in the direction parallel to the top plate and perpendicular to the strings and measuring the resulting velocity of the bridge in the same direction. (Note that this mobility is the inverse of the impedance plotted in Fig. 6.5) Each peak in Fig. 6.16 corresponds to a vibrational mode; studies of

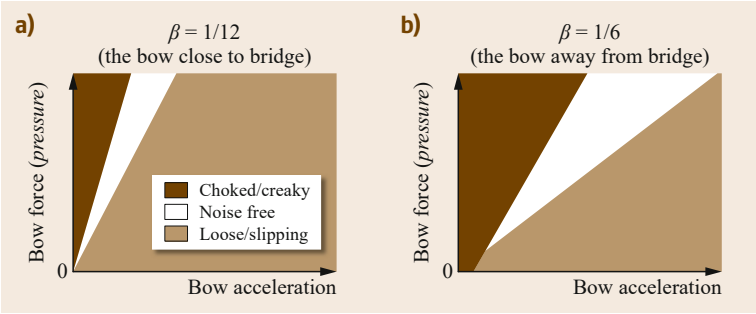

Fig. 6.15a,b Diagrams showing the combinations of bow force and bow acceleration that produce good Helmholtz motion quickly after initiation of bowing. For two different locations of the bow relative to the bridge: **(a)** close to the bridge; **(b)** relatively far from the bridge (after [6.5, 52])

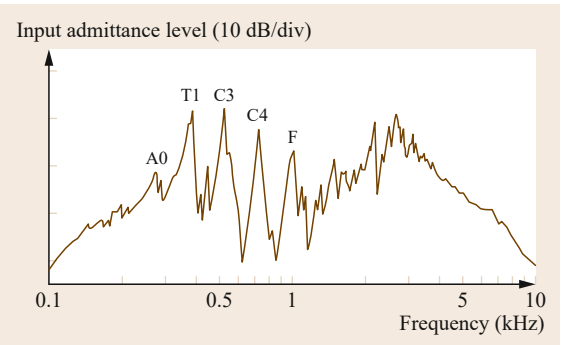

Fig. 6.16 Mobility (also called the admittance) of a violin bridge as a function of frequency (after [6.5, 57, 58])

violins containing different gases have shown that the mode labeled *A*0 in Fig. 6.16 involves strong mixing with a Helmholtz resonance, similar to that found with the guitar. In addition, certain features of the mobility curve, including the so-called *bridge hill* (labeled F in Fig. 6.16) have been found to correlate well with violin quality [6.57, 58]. As this term implies, the vibrational modes of the bridge play a role in determining the mobility at frequencies above a few kHz.

The modes of the top and bottom plates have also been identified as playing an important role in construction of a violin. As discussed by *Hutchins* [6.53, 54], many violin makers listen to the tap tones of the top and bottom plates while these plates are being brought to final form. In order to produce a high-quality violin, it is desirable to have certain relationships between the mode frequencies of these two plates. It is believed that this approach was practiced by the legendary violin makers.

The problem of understanding the origin of violin quality fascinates violinists and nonviolinists alike. That question can be stated as *what is the secret of master violin makers such as Stradavari?* and *why are the legendary (and old) violins best*? The first question remains unsettled (despite many claims about special varnish, etc.), but the second question has been addressed in some intriguing recent studies. Careful double blind comparisons of old and new violins have suggested that the violins made by the best modern makers are at least equal to the best old instruments [6.59]. This result will probably be hard for some to accept.

6.3.5 Violins are Complicated

Because of space limitations, this article has not been able to cover many interesting issues. This has been especially the case for the violin. Indeed, while the violin has been studied more than any other instrument, the physics of bowed strings and the complex shape and structure of the violin lead to many complications that are still the object of intense study [6.60]. These complications include torsional motion of the string due to the torque produced during bowing, devising realistic descriptions of the frictional force between the bow and string, the effects of finite bow width, string stiffness and string damping, the effect of the body modes on string motion and the different radiativities of different vibrational modes of the violin body and of different violins [6.61]; and this is by no means a complete list!

6.4 Summary

This chapter has reviewed some essential elements of stringed instruments. We have tried to emphasize the common features of all stringed instruments while highlighting the important differences. Because of space limitations we have had to omit many interesting issues. Hopefully the references contained herein will give the interested reader a window into further study of this important class of instruments.

Acknowledgments. I am grateful to A. Askenfelt, R. Bader, A. Chaigne, T. Rossing, and G. Weinreich for many enlightening discussions and to the authors who have graciously allowed me to show figures with their results. I also thank R. Bader for inviting me to contribute to this chapter.

7. Modeling of Wind Instruments

Benoit Fabre, Joël Gilbert, Avraham Hirschberg

Wind instruments driven by a constant pressure air reservoir produce a steady oscillation and associated sound waves. This self-sustained oscillation can be explained in terms of a lumped element feedback loop composed of an exciter, such as a reed-valve or an unstable jet, coupled to an acoustical air column resonator, usually a pipe. In this chapter this simplified model is used to classify wind instruments. Five prototype wind instruments are selected: the clarinet, the oboe, the harmonica, the trombone and the modern transverse flute. The elements of this feedback loop are described for each instrument. In simplified models the player is reduced to the role of a pressure reservoir. The player's control, also called the embouchure is however essential. This aspect is discussed briefly for each instrument.

7.1 A Classification of Wind Instruments

A wind instrument driven by an air flow from a reservoir at constant pressure will, for appropriate pressure ranges, oscillate at a constant pitch (frequency) and amplitude. This sustained oscillation will generate sound waves that reach the listener.

While the steady oscillation is very important under normal playing conditions, other aspects such as slow variations of control parameters, rapid transients, *vibrato* and broad-band turbulence flow noise are essential for musical sound quality. The discussion presented here will however mainly be based on the description of the steady oscillation. The other aspects, which are closely related to the player's control of the sound quality, will be introduced as complementary information.

A systematic description of wind instruments is provided by *Baines* [7.1]. The physics of wind instruments has been extensively discussed in many textbooks [7.2–11]. Some additional references will be provided for specific topics or can be found in a review paper [7.12].

The self-sustained oscillation in wind instruments is driven by a feedback loop (Fig. 7.1). A pressure reservoir is the energy source. One distinguishes *reed instruments* in which the air flow is modulated by an oscillating mechanical valve from the *flue instruments* in which mechanical vibrations are negligible (Fig. 7.2). The exciter is an amplifier. It is fed by acoustic oscillation in the resonator. It drives a sound source that reinforces the acoustic oscillation in the resonator. Under normal playing conditions the oscillation mode corresponds to a frequency (pitch) close to an acoustical resonance of the pipe. The pipe behaves then as a narrow-band filter. In order to reach a steady oscillation, a nonlinear saturation mechanism must exist to limit the amplitude of the oscillation of a feedback loop. Hence wind instruments are essentially nonlinear oscillators. This implies that next to stable limit cycle oscillation, they can display chaotic behavior [7.13, 14].

In reed instruments the flow control is due to separation of the flow from the wall, resulting in the formation of a jet downstream of the valve (Fig. 7.2a). The jet thickness is determined by the valve opening. In the jet, the kinetic energy of the flow is dissipated by a chaotic motion called turbulence. There is almost no pressure recovery. This makes the volume flux through the valve vary proportionally to the valve opening. When the valve oscillates the oscillating volume flux acts as a piston (speaker) on the air column in the pipe. This drives acoustic waves in the pipe. The resulting oscillating pressure in the pipe controls the valve oscillation, which closes the feedback loop.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_7

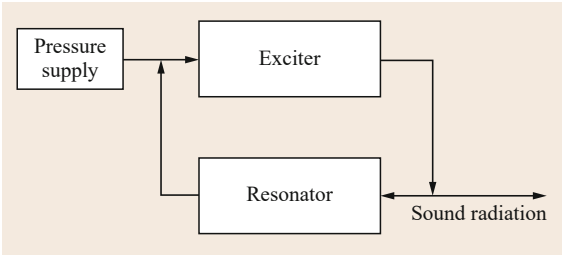

Fig. 7.1 A woodwind instrument uses a continuous pressure supply to generate an oscillating flow, which drives sound waves. This is obtained by a feedback loop consisting out of a nonlinear *exciter* (amplifier) coupled to an acoustical *resonator* (narrow-band filter), usually a pipe. One distinguishes *reed instruments* in which the *exciter* is an oscillating mechanical valve from *flue instruments* driven by a flow instability without significant mechanical vibration (Fig. 7.2)

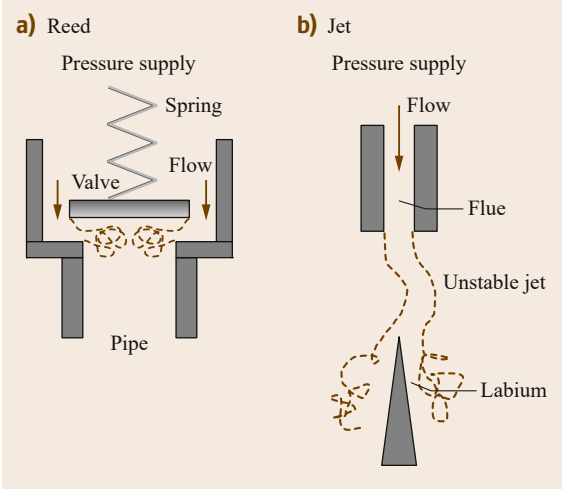

Fig. 7.2a,b One distinguishes *reed instruments* from *flue instruments* (Fig. 7.1): **(a)** The sound generation in reed instruments is driven by the mechanical oscillation of a valve controlling the flow entering a resonator (pipe). **(b)** Flue instruments are driven by an intrinsically unstable flow, usually a jet impinging on a sharp edge called the labium attached to the resonator (pipe)

In flue instruments the flow oscillation is a result of an instability of the air flow. The player produces a narrow relatively high-speed air jet. A *jet* is a narrow high-speed flow surrounded by stagnant fluid. Jets are intrinsically unsteady. Their movement is controlled by the oscillating flow associated with the acoustic oscillation of the resonator. This flow is in the direction perpendicular to the jet flow. It induces perturbations in the jet at the origin of the jet (flue exit), which are amplified as they are convected towards a sharp edge called the *labium*. It is the force of this edge on the flow that is the source of sound driving the acoustic oscillation in the resonator. Some authors refer to this jet as an air reed. This is rather confusing, as the sound generation mechanism is essentially different from that in reed instruments as will be explained in detail later (Sect. 7.6). Flue instruments appear all over the world in different cultures and have very different geometries and playing techniques. The flue instruments that have been most widely studied from the physical modeling point of view are the modern transverse flute, the recorder, the shakuhachi, the whistle and the flue organ pipe.

The oscillating mechanical valve in reed instruments is called a reed, because it is in some instruments made of a bamboo-like wood. Reeds can be a single striking reed (clarinet, saxophone, reed organ pipe), double reeds (oboe, bassoon), free reeds (harmonica) and lips (brass instruments). *Helmholtz* [7.2] distinguishes reeds that close when the difference $p_r = p_m - p_p$, between the supply (mouth) pressure p_m and the pipe inlet pressure p_p, is increased from reeds that open when p_r increases, respectively the *closing and opening reeds* (Fig. 7.3). Helmholtz demonstrated that the oscillation frequency of a closing reed will be lower than both the reed mechanical resonance frequency and the pipe acoustical resonance frequency. The opening reeds should have the opposite behavior; the oscillation frequency is higher than the reed and the pipe resonance frequencies. The closing reeds of instruments such as the clarinet, the oboe and the reed organ pipe do indeed display this behavior. One defines brass instruments as lip-driven wind instruments; they are not necessarily made of brass. The lips of a brass player do, in first approximation, behave as opening reeds. However, lips' behavior can be much more complex because they can display self-sustained oscillations involving at least two mechanical degrees of freedom, which will be discussed later. In this sense lips can behave as vocal folds.

One distinguishes striking reeds (single striking reeds, double reeds and lips) from free reeds. The motion of striking reeds is limited by full closure. The reeds sketched in Fig. 7.3 are striking reeds. In principle they can close completely. Free reeds are thin tongues attached on one side to a plate containing an aperture through which the reed can pass. They act as swinging doors. There always remains a thin slit opening between the tongue and the support plate. The reed never closes completely. When the tongue is fixed on the high pressure side of the plate, it will initially behave as a closing reed. At high pressures p_r, if the plate is thin enough, the tip of the tongue can pass to the low-pressure side of the plate so that the reed will start behaving as an opening reed.

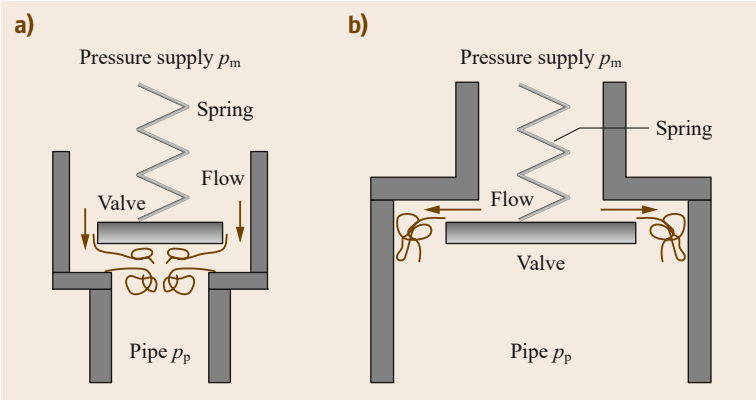

Fig. 7.3a,b One distinguishes **(a)** *closing reeds* from **(b)** *opening reeds*: A closing reed closes as the pressure difference $p_m - p_p$ increases. In opening reeds we have the opposite behavior. The clarinet and oboe have closing reeds. The lips of a brass player can in first-order approximation be described as an opening reed

An important parameter is the ratio f_{reed}/f_{pipe} of the reed mechanical resonance frequency and the acoustical pipe resonance frequency. In the normal playing range of the clarinet, saxophone, oboe and bassoon the reed frequency f_{reed} is much higher than the pitch f of the note played, which is close to the pipe frequency f_{pipe}. In most reed organ pipes and brass instruments f_{reed} is close to the pitch f of the note played. A brass player will adjust the lip vibration frequency f_{reed} by tuning the muscular tension. The player is able to do this without contact of the lips with the instrument or by placing their lips against the mouthpiece without a pipe [7.15]. In Asian free-reed instruments such as the sheng, sho and khaen, the pitch is determined by a pipe acoustical resonance frequency f_{pipe}. In Western free-reed instruments, such as the harmonica, harmonium and accordion, the pitch is close to f_{reed}.

In order to provide a more specific discussion, five prototype instruments have been selected: the clarinet, the oboe, the harmonica, the trombone and the flute. The following Sects. 7.2–7.6 are devoted to these instruments.

The actual geometry of the pipe of woodwinds is much more complex than a simple cylinder or a truncated cone. For example, in instruments with side holes, the closed holes form cavities that significantly affect the effective acoustic pipe length [7.6], while we will see that open holes promote sound radiation at high frequencies. However, most instruments display either a dominantly *cylindrical* or *conical* behavior. This explains some essential differences between these families of instruments that will be discussed later. The clarinet has a single reed and an approximately cylindrical pipe. The oboe is commonly played with a double reed and has a more or less conical pipe. The harmonica is a free-reed instrument with a less obvious coupling to a resonator. The trombone is a typical brass instrument with a large portion of cylindrical bore. The modern transverse flute designed by *Boehm* [7.16] is the most sophisticated flue instrument. The main pipe is almost cylindrical but the mouthpiece (head) as a complex geometry [7.17].

In our classification of wind instruments, we could also have considered the typical blowing pressure p_m and the volume flow Φ_r. The oboe is a high-pressure low-volume flow instrument. Typically mouth pressures of a few kPa are used. In the flute blowing pressures are commonly lower than 1 kPa but the volume flow is high. In brass instruments at low pitches the volume flow is high and the blowing pressure relatively low. For high pitches the blowing pressure is high and the flow relatively low. As a rule of the thumb the amplitude of the acoustical pressure oscillation within the pipe of the wind instruments is of the order of p_m.

The musical sound that reaches the listener is a minute fraction of the pressure oscillations within the pipe. Upon radiation there is a strong shift towards high frequencies, which are much more efficiently radiated than the fundamental oscillation frequency, driving the feedback loop. There is therefore no simple relationship between the amplitude (sound pressure level) of the radiated sound and the driving pressure p_m. Furthermore, the perceived sound pressure level depends on the spectral distribution of the sound.

7.2 The Clarinet

Globally the clarinet (with closed tone holes) is a cylindrical pipe terminated by a short bell (horn). Tone holes can be open; this reduces the effective acoustic length and increases the pitch. The acoustics of tone holes is

Fig. 7.4 (a) Clarinet (courtesy of Buffet-Crampon Co.) and (b) its mouthpiece with reed (courtesy of Vandoren Co.)

discussed in depth by *Nederveen* [7.6] and *Dalmont* et al. [7.18]. At the inlet, the mouthpiece opening is partially covered by a thin wedge-shaped slice of cane wood (reed). The thick end of the reed is rigidly attached to the mouthpiece (Fig. 7.4). The free end of the reed is pressed by the player's (lower) lip against the side walls of the mouthpiece opening – the lay. The curvature of the lay, the position of the lip on the reed and the lip pressure determine the initial height h_0 of the slit through which air is blown into the pipe.

The thin reed tip can be described as a spring with stiffness K_r, which bends under influence of the difference $p_r = p_m - p_p$ between the player's mouth pressure p_m and the pressure p_p in the mouthpiece, at the inlet of the pipe. In the framework of a lumped model approximation the reed is described as a mass-spring system

$$m_r \frac{d^2 h_r}{dt^2} + \gamma_r \frac{dh_r}{dt} + K_r(h_r - h_0) = -S_r p_r \,, \qquad (7.1)$$

where $h_r \geq 0$ is the slit opening at the tip of the reed, m_r is the effective mass of the reed, γ_r is the damping and S_r is the effective reed surface. The effective mass m_r is smaller than the actual mass of the reed to account for the fact that the displacement velocity is

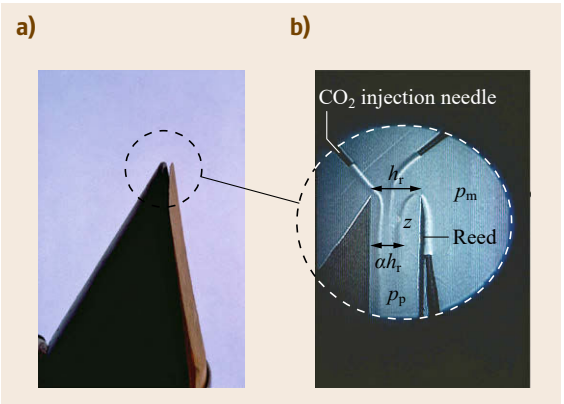

Fig. 7.5a,b Flow through reed channel of height h_r: (a) Tip of mouthpiece and reed (b) Schlieren flow visualization (after [7.9]); stream lines are made visible in an upscaled ($10\times$) static model by injection of carbon dioxide through three needles. We observe that the jet just downstream of the inlet of the reed channel is narrower than the reed channel height h_r by a factor α (vena contracta)

not uniform over the reed surface [7.6]. It varies between zero and dh_r/dt. For the same reason the surface S_r is an effective reed surface, which is not the actual reed surface. Typically the reed resonance frequency $f_{reed} = \sqrt{K_r/m_r}/(2\pi)$ is, for the lower register of a clarinet, much higher than the pitch f of the note played. Without sufficient damping by the player's lip the reed will oscillate close to its resonance frequency, resulting in a nasty *squeak* sound. Note that the drone pipes of a bagpipe are cylindrical and have single reeds. The frequency of these reeds is adjusted to approach the acoustical resonance frequency of the pipe, so that they can be played without lip contact with the reed.

The effective reed stiffness K_r is not constant and is not only determined by the material properties of the reed. In particular, due to the limitation of the reed movement by the lay the effective reed stiffness K_r is a strongly nonlinear function of h_r. The curvature of the lay, the exact shape of the reed and the player's lip position on the reed all have a strong influence on the playing comfort and the quality of the sound produced. Also moisture strongly affects the mechanical properties of wooden reeds.

In first approximation the volume flow Φ_r entering the pipe is given by

$$\Phi_r = \mathrm{sign}(p_r)\alpha W h_r \sqrt{\frac{2|p_r|}{\rho_0}} - A_r \frac{dh_r}{dt} \,, \qquad (7.2)$$

where W is the effective slit width, ρ_0 the air density and A_r the effective surface of the moving part of the reed. The first term of (7.2) is the quasistatic approximation

assuming the formation of a free jet of cross-sectional area $\alpha h_r W$ by flow separation at the sharp tip of the reed (Fig. 7.5). The vena contracta factor α is in the range $0.5 < \alpha < 1.0$ depending on the channel inlet geometry [7.19–21]. The frictionless equation of Bernoulli is used to estimate the velocity in the jet $U_j = \sqrt{2|p_r|/\rho_0}$. It is however important to realize that friction is assumed implicitly, because it causes flow separation, which results in the formation of the jet. The model assumes a dissipation of all the kinetic energy in the free jet by turbulent dissipation. Obviously when the reed is closing completely, beating on the lay, the slit opening will become so small that friction will eventually dominate the entire flow through the reed channel and the equation of Bernoulli should not be used [7.9, 20, 22]. The second term of (7.2), $A_r(dh_r/dt)$, is the volume flow due to the displacement of the reed. As the reed is fixed at one end, its displacement velocity varies between zero and the tip velocity (dh_r/dt). The effective acoustical surface area of the reed A_r is therefore smaller than the actual reed surface area. Inertia and this displacement flow become important at very high pitches. A measure for the importance of unsteadiness is the Strouhal number $\mathrm{Sr}_r = L_r f/\sqrt{2p_m/\rho_0}$ based on the length of the reed channel L_r. Significant deviation from the quasisteady behavior is expected for $\mathrm{Sr}_r \geq 10^{-1}$ as found in the simulations of *da Silva* et al. [7.20].

While (7.1) and (7.2) are essentially nonlinear, the acoustical response of the pipe and the respiratory system to the fluctuations in the volume flow are reasonably well described by linear acoustics. At moderately high amplitudes, the oscillating pressure is dominated by the first harmonic. One can therefore approximate the acoustical response of the system by a purely sinusoidal fluctuation $\hat{\Phi}_r \exp(i\omega t)$ of the reed volume flow around an averaged value $\overline{\Phi}_r$, where $\omega = 2\pi f$ and the complex notation is used ($i^2 = -1$). Similarly one has $p_k = \overline{p}_k + \hat{p}_k \exp(i\omega t)$ $(k = p, m)$, where the complex amplitudes $\hat{p}_k$ are related to the impedances Z_k $(k = p, m)$ of the pipe (p) and the player's respiratory system (m) by

$$\hat{\Phi}_r = \frac{\hat{p}_p}{Z_p} = -\frac{\hat{p}_m}{Z_m} \,. \tag{7.3}$$

This highly simplified model already indicates that the player can influence the oscillation of the instrument, by modifying the geometry of his vocal tract (mouth volume, tongue position, etc.). Hence while typically $|Z_m| \ll |Z_p|$ this allows some bending of the notes [7.23–25] in addition to changes in lip position and its pressure on the reed. Most physical models ignore this subtlety and assume $|Z_m| = 0$.

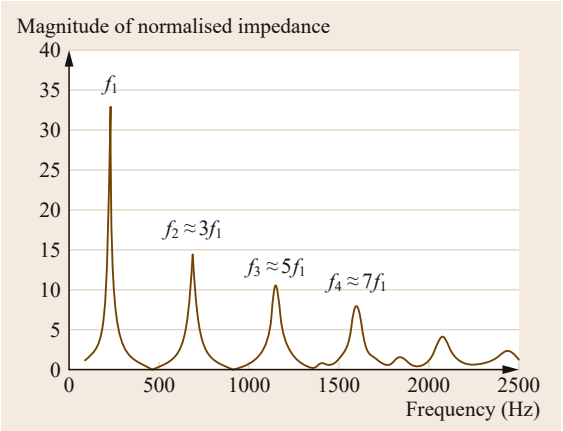

Fig. 7.6 Magnitude on a linear scale of normalized impedance $S_p|Z_p|/(\rho_0 c_0)$ of the pipe of a clarinet, with S_p the pipe inlet cross-section, as a function of the frequency for the note C4 (courtesy J.-P. Dalmont)

The amplitude (modulus) of the impedance of a cylindrical pipe $|Z_p|$ presents strong peaks at frequencies corresponding to resonance frequencies $f_n \simeq (2n-1)c_0/(4L)$, $(n = 1, 2, 3, \ldots)$ with c_0 the speed of sound and L the pipe length (Fig. 7.6). The period of oscillation at the first acoustical resonance (mode) f_1 is four times the travel time of the wave along the pipe. This is due to the fact that the traveling acoustic wave is inverted at the open pipe termination while it is reflected without inversion at the reed side.

The first impedance peak at frequency f_1 corresponding to the quarter-wavelength $(L \simeq c_0/(4f))$ resonance for a pipe length L is the strongest. The peak amplitude decreases with increasing frequency as a result of increasing viscous and thermal dissipation and radiation losses. Furthermore, the first Fourier components of the oscillating pressure in the mouthpiece are dominated by uneven multiples of the oscillation frequency. In order to make the instrument sound at $3f_1$ a register hole has to be opened, which lowers the first impedance peak at f_1.

In occidental music half tones are commonly used. However, for contemporary music quarter tones are used. A special clarinet with a side branch allows the player, by using a key, to shift the clarinet scale by a quarter tone [7.26]. Such a system was also designed for the modern transverse flute.

Linearization of (7.1) to (7.2) for small fluctuations $\hat{h}_r \exp(i\omega t)$ around h_0 yields in combination with (7.3) a homogeneous set of linear equations relating the complex amplitudes $\hat{h}_r, \hat{p}_p, \hat{p}_m$ and $\hat{\Phi}_r$. A nontrivial solution implies that the determinant of this set of equations should vanish, which yields a nonlinear characteristic equation. The real and imaginary parts of this equation

form a set of two equations. Assuming a steady harmonic oscillation, which implies a real frequency ω or equivalently $\mathrm{Im}\{\omega\} = 0$, one can obtain the threshold of the average pressure difference $\overline{p}_\mathrm{r} = \overline{p}_\mathrm{m} - \overline{p}_\mathrm{p}$ above which the instrument will start oscillating and the corresponding oscillation frequency $\mathrm{Re}\{\omega\}$. Alternatively, for given imposed pressure difference $\overline{p}_\mathrm{r} = \overline{p}_\mathrm{m} - \overline{p}_\mathrm{p}$ above the oscillation threshold, the real and imaginary parts of $\omega = \mathrm{Re}\{\omega\} + \mathrm{i}\,\mathrm{Im}\{\omega\}$ are the unknown. One finds for $\mathrm{Im}\{\omega\} < 0$ a complex frequency ω implying an exponential increase of the oscillation amplitude with time following $\exp(-\mathrm{Im}\{\omega\}t)$. As stated earlier, a steady oscillation amplitude is reached by nonlinear saturation of the oscillation amplitude and can therefore not be predicted by a linear model. A nonlinear saturation mechanism has to be taken into account to predict a steady oscillation.

As the amplitude increases a steady oscillation can be predicted by assuming the solution to be a function of a limited number of harmonics of the fundamental frequency. This is the so-called harmonic balance method [7.27, 28]. As stated before, for moderately high amplitudes near the oscillation threshold, an approximative harmonic solution can be considered. At higher amplitudes, more harmonics contribute to the oscillation. The sound becomes *richer* and *louder*.

One can also seek a solution of the equations in the time domain. Equation (7.3) becomes, in the time domain, an integral equation involving a convolution integral. As shown by *McIntyre* et al. [7.29] the model can also be written in terms of the impulse response of an extended semi-infinite pipe, which can be numerically more efficient. One calls this the reflection function approach. Alternatively, the acoustic response of the pipe can be discretized, solving directly for plane-wave propagation within the pipe. This so-called *wave guide* approach has become very sophisticated and is commonly used for sound synthesis by means of real-time solution. This provides so-called *virtual instruments* [7.30–34]. Systematic studies of the response of such models have been provided in the literature, displaying extremely complex behaviors, as do the actual instruments. In particular the virtual clarinet is a versatile musical instrument when it is controlled by a mouthpiece with a pressure sensor.

In the further discussion the reed dynamics are simplified by using the quasistatic approximation of Eqs. (7.1) and (7.2) to give (for $p_\mathrm{r} > 0$)

$$\Phi_\mathrm{r} = \alpha W \left[h_0 - \frac{S_\mathrm{r}}{K_\mathrm{r}} p_\mathrm{r} \right] \sqrt{\frac{2p_\mathrm{r}}{\rho_0}} \,. \tag{7.4}$$

In Fig. 7.7 this relationship between the volume flow Φ_r and the driving pressure difference $p_\mathrm{r} = p_\mathrm{m} - p_\mathrm{p}$

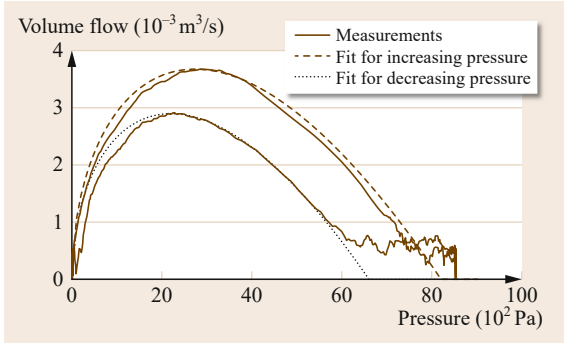

Fig. 7.7 Quasistatic volume flow Φ_r as a function of the driving pressure $p_\mathrm{r} = p_\mathrm{m} - p_\mathrm{p}$ for a closing reed with spring constant K_r, compared to experiments (after [7.19]). The measurements show an hysteresis: the volume flow is larger for increasing pressure than for decreasing pressure. This hysteresis is due to the viscoelastic properties of the reed (after [7.35])

for a constant reed stiffness K_r is compared to experiments [7.19]. Of course Φ_r vanishes at $p_\mathrm{r} = 0$. In other words when we do not blow into the pipe there is no flow. Above the critical pressure difference $p_\mathrm{c} = K_\mathrm{r} h_0 / S_\mathrm{r}$ the reed closes completely and the flow vanishes again. A maximum of reed flow is found, following (7.4), for $p_\mathrm{r} = p_\mathrm{c}/3$. The time-averaged acoustic power $\overline{P}_\mathrm{acoustic}$ generated by a harmonic oscillation of the pipe pressure is given by the time average over a period of oscillation of the product of the reed-volume flow fluctuation $\Phi_\mathrm{r}' = \Phi_\mathrm{r} - \overline{\Phi}_\mathrm{r} = \hat{\Phi}_\mathrm{r} \exp(\mathrm{i}\omega t)$ and the pipe-inlet pressure fluctuation $p_\mathrm{p}' = p_\mathrm{p} - \overline{p}_\mathrm{p} = \hat{p}_\mathrm{p} \exp(\mathrm{i}\omega t)$. The over bar indicates a time averaging over a period of oscillation. Hence the power is given by

$$\begin{aligned} \overline{P}_\mathrm{acoustic} &= \frac{\omega}{2\pi} \int_0^{2\pi/\omega} \Phi_\mathrm{r}' p_\mathrm{p}' \mathrm{d}t \\ &= \frac{1}{2} \left\{ \mathrm{Re}\{\hat{p}_\mathrm{p}\}\,\mathrm{Re}\{\hat{\Phi}_\mathrm{r}\} + \mathrm{Im}\{\hat{p}_\mathrm{p}\}\,\mathrm{Im}\{\hat{\Phi}_\mathrm{r}\} \right\} . \end{aligned} \tag{7.5}$$

For small oscillations, in linear approximation the reed volume flow fluctuation $\hat{\Phi}_\mathrm{r}$ is the product of the slope $\mathrm{d}\Phi_\mathrm{r}/\mathrm{d}p_\mathrm{r}$ of the volume flow characteristic and the amplitude of the pressure fluctuation $\hat{p}_\mathrm{r} = -\hat{p}_\mathrm{p}$, where the negative sign takes into account the fact that an increase of the pipe-inlet pressure p_p results in a decrease of the driving pressure $p_\mathrm{r} = p_\mathrm{m} - p_\mathrm{p}$ across the reed. So we find for the amplitude of the volume flux fluctuations

$$\hat{\Phi}_\mathrm{r} = -\left[\frac{\mathrm{d}\Phi_\mathrm{r}}{\mathrm{d}p_\mathrm{r}} \right] \hat{p}_\mathrm{p} \quad \text{and} \quad \overline{P}_\mathrm{acoustic} = -\frac{\left[\frac{\mathrm{d}\Phi_\mathrm{r}}{\mathrm{d}p_\mathrm{r}} \right] |\hat{p}_\mathrm{p}|^2}{2} \,.$$

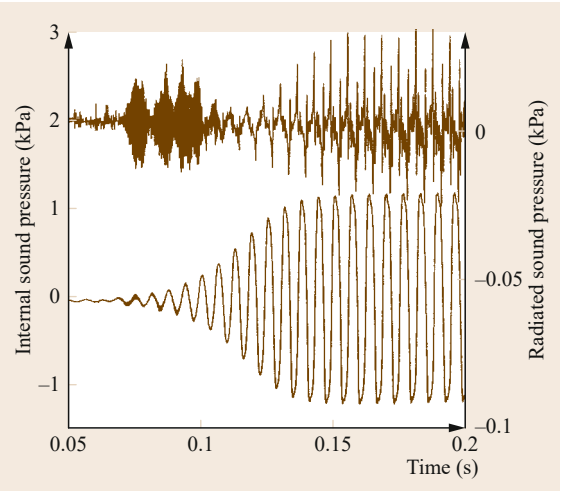

Fig. 7.8 Mouthpiece pressure and radiated pressure during the attack of a clarinet. We observe that a steady oscillation is reached within a few oscillation periods. Furthermore we see that the mouthpiece pressure is dominated by the fundamental, while the radiated sound (music) is much richer in higher harmonics

Hence for $0 < p_r < p_c/3$ as $d\Phi_r/dp_r > 0$ sound is absorbed. Sound is generated by the reed oscillation when $p_c/3 < p_r < p_c$. Indeed the musician will have to overcome a critical mouth pressure threshold of the order of $p_r = p_c/3$ to initiate oscillations. Furthermore at very high blowing pressures the reed indeed closes completely, eventually stopping any oscillation.

Some insight into the finite-amplitude dynamical behavior of the clarinet can be obtained by considering a lossless cylindrical resonator [7.11, 29]. The limit cycle oscillation of this system corresponds to a symmetric square-wave oscillation between the two points p_A and p_B corresponding to a fixed volume flow Φ_r on the two branches ($p < p_c/3$ and $p_c/3 < p < p_c$) of quasistatic reed characteristics. The actual large amplitude oscillation of the pressure in the mouthpiece of a clarinet approaches this behavior. Assuming frequency-independent energy losses upon reflection at the open pipe termination, one obtains an analytical model predicting many aspects of the dynamic response of the clarinet. Due to the fact that the transition from stationary flow to oscillating flow is a direct bifurcation, the player can play a note at low level. The instrument has a fast response and a large dynamical range, from pianissimo to fortissimo.

An essential property of the clarinet is that the limit cycle is reached within a few oscillations (Fig. 7.8). Attack transients are essential for the perception of musical sounds [7.36]. Note that the conical reed instruments, such as the oboe and the bassoon, have an even shorter attack transient than the clarinet, while flue instruments have very complex long attack transients of typically a few dozen oscillation periods [7.37, 38].

Until now we considered the pipe of the instrument as an acoustical resonator imposing the pitch of the note played. The effective acoustic length of the pipe is changed by opening tone holes along the pipe. A complex key system has been placed to facilitate this task. For the lowest harmonics of the fundamental oscillation frequency, the acoustic waves traveling down the pipe are strongly reflected at the open pipe termination. These acoustic waves are more strongly damped by viscous and thermal losses at the pipe walls than by radiation. However without radiation no musical sound would be generated by the instrument. There is a conflict between the necessity to keep acoustic waves traveling inside the pipe, regenerating the oscillation, and the need of radiation for the production of music. This apparent contradiction is resolved by the fact that the instrument is designed to radiate sound at high frequencies, for which our ear is most sensitive. At low frequencies $k_0^2 A < 1$ the real part of the radiation impedance Z_{rad} of an unflanged open pipe of cross-section A increases quadratically with the frequency $\mathrm{Re}\{Z_{rad}\} \simeq \rho_0 c_0 [k_0^2 A/(4\pi)]$. The wave number is defined by $k_0 = 2\pi f/c_0$, with c_0 the speed of sound, the propagation velocity of acoustic waves. For a given oscillation amplitude, this implies that the radiated acoustical power increases quadratically with the frequency for a small pipe outlet cross-section diameter compared to the wavelength.

While the bell of a clarinet has a catenoidal shape rather than an exponential shape [7.6], we will for simplicity discuss the acoustic behavior of an exponential, horn which has a similar behavior. At the lowest pitches a truncated exponential horn radiates select frequencies above a cutoff frequency of a few kHz. This acoustical behavior is predicted when considering plane-wave propagation in a pipe with exponentially varying cross-section $A(x) = A_0 \exp(\beta x)$ with β a positive constant. The linearized mass conservation, assuming a uniform acoustical pressure $p'(x)$ at position x along the pipe and neglecting friction and heat transfer, is

$$\frac{A}{c_0^2}\frac{\partial p'}{\partial t} + \rho_0 \frac{\partial A u'}{\partial x} = 0\,, \tag{7.6}$$

where u' is the fluid velocity. The x-component of the momentum equation is

$$\rho_0 \frac{\partial u'}{\partial t} + \frac{\partial p'}{\partial x} = 0\,. \tag{7.7}$$

This corresponds to the Lagrange–Webster approximation. Substitution of the plane outgoing wave solution

for the pressure $p' = \hat{p}\exp[\mathrm{i}(\omega t - kx)]$ and the velocity $u' = \hat{u}\exp[\mathrm{i}(\omega t - kx)]$, with $\omega = 2\pi f$, yields a set of linear equations for the amplitudes $\hat{p}$ and $\hat{u}$, which has only a nontrivial solution when its determinant vanishes. Using this characteristic equation one obtains

$$k = -\mathrm{i}\beta/2 + k_0\sqrt{1-(\beta/2k_0)^2}\,.$$

For $k_0 > \beta/2$ the wave will propagate and eventually be radiated at the outlet of the horn. Note that the amplitude of this wave decays following $\exp(-\beta x/2)$. This is a consequence of the conservation of the energy flux in the propagating wave as the pipe cross-section increases exponentially. For $k_0 < \beta/2$ the wave is evanescent; its amplitude will decay exponentially as $\exp[-\mathrm{i}kx]$, because k is purely imaginary. If the exponential horn is sufficiently long the low-frequency wave is reflected before it has reached the end of the horn. Hence the horn promotes the radiation of high frequencies $\omega > \beta c_0/2$ and keeps low frequency $\omega < \beta c_0/2$ waves within the instrument. The low frequencies take care of the regeneration of the oscillation. This very simple model can significantly be improved when considering the finite length of the horn and deviations from the plane-wave approximation. This more accurate theory becomes essential for brass instruments that have very large bells. Another function of the bell is to harmonize the resonances of the pipe for the lowest note of the clarinet [7.11].

When a few tone holes of the clarinet are open the horn becomes useless. The pipe segment with a series of open holes behaves as a row of Helmholtz resonators (lattice) with a similar radiation cutoff frequency behavior as an exponential horn [7.11, 39]. This cutoff frequency is about 1400 Hz in the example of clarinet impedance shown in Fig. 7.6. Hence the exact position and size of tone holes is not only important to determine the pitch but also the radiation [7.39, 40]. The radiation does not only involve the acoustical power radiated, but also the directivity of this radiation. In first-order approximation each tone hole behaves as a monopole sound source. The interference between the radiated sound from these different sources determines the directivity.

It is interesting to note that at *fortissimo* levels, the acoustic flow through open tone holes will be nonlinear. Vortex shedding will occur at sufficiently low Strouhal numbers $fd/|\hat{u}_{\mathrm{ac}}| < 1$ based on the tone hole diameter d and the amplitude $|\hat{u}_{\mathrm{ac}}|$ of the surface-averaged acoustic velocity passing through the tone hole. This so-called acoustical streaming induces a jet flow, which can blow the flame of a candle placed close to the tone hole [7.41, 42]. A similar jet flow also occurs inside the instrument, which can slightly affect the temperature profile along the pipe, because the jet flow entering the pipe transports air from the surroundings, which is cooler than the air blown by the musician [7.43]. The vortex shedding induces energy losses that for a given acoustical pressure amplitude in the instrument are inversely proportional to the third power of the tone hole cross-sectional area. Vortex shedding also generates higher harmonics of the fundamental. It is expected that details of the tone-hole design, such as sharp edges, will affect this. In a clarinet, the nonlinearity of the interaction of the reed with the lay is much more important for the sound quality than the vortex shedding at tone holes. It has been argued by *Bouasse* [7.4] that a horn at a pipe termination does not only enhance radiation but also reduces losses due to vortex shedding. This could be particularly significant for brass instruments at low pitches. In a flute or recorder the vortex shedding induced by the acoustic flow through the sharp edge (labium) of the mouth of the instrument appears to be important both for the saturation of the oscillation amplitude and for the sound quality.

7.3 The Oboe

While the clarinet has a *quasi*cylindrical pipe and a single reed the oboe has an almost conical pipe (of length L) that is truncated. The oboe is commonly played with a double reed (Fig. 7.9). The volume between the two reeds corresponds roughly to the volume of the missing part, of the truncated cone, of length r_0.

Single reeds have been developed for the oboe, but are rarely used. The quasisteady flow model described for the single reed of the clarinet appears to be quite reasonable for double reeds. There are some subtle differences between the volume flow characteristic of a double reed and that of a single reed [7.44]. The assumption that the static flow resistance downstream of the reed strongly influences these characteristics [7.9] has not been verified experimentally for the oboe [7.45] and bassoon [7.44]. Some ancient cylindrical double-reed instruments (Rausch pipes) do have a neck just downstream of the double reed, which does drastically influence the reed characteristics. This neck stabilizes the lowest register, which otherwise has a chaotic behavior [7.9].

The essential difference between the oboe and the clarinet is due to the conical shape of the pipe of the oboe. The acoustic field in a conical instrument is in

Fig. 7.9a,b Oboe (a) and its double reed (b) (courtesy of Buffet-Crampon Co.)

first-order approximation described for low frequencies by the modified solution of d'Alembert for harmonic spherical waves

$$rp' = A^+ \exp[\mathrm{i}(\omega t - k_0 r)] + A^- \exp[\mathrm{i}(\omega t + k_0 r)] \,, \tag{7.8}$$

where r is the distance from the apex of the cone and $A^\pm$ are the amplitudes of the outgoing (A^+) and incoming (A^-) waves. This solution is also obtained when using the Lagrange–Webster approximation (7.6) and (7.7), for a pipe cross-section A increasing linearly with r. The factor r at the left-hand side of (7.8) takes into account the energy conservation in the traveling waves, as done by the factor $\exp(-\beta x/2)$ for the exponential horn. The radial fluid particle velocity u'_r is found by substituting the wave solution (7.8) into the momentum equation (7.7) (with x replaced by r)

$$r^2 u'_\mathrm{r} = \frac{1}{\rho_0 c_0}\left\{\left(\frac{1}{\mathrm{i}k_0} + r\right) A^+ \exp[\mathrm{i}(\omega t - k_0 r)] + \left(\frac{1}{\mathrm{i}k_0} - r\right) A^- \exp[\mathrm{i}(\omega t + k_0 r)]\right\} . \tag{7.9}$$

As at the apex of a cone $\lim_{\mathrm{r}\to 0}[r^2 u'_\mathrm{r}] = 0$ we see from this equation that the pressure waves are inverted $A^+ = -A^-$ at the apex of a cone $r = 0$. This remains a fair approximation as long as the missing length of the cone r_0 remains short compared to the wavelength $k_0 r_0 \ll 1$. Combining this condition with the ideal open pipe termination condition $p'(L) = 0$ at $r = r_0 + L$, we find for a cone of length $r_0 + L$ the resonance frequencies $f_n \simeq nc_0/[2(r_0 + L)]$. Consequently conical instruments have maxima of the pipe impedance for each harmonic of the oscillation frequency, including the even harmonics. This is illustrated by the pipe inlet impedance amplitude $|Z_\mathrm{p}|$ shown in Fig. 7.10.

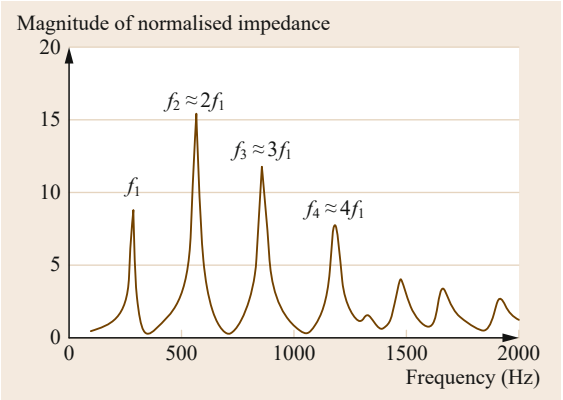

Fig. 7.10 Magnitude of the normalized impedance $S_\mathrm{p}|Z_\mathrm{p}|/(\rho_0 c_0)$, with S_p the pipe inlet cross-section, of the pipe of an oboe as a function of the frequency for the note D4 (courtesy J.-P. Dalmont)

Note that at low frequencies, the peak amplitudes of $|Z_\mathrm{p}|$ increase initially with the frequency. This is due to the increase in radiation impedance of spherical waves at the pipe inlet, as the frequency is increased $\mathrm{Re}\{Z_\mathrm{rad}\} \sim \rho_0 c_0 (k_0 r_0)^2/4$. At higher frequencies the peak in $|Z_\mathrm{p}|$ decreases as a result of increasing viscous/thermal losses and radiation losses, as was already observed in the clarinet. The increase in $|Z_\mathrm{p}|$ with the frequency for the lower frequencies implies that the instrument tends to sound spontaneously an octave higher than the first acoustic mode. Another important consequence of this frequency dependence of the impedance is that the oboe displays an inverse bifurcation. This means that upon a monotonous increase of mouth pressure, at the onset of oscillation the amplitude jumps suddenly towards a finite amplitude [7.46]. It is difficult to play this instrument at piano levels. Another difference with the clarinet is that the oboe will oscillate at the pipe resonance frequency even when the reed is not damped by the player's lips. However, without lip damping the inverse bifurcation behavior is more pronounced. Other conical instruments such as the saxophone and chanter of the bagpipe can also be played without lip contact with the reed.

As in the case of the clarinet, the simplified analytical model of *Chaigne* and *Kergomard* [7.11] provides insight into the limit cycle behavior of the instrument. In a clarinet the time intervals when the reed is closed or opened during an oscillation cycle are roughly equal. In an oboe with a truncated apex of length r_0 the ratio of closed to opened reed time intervals is r_0/L. As typically $r_0 \ll L$ the reed only closes during a short time interval, of the order of magnitude $2r_0/c_0$, during which the pipe inlet pressure p'_p drops suddenly. *Chaigne* and *Kergomard* [7.11] call this a Helmholtz motion in analogy to the velocity of the string in the violin. This yields a series of sharp downwards peaks, corresponding to a spectrum rich in higher harmonics. Therefore the sound of the oboe is much brighter than that of the clarinet. This is one of the reasons that oboe players provide the *A* note used in an orchestra to adjust the tuning of all instruments.

Other instruments, such as the bassoon, the saxophone and the chanter of a bagpipe, also display the typical behavior of conical instruments. Of course the actual geometry of the pipe is more complex than a simple truncated cone. This is necessary to adjust the tuning for all the notes played with the instrument [7.47].

7.4 The Harmonica

The harmonica is a very popular Western free-reed instrument. Like for the harmonium and the accordion the reed is a thin brass tongue. The fine tuning of tongues can be obtained by changing their mass (removing or adding material) or adjusting the reed stiffness in the area close to the clamped end of the tongue. A sometimes complex shape determines the initial opening of the reed (Fig. 7.11).

As shown in the sketch in Fig. 7.12, of the expected quasistatic flow characteristics, the reed behaves at low pressures as a closing reed (Sect. 7.1). Above a critical pressure the volume flow decreases with increasing $p_r = p_m - p_p$. At very high pressures the flow increases again as the reed tip has passed through the plate [7.8] and the reed behaves as an opening reed.

In the harmonica, harmonium and accordion there are no pipes attached to the reeds. It is therefore often assumed that free reeds can oscillate without acoustical feedback. The theoretical models of *St. Hilaire* et al. [7.48] and *Ricot* et al. [7.49] demonstrate that the inertia of the local flow around the reed at the upstream side can induce self-sustained oscillation. Unfortunately these models contain some arbitrariness in the coupling of a two-dimensional near-field flow model to a three-dimensional far-field model. Furthermore, no argument is given to justify neglecting the inertia of the flow at the downstream side of the reed. Furthermore, there is clear experimental evidence for the importance of the acoustical response of the pressure supply system [7.50, 51]. This is most spectacular for the harmonica where the musician modifies the geometry of his vocal tract, taking configurations corresponding to different vowels, in order to bend the pitch. The pitch remains close to the reed frequency f_{reed} and can only be lowered. For the harmonica, this appears to involve a coupling between two reeds attached to a single chamber. The first one oscillates upon blowing while the second is played upon drawing. Experiments

on a single opening reed demonstrate that also the upstream volume (of the player's mouth) can strongly influence the pressure threshold for the onset of oscillation and the oscillation frequency of a free reed [7.8].

Paradoxically the free-reed instruments seem the most simple wind instruments, but the physical models for these instruments are yet to be confirmed.

7.5 The Trombone

The trombone, like the trumpet, has a long narrow cylindrical section attached to a conical section, which is terminated by a flaring bell (Fig. 7.13). As for the clarinet, the bell promotes the radiation at high frequencies, keeping the low-frequency waves within the pipe. Also the bell harmonizes the resonance frequencies of the pipe [7.7, 8, 11, 39]. A mouthpiece is fixed to the pipe inlet. The rim of the mouthpiece is wider than the pipe. When the player presses their lips against the rim a volume V_c is delimited between the lips and the cup of the mouthpiece. At the bottom of the cup a narrow channel of section S_c and length L_c forms a choke between the mouthpiece and the cylindrical section of the trombone.

The choke (tail pipe) acts as an acoustic mass, while the volume of the cup is a spring. The corresponding mass-spring resonance frequency is called the Helmholtz resonance frequency [7.11, 39, 52]

$$f_H \simeq \frac{c_0}{2\pi}\sqrt{\frac{S_c}{V_c L_c}}\,.$$

The radiated sound is enhanced in a so-called formant around this frequency, which is one of the parameters chosen by the player when selecting a mouthpiece. The amplitude of the acoustic impedance $|Z_p|$ of the instrument displays a series of peaks. One distinguishes the higher acoustic resonances that are close to a harmonic series $f_n \simeq nf_1$ $(n = 2, 3, 4, \ldots)$ from the lowest peak that typically has a frequency $f \simeq 0.7f_1$ (Fig. 7.14).

Fig. 7.13 **(a)** Trombone and **(b)** its mouthpiece (courtesy of Courtois Co.)

Hence when playing f_1 the musician uses a lip oscillation sustained by a series of higher harmonics rather than the fundamental. This particular note, called the *pedal note*, is difficult to play for a trumpet, but easy to play for a trombone.

As the trombone has a long cylindrical pipe, one would expect the impedance peaks to approach a series of uneven harmonics ($f = (2n-1)f_1$ with $n = 1, 2, 3, \ldots$). This was what occurred for the clarinet. The long cone followed by the large flaring bell are essential in making the series correspond to an almost full harmonic series ($f = nf_1$ with $n = 2, 3, 4, \ldots$) as we see in Fig. 7.14. Only the lowest impedance peak is not matching this harmonic series. In conical brass instruments, such as the French horn, the bell is not essential for the harmonicity of the resonance peaks. In some French horns the bell can be removed for transport convenience. Without the bell the instrument remains playable.

The frequency f_n is controlled by the length of the cylindrical section of the instrument. In order to play the full musical scale, the musician has to change this length. In a trombone this is done by using a slide. This allows a continuous change of the pitch providing the musician with a large flexibility, but limiting the

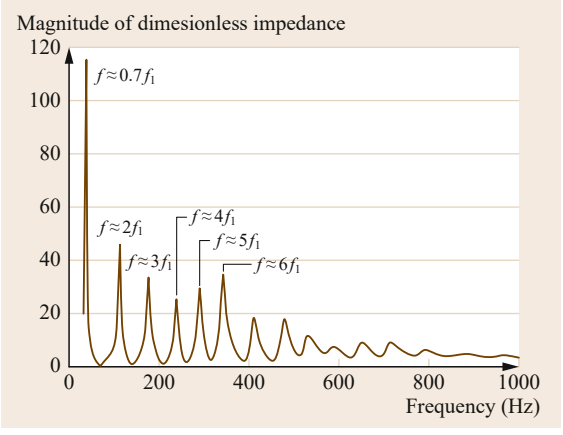

Fig. 7.14 Typical impedance of a trombone showing the series of harmonic resonances $f \simeq nf_1$ $(n = 2, 3, 4, \ldots)$ and the nonharmonic first peak $f \simeq 0.7f_1$. The lowest note f_1 is called the *pedal note*. In this example the Helmholtz resonance of the mouthpiece is around $f = 5f_1$

speed at which different notes can be played. In other instruments, such as the trumpet or the French horn, this problem is solved by using valves in order to modify the pipe length. In the French horn, the musician can place their hand within the bell to slightly affect the tuning, which is a common playing technique. Some baroque brass instruments (cornetto and serpent) have pipes with side holes [7.7].

When a musician plays a higher note for a given f_1, the pipe length can be much longer than the wavelength. A first consequence of this is that the player has to make their lips vibrate at the required pitch a few periods before they receive any acoustic feedback in order to sustain this oscillation. This is consistent with the observation that the reed (lip) frequency should be close to the pipe frequency $f_{\text{reed}}/f_{\text{pipe}} \simeq 1$ for brass instruments. The player can adjust f_{reed} by modifying the muscular tension (embouchure) in their lips. If the lips were simple opening (striking) reeds the acoustical feedback would be necessary in order to maintain an oscillation. The initial buzzing frequency of the lips would be strongly dependent on the configuration of the vocal tract, which would provide the acoustical feedback. The effect of the mouth impedance on trombone and trumpet playing is controversial [7.53, 54].

A more plausible explanation is that lips can display self-sustained (autonomous) oscillations due to the coupling of two mechanical modes of vibration with the flow [7.55–57]. This so-called flutter is the commonly accepted oscillation mechanism for the vocal folds in so-called voiced sound production. The energy transfer between the flow through the lip channel is the result of an asymmetry between the opening and closing phases of the lip movement. This is analogous to the asymmetry between the opening and closing phases of the swimmer's breast stroke, resulting in a net propulsion. During the opening phase, the lips form a converging flow channel that diverges abruptly at its exit. The neck of the channel is far downstream, just upstream of this abrupt exit. During the closing phase, the neck is more upstream. The lips form a gently diverging channel down to the abrupt exit. At the abrupt exit, flow separation occurs, forming a free jet in which the kinetic energy of the flow is dissipated with little pressure recovery. This dissipation provides the volume flow control by the opening of the reed as in any other reeds. The pressure in the jet is close to the pressure p_c in the cup of the mouthpiece. The volume flux $U_j S_j$ through the lips, with

$$U_j = \sqrt{2(p_m - p_{cup})/\rho_0}$$

the jet velocity in the cup and S_j the jet cross-section, is determined by the flow separation. Assuming a quasistatic incompressible one-dimensional flow between the lips, the local flow velocity $U = S_j U_j / S$ is inversely proportional to the local channel cross-sectional area S. The pressure p in a cross-section of the channel can then be deduced from the equation of Bernoulli $p = p_m - \rho_0 U^2/2$. Hence from the mouth to the flow separation point the pressure will be larger than the mouthpiece cup pressure $p \geq p_{cup}$ for the converging channel during the opening phase. Due to delayed flow separation in the gently diverging part of the flow channel, during the closing phase there will be a large region around the neck of the channel in which $p \leq p_{cup}$. Hence the lateral force due to the pressure in the flow will help opening the lips and help closing them. There is a net energy transfer from the flow to the lip oscillation, without need of an acoustical feedback. This process however involves the oscillation of two mechanical structural modes in order to obtain different geometries during the opening and closing phases of the oscillation. With rigid arms and legs (one degree of freedom) we could not swim (the breast stroke).

A consequence of the large length of the cylindrical section of a trombone is that, at high dynamical levels and especially at high pitches, the acoustic wave propagation is affected by nonlinear wave distortion effects. The high pressures occurring at high dynamical levels induce a local unsteady increase in speed of sound c in the compression part of the propagating pressure wave, corresponding to the adiabatic increase in temperature upon compression. The speed of sound in air is proportional to the square-root of the absolute temperature. For outgoing acoustic waves the increase in pressure also induces a particle velocity u' in the direction of the pressure wave propagation. Small perturbations propagate with the increased velocity $u' + c$ compared to the averaged speed of sound c_0. The expansion part of the wave will be slowed down by the same physical effects. As the expansion part of the wave is slow, it will tend to be overtaken by the fast compression part of the wave. This results into a steepening of the compression part of the wave. In contrast to water waves at the seashore where the top of the surface water wave overtakes the trough of the wave, the compression wave cannot actually overtake the expansion wave. This would correspond to a multiple-valued pressure distribution (three pressures in one point). The compression wave becomes eventually *infinitely* steep, which we call a shock wave. This occurs after a distance L_s, which we call the shock-wave formation distance. Neglecting the effect of reflection at the open pipe termination and friction along the pipe one finds

$$L_s \simeq \frac{2\gamma p_0 c_0}{(\gamma+1)\left(\frac{\partial p_p}{\partial t}\right)_{max}}, \tag{7.10}$$

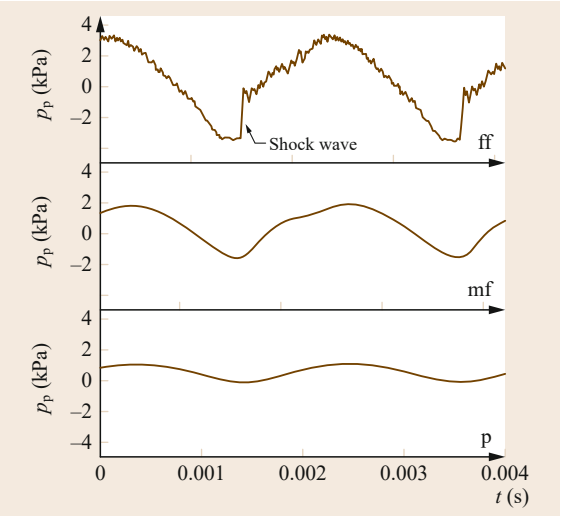

Fig. 7.15 Pressure oscillation at the end of the cylindrical section for a trombone played at various levels (*piano* p, *mezzoforte* mf, *fortissimo* ff). At *fortissimo* levels we observe a shock wave, which is a traveling pressure discontinuity (after [7.58])

where $\gamma = 1.4$ is the adiabatic exponent for air and p_0 is the atmospheric pressure. As demonstrated by experiments, shock waves can indeed be formed in brass instruments [7.58] (Fig. 7.15). When such a shock wave reaches the pipe exit, all the high frequencies in the wave are radiated away. The radiated pressure corresponds roughly to the time derivative of the incoming pressure signal in the pipe. The result is a periodic emission of sharp pressure peaks, corresponding to a spectrum with uniform harmonic amplitudes up to very high frequencies. This is recognized as brassy sound. Hence this is not related to the material of the instrument, but is sensitive to the length and shape of the bore, the geometry of the mouthpiece and the embouchure of the player. Note that before shock waves are reached the sound is already significantly affected by wave steepening with increasing dynamical levels [7.59]. In conical brass instruments this effect is reduced [7.60, 61]. One can therefore distinguish bright from mellow brass instruments depending on the bore shape.

It is interesting to note that earlier trombones have narrower bores than modern ones. Therefore in order to reach a certain dynamical level, i. e., radiate a certain acoustical power, one has to induce larger pressure fluctuations within the instrument in earlier trombones than in a modern one. This explains why these earlier trombones are brassier than modern instruments [7.60].

Note that due to heat transfer between the hot air blown by the musician and the walls of the instrument there is a temperature gradient along the pipe. Consequently the time-averaged speed of sound c_0 is not uniform in the pipe. This results in a modified effective acoustic length of the instrument. This is a linear effect and it is not related to the unsteady amplitude-dependent nonlinear variation in wave propagation speed $c + u'$, discussed above.

In contrast with other wind instruments, most brass instruments only radiate sound through the open pipe termination. This allows the use of a mute. The mute is usually designed to continue the horn shape, so that low frequencies taking care of the acoustical feedback are reflected as in the absence of mute. The mute does however reduce or modify the radiation. This is not only used for silent training but is extensively used for particular musical effects. The *wahwah* mute is an example. It is used for the trumpet in jazz performances.

7.6 The Flute

The modern transverse flute has a cylindrical pipe open at one side and is terminated by a mouthpiece at the other side (Fig. 7.16). The mouthpiece or head joint is closed at its end, but has a relatively large side opening called the blowhole or embouchure hole (called mouth in organ pipes). Sound is generated by blowing a thin grazing air jet across the blowhole towards the side called the labium. The labium of a modern transverse flute has a fairly acute angle (about 60°) and has a sharp edge. The labium of a recorder has an edge angle of about 20°. Rounding the tip of the labium strongly affects the sound quality and in extreme cases the playability of the instrument. In the transverse flute, the player blows in a direction normal to the pipe axis using their lips to form a slit from which the jet emerges. The player can modify the jet thickness (height), the direction of the jet and the length of the jet (distance from lips to edge of the labium). These parameters provide the player a control on the sound produced that is not available in the recorder or flue organ pipe. There the slit (flue) is incorporated in the instrument and has a fixed geometry. In the recorder and the flue organ pipe the jet flows are in the direction of the pipe axis.

In flue instruments, the acoustical oscillation in the pipe induces an oscillating transversal flow through the blowhole, which perturbs the jet at the flow separation point on the lips of the player (or flue exit in other in-

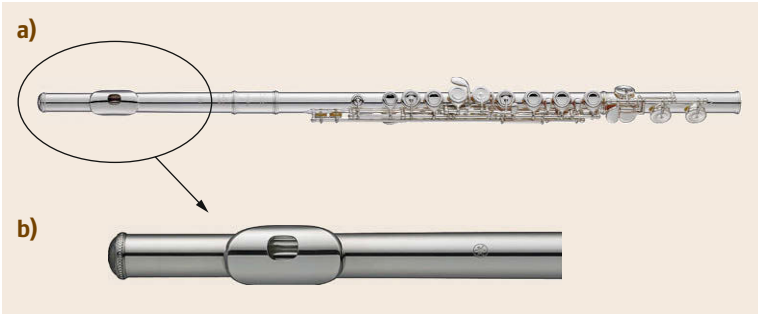

Fig. 7.16 **(a)** Boehm flute and **(b)** its head joint (mouthpiece) with the blowhole (courtesy of Yamaha Co.). Note that between the blowhole and the closed pipe termination of the head joint there is a cavity. The magnitude of this cavity can be adjusted with the cork. This cavity is essential for the harmonicity of the acoustic resonances of the flute

struments). At low amplitudes the jet perturbation can be described as a lateral displacement of the jet. The perturbation is convected by the flow at about half the center-line jet velocity $U_\mathrm{j} \simeq \sqrt{2p_\mathrm{m}/\rho_0}$, while it grows exponentially, in linear approximation. At the labium the jet is split into a volume flow Φ_in entering the pipe (below the labium) and a complementary volume flow Φ_out leaving the pipe (above the labium). For a total jet flow Φ_jet reaching the labium, one has $\Phi_\mathrm{jet} = \Phi_\mathrm{in} + \Phi_\mathrm{out}$. In terms of fluctuations, if we assume that Φ_jet is constant we have $\Phi'_\mathrm{in} = -\Phi'_\mathrm{out}$. Fluctuations are defined by $\Phi'_k = \Phi_k - \overline{\Phi}_k$ (k = in or out) where $\overline{\Phi}_k$ is the time-averaged flux.

Under normal playing conditions the travel time of jet perturbations across the blowhole is about a third of the oscillation period, hence this corresponds to a Strouhal number $\mathrm{Sr_W} = Wf/U_\mathrm{j} \simeq 0.15$, where W is the blowhole width, corresponding to the jet length. The transverse flute player adjusts the jet length W (by moving their lips or rotating the flute), the jet velocity U_j and the jet thickness in order to play in tune at different dynamic levels. In a recorder the jet length and jet thickness are fixed. Hence, the player has less control parameters. To reach a high pitch the recorder player has to blow much harder than for low notes.

At low blowing velocities, oscillations for $\mathrm{Sr_W} = O(1)$ can be observed, when the jet thickness h is sufficiently small compared to its length W ($W/h > 4$). In that case the jet flow breaks down into a vortex street; two rows of discrete vortices spinning in opposite direction (Fig. 7.17). We call these multiple vortex flow patterns ($\mathrm{Sr_W} \geq 1$) the higher-order hydrodynamic modes.

The sound generation mechanism in flue instruments has long been a subject of debate. *Helmholtz* [7.2] suggested that the volume flow entering the pipe Φ_in was acting as a monopole sound source. *Rayleigh* [7.3] argued that the sound source should be a fluctuating force because the sound source was located close to a pressure node of the acoustic standing wave, where a volume source would be rather ineffective. The work of *Powell* [7.62] and *Coltman* [7.63] has definitively established that the sound is produced by the reaction force $\boldsymbol{F}_\mathrm{h}$ of the walls to the unsteady hydrodynamic force due to the jet interaction with the walls. Using the so-called *aero-acoustical analogy* of Lighthill–Curle one can demonstrate mathematically from the mass conservation law and the momentum equation for a fluid that this force is a source of sound [7.9, 62]. In a lumped element model, it is most convenient to describe the sound source as a fluctuating discontinuity $\Delta p_\mathrm{source} = \boldsymbol{F}_\mathrm{h} \cdot \boldsymbol{n}/S_\mathrm{b}$ in the acoustical pressure across the blowhole of surface S_b with normal vector $\boldsymbol{n}$. At low Strouhal numbers the jet behavior can be described by a linear model: the so-called *jet drive*. In this model the jet flow is separated at the labium into a part entering the pipe and a part leaving the pipe. Acoustically this corresponds to two complementary volume sources $\Phi'_\mathrm{in} = -\Phi'_\mathrm{out}$ placed close to the edge of the labium and oscillating in opposite phase [7.64, 65]. In first-order approximation these sources form a so-called dipole. In terms of acoustic power we have

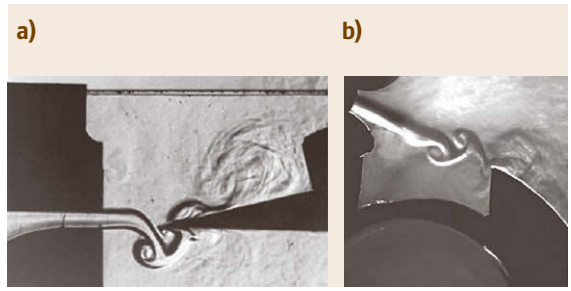

Fig. 7.17a,b Typical jet flow across the blowhole **(a)** of a recorder at $\mathrm{Sr_W} = 0.15$ and **(b)** of a transverse flute at $\mathrm{Sr_W} = 1$. Note the vortex shedding at the labium for low Strouhal numbers **(a)**. At the lower blowing velocities (higher Strouhal numbers) the jet breaks down into discrete vortices **(b)** before reaching the labium

$$\overline{P}_\mathrm{ac} = \frac{\omega}{2\pi} \int_0^{\frac{2\pi}{\omega}} \Delta p_\mathrm{source} u'_\mathrm{b} S_\mathrm{b} \mathrm{d}t \,, \tag{7.11}$$

where $u'_b S_b$ is the acoustic volume flux through the blowhole. Hence the source needs a large acoustical velocity to produce sound. This occurs at maxima of the amplitude (modulus) of the pipe admittance $1/|Z_p|$ [7.66]. When at higher Strouhal numbers the jet breaks down into discrete vortices (higher hydrodynamic modes), the so-called vortex-sound theory [7.67] provides an order of magnitude estimate for the sound source [7.65]. It would be however simplistic and misleading to think that sound is produced by the vortices. It is the interaction of the unsteady flow with the wall that produces sound. The motion of the vortices is associated with the hydrodynamic force on the wall. This vortex-sound theory allows the deduction of the force on the walls from an observation of the evolution of these vortices. The reaction force of the wall on the air is the source of sound. An accurate description of the sound production in flue instruments can only be reached by a solution of the equations describing the fluid motion (Navier–Stokes equations). Due to the nonlinearity of the equations, this is still a nontrivial numerical problem. Furthermore such a solution is actually a numerical experiment, which provides detailed information but little global insight. The jet-drive model and the discrete vortex model do provide some global understanding. Moreover, these caricatures can be used in lumped-element physical models for sound synthesis [7.68].

The amplitude of the transversal acoustic velocity u'_b through the blowhole reaches values as large as 25% of U_j [7.64, 65]. A consequence of this is that this transversal flow induces vortex shedding at the labium [7.69], which results in a nonlinear dissipation of the acoustic energy. This vortex shedding at the labium is a major amplitude limiting mechanism in flue instruments. It is interesting to note that when developing the modern flute Boehm increased the blowhole open area [7.16]. By doing this he increased the power. He thought that this was due to an enhanced radiation of sound. Actually this increased the jet flow velocity (at constant Sr_W) and reduced the nonlinear losses, for a given pressure amplitude in the pipe. The larger tone holes also improved the acoustics of the transverse flute [7.66].

An essential point is that the sound production in the flue instruments is due to the unsteadiness of the jet flow and primarily does not involve wall vibration. Consequently the material from which the walls are made is not critical and a golden flute is not necessarily better than a silver flute [7.70]. Of course the instrument maker can spend more time when building an expensive golden flute, so that such an instrument can be excellent.

While the sound production mechanism described above is common to all flue instruments, the acoustical response of the modern transverse flute is very peculiar and quite sophisticated. First of all, there is within the head joint a small cavity between the blowhole of the instrument and the end of the pipe closed by a *cork* (Fig. 7.16). This cavity is essential for the acoustics of the resonator. The depth of this cavity can be tuned to approach the response of a perfect open-open pipe with harmonic acoustical resonances $f_n = n\ f_1$ [7.7, 8, 39]. The cavity corrects for the fact that the pipe blowhole is narrow compared to the pipe cross-section ($S_b/S_p < 1$) inducing a locally higher acoustic velocity through the blowhole than in the pipe just upstream of the blowhole. This locally higher acoustic velocity induces an additional inertia of the acoustic flow through the blowhole. The fundamental frequency of the instrument corresponds to that of an open-open pipe with the actual pipe length L extended by a length correction δ_b: $f_1 = c_0/(L + \delta_b)$. The cavity provides the compliance corresponding to this additional pipe length. Because the cavity is closed (has a uniform pressure), while the virtual additional pipe segment is open (pressure increasing linearly with the distance from the pressure node at the open end), the cavity depth should be $\delta_b/2$ about half the virtual pipe segment length δ_b. Note that the pipe length L should also include another length correction δ_p to take into account the inertia of the acoustic flow around the open pipe termination. This so-called end correction is of the order of $\delta_p \simeq 0.7\sqrt{S_p/\pi}$. The exact value depends strongly on the ratio of pipe wall thickness to diameter and is strongly affected by the position of the player's lips. The closed chimneys of the tone holes also induce a difference between the effective acoustic length of the pipe and its actual length [7.6].

One of the subtleties of the Boehm flute is that the head joint is not cylindrical, as it was in baroque flutes. The head joint has a small convergence from 19 mm in the pipe towards 17 mm at the cork (closed-end). This is to make the correction for the harmonicity of the modes needed at higher pitches. For a stationary flow the pitch is constant, so that the sound source produces a signal consisting of pure harmonics of the fundamental frequency. We have a line spectrum. When the acoustic resonances of the pipe are also harmonically related, the sound is efficiently radiated. This makes the modern transverse flute sound rich in harmonics even though the labium is not as acute as in a recorder. In addition to this the musician can vary the distance between their lips and the labium by rotating the instrument around the pipe axis or modifying their lip's position. This allows for a correction of the pitch when changing the blowing pressure to achieve different dynamical levels. Hence the instrument can be played in tune for a much larger dynamical range than a recorder.

As the jet velocity is increased the jet becomes turbulent (Fig. 7.18) when the Reynolds number $\mathrm{Re}_h = U_j h/\nu$, with ν the kinematic viscosity of air, exceeds 10^3. Blowing with a turbulent jet against a sharp edge produces broad-band noise. Blowing with closed teeth produces such broad-band noise. This can be considered as musically interesting and is exploited in the Japanese flute (shakuhachi) and South American traditional flutes. The shakuhachi has a very sharp and acute labium, with edge angle of about 30°, which enhances the broad-band sound (noise) due to turbulence. In the Boehm flute the labium angle is about 60°, reducing the broad-band noise production. It is further interesting to note that turbulence tends to excite standing acoustic waves transversal to the pipe axis. The first of these transversal resonances has a *cutoff frequency* f_c corresponding roughly to a wavelength of twice the pipe width H. For square pipe cross-sections $f_c = 0.5c_0/H$ and $f_c \simeq 0.6c_0/D$ for cylindrical pipes of diameter D. For a piccolo flute $D \simeq 1$ cm corresponding to $f_c \simeq 20$ kHz, which is above the audio range. For a normal flute one finds $f_c \simeq 10$ kHz, which is high in the audio range. For a bass flute or a large organ pipe one finds $f_c \leq 5$ kHz, which is in the most sensitive frequency range of our hearing. Also the jet flow in large organ pipes will certainly be turbulent, while it remains laminar in a recorder. This partially explains the stronger broad-band sound in larger flue organ pipes compared to recorders [7.71].

Flue instruments have relatively long attack transients. While reed instruments, such as the clarinet and the oboe, reach a steady limit cycle within a few oscillation periods, the attack transient of a flue instrument can be several tens of oscillation periods $1/f_1$. This attack transient depends strongly on the initial perturbation in the instrument and the steepness of the increase in blowing pressure. When impulsively closing the holes in the pipe of an instrument, one can make the pipe oscillate. The instrument can be used as a percussion instrument, in the so-called *pizzicato* technique. For normal playing the initial oscillation obtained by abruptly closing the tone holes can significantly shorten the attack transient. In large (bass) recorders this technique is essential, because the instrument does not speak easily. When the pressure is increased without such an initial percussive drive, the instrument tends to start oscillating at a higher frequency than its fundamental pitch. This depends strongly on the ratio W/h of blowhole width W to jet thickness h. For $W/h \geq 10$ as in flue organ pipes one can observe an initial oscillation at about three times the pitch. This is because at small oscillation amplitudes (linear response) the low frequency amplification of perturbations convected by the jet is about a factor $\exp(2\pi) \simeq 530$ for each hydrodynamic wavelength $U_j/(2f)$ along the jet. Hence the third hydrodynamic jet mode is amplified about a factor 2.5×10^5 more than the first mode. This huge linear amplification will however soon induce nonlinear saturation by the formation of discrete vortices as shown in Fig. 7.17. Then the second hydrodynamic mode gets a chance to compete, and becomes dominant. Finally, the first mode slowly takes over, because it has lower radiation and viscous/thermal losses than the higher pipe modes. This complex attack transient can be reduced by using a short blowhole width $W/h \simeq 4$, such as in the recorder. For hydrodynamic wavelength shorter than about three times the jet thickness $fh/U_j > 0.2$ the jet does not amplify hydrodynamic perturbations. This implies that the attack transient of a recorder involves the second pipe mode (acoustic resonance), but not a third mode (Fig. 7.19).

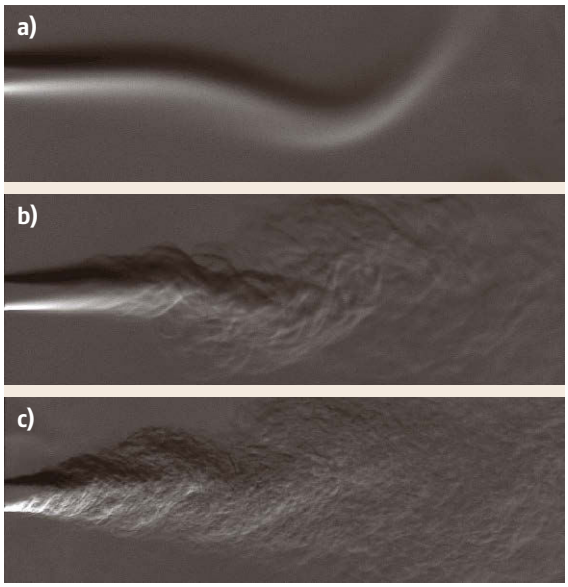

Fig. 7.18a–c Difference between laminar and turbulent jets: $\mathrm{Re}_h = hU_j/\nu = 200$ **(a)**, 500 **(b)**, and 3000 **(c)**. The jet is placed between two loudspeakers, inducing a transversal acoustic flow. This drives a jet oscillation as found in the blowhole of a flute

The higher hydrodynamic modes do not only appear during the initial phase of the attack transient. When blowing very softly they can produce sustained oscillations, which are called *whistle tones*. They are not only very weak, they are also less stable than the louder sounds obtained under normal playing conditions.

Under normal playing conditions, the acoustic oscillation of the pipe dominates the feedback loop, imposing a pitch close to a pipe resonance frequency. Flue instruments can however display, at low blowing pressures, oscillations dominated by local hydrody-

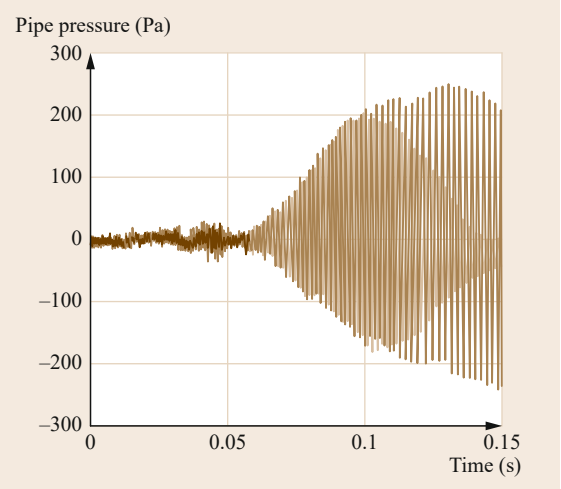

Fig. 7.19 Attack transient of a recorder (Ganassi flute of P. Bolton). Pressure in the pipe close to the labium. One clearly observes a dominance of the second acoustic pipe mode during the transient. In the initial phase of the transient even higher frequencies are shortly excited

namic feedback. This corresponds to so-called *edge tones* [7.62]. Edge tones can be recognized by the fact that the pitch increases linearly with the jet flow velocity. Such oscillations are called *mouth sounds* in organ pipes and are perceptively important [7.37, 38]. The perception of the sound quality is not only strongly affected by the attack transient, but also small variations in control parameters during the *limit cycle* oscillation strongly contribute. The flute player can vary the jet flow velocity U_j, the jet length W (distance between lips and labium edge), the jet thickness h and the offset y_{off} of the jet at the labium. By adjusting the Strouhal number $Sr_W = Wf/U_j$ the player can optimize the produced sound power or adjust the oscillation frequency f. The player can also vary the sound power by increasing h or U_j. When increasing the jet velocity U_j, the player has to change the jet length W in order to keep the pitch constant. This is commonly obtained by rotating the instrument around the pipe axis and/or moving the lips towards the labium. This also affects the passive acoustic response of the pipe, because it changes the end correction of the mouth of the pipe (the acoustic flow through the blowhole). The variation of h does not only affect the produced power, it also affects the attack transient. Indeed the ratio W/h determines the importance of higher hydrodynamic modes in the initial phase of the attack. It also influences the steepness of the attack. Also the offset y_{off} of the jet at the labium is crucial for the attack and the sound quality. When the jet is symmetrical with respect to the labium $y_{off} = 0$ the second harmonic in the sound is reduced. In the pipe, the amplitude of the second harmonic is typically reduced by an order of magnitude compared to the case $y_{off}/h = 0.4$, which is typical for a recorder. This will not only affect the sound quality, but also the pressure threshold for overblowing to a higher octave. The offset is not only determined by the flow direction at the outlet of the lip opening (flue). Due to the Coanda effect (pressure gradient induced by viscous flow entrainment), the jet tends to deflect towards the pipe wall. This effect is stronger for turbulent jet flow because turbulence enhances flow entrainment. This effect is so strong at the labium that a turbulent jet tends to *glue* to the labium, which reduces the offset at the labium. Hence upon laminar-to-turbulent transition one observes a drastic reduction of the second harmonic in the internal spectrum of the flute. In flue organ pipes this attachment of the turbulent jet to the labium is avoided by the use of very large mouth height ($W/h > 10$). A consequence of this is that higher hydrodynamic modes appear during the transients.

Small modulation of the sound, *vibrato*, during the limit cycle oscillation is often used to increase the liveliness of the sound. In extreme cases, this can be obtained by the player by singing into the flute (phonation).

This short discussion indicates that a virtuoso player has to control a lot of parameters to obtain a certain sound quality. This also makes modern transverse flute playing quite difficult. Indeed, this corresponds to an *expert* skill for which a typical intensive training period of ten years [7.72] is required before playing at professional level. As a result of this training, players produce highly repeatable and personal control on the instrument, as can be observed for instance from the dynamic shaping of the blowing pressure.

8. Properties of the Sound of Flue Organ Pipes

Judit Angster, András Miklós

This chapter is an overview of the characteristic sound properties of flue organ pipes. The characteristic properties of the stationary spectrum and attack transient have been surveyed and assigned to properties of the physical systems (air column as acoustic resonator, air jet as hydrodynamic oscillator, and pipe wall as mechanical resonator) involved in the sound generation process. The measurements presented underline the primary role of the acoustic resonator in the stationary sound and of the edge tone in the attack.

The pipe organ produces a majestic sound which differs from all other musical instruments. The richness and variety of timbre cannot be matched, because of the almost uncountable possibilities for mixing the sounds of different stops. The different stops of the organ also show a large variety in the richness of timbre; this is achieved by the proper selection of pipe shape, dimensions, wall material, shape and size of the opening(s) etc. The flue pipe ranks are divided into three groups according to their characteristic sound. The flutes produce a fundamental sound with fast attack, the diapason family can be characterized by their strong second partial especially in the attack, while the string family has a very bright sound with more than 20 harmonic partials, but with a slow attack.

Although the main features of the sound of flue organ pipes have been investigated extensively [8.1–6], the understanding of the connection between sound character and pipe shape and dimensions is still incomplete. Conversely, the sound character of the different ranks is unambiguously associated with pipe shape and measurements in the tradition of organ building [8.7–9]. Although the timbre, especially the attack, may be changed significantly by voicing adjustments, the main characteristics of the sound are quite stable for a given stop, and depend mostly on the form and scaling of the pipes. Nevertheless, the organ-building tradition cannot provide a proper explanation of the great variability of the sound character among the different stops on one hand and an explanation of the high stability of the sound character within one stop on the other hand. It is of interest to scientists that only a limited number of all the possible dimensions (diameter, wall thickness, cut-up height, flue width, etc.) and materials, which could be varied are actually used for organ pipes. Some of these limitations are technological in nature, but most of them have no basis in science. Consequently, several researchers have shared the view that the limitations of organ building need not be taken into account in experiments. This is the critical point of many of the scientific investigations carried out to date. Many scientific experiments published in the acoustic literature have been performed on models which differ considerably from real organ pipes. Consequently, the dimensions, shapes, and materials often did not fall within the narrow ranges used in organ building. According to the opinions of organ experts such experiments cannot model the operation of real organ pipes and, therefore, the results are useless for organ building. This view expressed by most organ builders, has frequently resulted in a rejection of attempts at mutual cooperation.

According to the opinion of the authors the right way lies somewhere in the middle. When basic phenomena are studied, experiments on models are ac-

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_8

ceptable. But the fine details of pipe sounds should be investigated on real organ pipes. Moreover, all physical effects contributing to the production of sound should be taken into account; an investigation limited to a specific parameter may lead to misinterpretation of the results. During the last 15 years the authors have carried out numerous experimental and theoretical investigations concerning the acoustic properties of flue organ pipes and the possible mechanisms of their sound generation. Although several questions are still unanswered, a better understanding of the processes involved and their interactions has been achieved.

8.1 Experimental Methodology

Although flue pipes offer a very wide variety of sound, the measured properties of these sounds contain several common elements which can be used to characterize them. In order to determine such characteristics, reproducible measurement methods have to be applied. The fact that open flue pipes radiate sound from both openings [8.10] should be taken into account when planning measurements. Since a sounding pipe produces an interference field even in an anechoic room, the measurement is extremely sensitive to the location of the microphone. The spectral envelope especially can change drastically with location, because changes in the distances to the openings mean different phase shifts for the different partials. Therefore, the measured spectrum may be more characteristic of the microphone location than of the properties of the pipe.

If the microphone is placed close to one opening of the pipe, the signal radiated from the other opening is negligible because of the much larger propagation distance. Although the magnitudes of the measured spectral components will decrease rapidly with the microphone-opening distance, their phases will remain almost constant, because the source-microphone distance is much smaller than their wavelengths. The sound pressure level of every spectral component will change by the same decibel value when the distance changes. Thus, the relative strengths of the spectral components will be quite insensitive to the location of the microphone. Therefore, the simplest method for obtaining reproducible spectral envelopes is the measurement in the vicinity of one of the openings.

The research was carried out mostly by laboratory experiments, although in situ measurements were also performed. A small slider chest was placed in the anechoic room; the wind was supplied by a centrifugal fan through a bellows. The fan and the bellows were located outside the anechoic room. A flexible tube with 80 mm diameter was used for connecting the bellows to the slider chest. The pallet in the slider chest was operated by an electromagnet, or it was manually fixed in an open position for measuring stationary sound.

For the characterization of the pipe sound usually three measurements were used: the stationary spectra at the mouth and the open end, and the attack transient at the mouth.

- *Stationary spectra* were measured and analyzed by a two-channel spectrum analyzer (HP35670A). In order to avoid interference the microphones usually were placed close ($\approx 3-5$ cm) to the openings of the pipes.
- *Attack transients* were directly converted to digital data and were evaluated using a special computer program [8.11] developed by the authors. The time evolution of the first 18 harmonic partials can be followed with this program. The results can be displayed in two groups (1–9th or 10–18th partials).

8.2 Steady-Sound Characteristics

In the last 15 years several hundred flue organ pipes have been investigated in our laboratory. The detailed evaluation and comparison of the measured spectra have revealed several features, which seem to be characteristic properties of the spectra of flue organ pipes.

The stationary spectra of a Diapason pipe can be seen in Fig. 8.1. These spectra show the most important properties of the sound of flue pipes. Characteristic features of the sound spectrum of a flue organ pipe can be listed as follows:

1. A series of harmonic partials
2. A second series of smaller and wider peaks, which are not harmonically related, but slightly stretched in frequency
3. A frequency-dependent base line

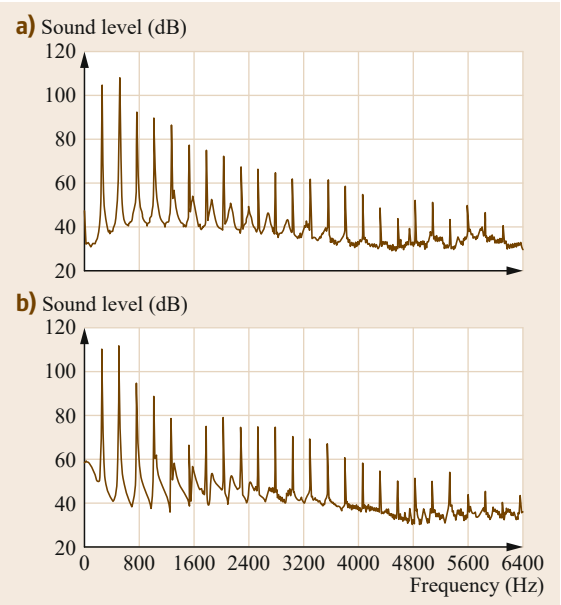

Fig. 8.1a,b Typical stationary spectrum of a flue organ pipe **(a)** at the open end, **(b)** at the labium

4. Envelope of the harmonic partials
5. Different spectral envelopes at the mouth and open end
6. Irregularities in the high-frequency part of the spectrum
7. Sharp, nonharmonic lines in the high-frequency part of the spectrum
8. Weak subharmonic components halfway between the partials.

Features 1–6 can be recognized in Fig. 8.1. Spectra containing features 7–8 will be shown later. In the following, the above features will be demonstrated with several measured spectra.

8.2.1 Physical Phenomena Related to the Observed Characteristic Features

The features of the spectrum are related to the physical properties of the flue pipe. The assumed physical reasons are summarized in Table 8.1. More detailed description of the phenomena can be found in the references given in the last column of Table 8.1. Short explanations for all items found in the second column of Table 8.1 follow:

1. It is well known from the elements of Fourier theory [8.12] that a periodic signal can be regarded as the convolution of only one period with an infinite series of Dirac-delta pulses separated by the period T. The Fourier transform (FT) of such a convolution will be the product of the FTs of the components. Thus, the FT of a periodic signal contains a series of harmonic partials (FT of the Dirac-delta pulse train) multiplied by an envelope determined by the FT of a single period. Therefore, any periodic signal with complex time waveform must have a lined spectrum with several partials and a complicated spectral envelope.
2. The small, broad peaks shown in the spectrum demonstrate the presence of acoustic eigenmodes of the pipe. This statement can be tested experimentally by using external acoustic excitation. Such demonstrations are regularly presented on the organ acoustic courses of the authors [8.13]. If a pipe is placed in the sound field generated by a loudspeaker, it will amplify the frequency components which correspond to the eigenresonances. Placing a small microphone in the pipe and using white noise excitation the eigenresonance spectrum can be determined. Such a spectrum is shown in Fig. 8.2 for a cylindrical tube. The 60 cm long 31 mm diameter tube was made of a lead-tin alloy (organ metal). The eigenresonances are slightly stretched; the frequencies are a bit higher than the harmonics of the first resonance. The stretching of the eigenfrequencies is much more pronounced in open organ pipes. In the spectrum of a Diapason pipe (Fig. 8.1a) the 9th eigenresonance lies about halfway between the 9th and 10th harmonic partials. The stretching becomes larger for larger diameter/length ratio and for smaller openings at the pipe ends. Conversely, conical pipes have smaller stretching, which decreases with increasing angle. At a certain angle the

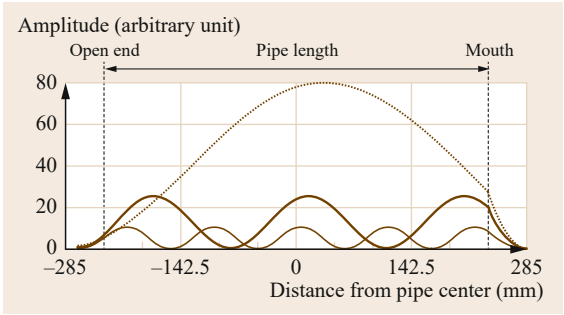

Fig. 8.3 Standing waves in an organ pipe. The sound pressure distributions of the 1st, 3rd, and 5th eigenmodes in a Nachthorn pipe

eigenresonances are harmonically related; above this angle they are even compressed.

These experimental facts can be understood by taking into account the physical properties of the organ pipe as an acoustic resonator. The air column in the pipe has several eigenmodes (standing wave patterns) with characteristic resonance frequencies (eigenfrequencies). Since the diameter is always much smaller than the length of the air column, the pure longitudinal eigenmodes appear first. Their frequencies are not harmonically related because of the *end correction* [8.10], which decreases with the frequency. As the *end correction* is proportional to the pipe diameter the stretching of the eigenfrequencies is larger for wide pipes than for narrow ones. Moreover, the *end correction* for a small opening (mouth) is larger than that of the larger open end. Therefore, the eigenfrequency stretching of an organ pipe is larger than that of a tube with the same length and diameter. Because of the different end corrections at the openings the standing wave is located asymmetrically inside the organ pipe [8.18]; it is shifted towards the smaller opening.

The measured asymmetry of the 1st, 3rd, and 5th eigenmodes in a Nachthorn (fairly wide) pipe are shown in Fig. 8.3. Besides the asymmetry it can also be observed that the phases of the measured sound pressure signals at the ends are fairly different from the multiples of π, because of the end corrections.

The pipe resonator can be unambiguously characterized by its eigenmodes. Each eigenmode is represented by three quantities: the resonance frequency, the quality (Q)-factor, and the position of the standing wave inside the pipe.

The pipe resonator, as all resonant physical systems, can collect and store energy in its eigenmodes. In case of a continuous excitation an equilibrium will be reached when the energy gain taken from the excitation compensates for the energy losses of the eigenmodes. The equilibrium ratio of the energy stored in an eigenmode to the energy lost in a period defines the Q-factor of the eigenmode. The numerical value of the Q-factor can be easily calculated by dividing the resonance frequency by the FWHM (full width at half maximum) value of the resonance curve. Since a resonator can absorb and emit energy only in small amounts, several periods are needed to reach equilibrium during the excitation or to lose the energy after the excitation ceased. The number of periods necessary to gain or lose 99.8% of the stored energy is given by 2Q. Therefore, the Q factor limits the speed of the attack significantly. The speech of a high-Q pipe must be slow, while a low-Q pipe can have a prompt onset. Conversely, the Q-factor gives the value of the peak amplification of the resonator. Thus, the sound pressure inside the pipe is usually much higher for a high-Q pipe than for a low-Q pipe.

3. The base line of the spectrum (Fig. 8.1) is determined by the broadband noise at the mouth of the pipe. This noise is produced at the flue and the upper labium [8.14, 27]. Quasirandom changes of the jet direction caused by turbulence in the foot [8.15] of the pipe also influences the noise. Moreover, tonal components (edge tone, see later) are also present in this background. Since the resonator amplifies this noise around the eigenresonances, the amplified noise may dominate the sound of the pipe in the high-frequency range, where the partials of the fundamental are usually weak. The high-frequency noise content can be very effectively reduced by nicking [8.16]. This method can increase the ratio of the harmonic partials to the base line very significantly.

4a. The form of the envelope depends on the total losses in the pipe; these consist of the sum of the volume losses in the air, the surface losses at the pipe

	Viscous loss	Radiation loss		Total loss	Quality factor Q	Spectrum
		Open end	Labium			
Narrow pipe (–12 HT)	9.7	0.8	4	14.5	70	
Normal pipe	5.7	2.4	12	20.1	50	
Broad pipe (+12 HT)	3.5	6.7	34	44.2	23

wall due to viscosity and heat conduction, the radiation losses at the openings, and the energy loss due to the coupling of sound to wall vibrations. For organ pipes surface and radiation losses are much larger than the other two effects. The surface losses are theoretically [8.17] proportional to the factor $1/R\sqrt{f}$, while the radiation losses scale with R^2f^2, where R and f are the pipe radius and frequency, respectively. At the same frequency surface losses are relatively larger and radiation losses relatively smaller for narrow pipes than for wide pipes. Since surface losses decrease and radiation losses increase with the frequency a loss minimum occurs at a certain frequency. Indeed, such a loss minimum can be observed in narrow pipes, i. e., the largest amplitude occurs not for the fundamental, but for a higher partial. The theoretical frequency dependence of the envelope, which is inversely proportional to the total loss, is shown in Fig. 8.4 for narrow, normal, and wide organ pipe resonators. Measured spectra of a narrow and a wide pipe are shown in Fig. 8.5. In the case of the wide pipe resonator there are less higher partials, the amplitudes decrease faster with frequency and the stretching of the eigenmodes is bigger than by the narrow pipe resonator.

4b. Organ pipes radiate sound mostly at their openings. Although the pipe body can also radiate sound, this contribution can be neglected (see 6b in this list). Since the openings are much smaller than the wavelength of the sound, both of them can be regarded as simple sources (monopoles) with the source strength given by the acoustic flow at the openings [8.10, 18]. The envelope of the harmonics of the radiated spectrum shows a formant-like structure with a minimum (around the 6th partial in Fig. 8.1b). Although this phenomenon has been observed for sounding pipes, it can be explained by taking into account only the properties of the acoustic resonator. It is well known that the half-wavelength of the sound is longer than the length of the pipe (the *end correction* problem). Thus, the sound pressures at the open ends are nonzero. Assuming an end correction ΔL_m at the mouth the

sound pressure can be written as $p = P\sin\{k_1(x + \Delta L_m)\}$, where $k_1 = 2\pi/\lambda$ is the wavenumber. The spatial phase (the argument of the sine function) at the mouth ($x = 0$) then equals $\varphi_1 = k_1 \Delta L_m$. That is, the spatial phase of the standing pressure wave is larger than zero at the mouth [8.18]. The deviation φ_1 can be regarded as a phase correction for the mouth.

The spatial phase for the harmonic partials at the mouth can be determined simply by substituting the wavenumber of the fundamental k_1 with the corresponding wavenumber of the N-th partial, $k_N = Nk_1$. The spatial phase for the N-th partial at the mouth can then be written as $\varphi_N = N\varphi_1$. Since the acoustic flow depends on the cosine of the spatial phase [8.18], the sound pressure radiated from the mouth will have a minimum when $N\varphi 1$ approaches $\pi/2$. The first minimum of the envelope is determined by the diameter of the pipe and the size of the mouth opening. For normal Diapason pipes (mouth width $\approx 1/4$ circumference, mouth height $\approx 1/4$ mouth width) the first minimum lies in the range of the 5–6th partial (see Fig. 8.1b). For wide pipes the minimum may occur already around the 3rd partial (Fig. 8.5b), for narrow pipes it is shifted up to the 7–8th partials (Fig. 8.5a).

4c. As was mentioned in 1a above, the spectral envelope is determined by the spectrum of a single period of the sound. The shape of the temporal signal depends also on the excitation by the air jet. It was shown [8.20] that by changing the relative position of the jet and the upper lip the harmonic content of the sound can be influenced. When the jet moves symmetrically around the upper lip, no even harmonics are excited [8.10]. Probably such a symmetry effect is responsible for the weakness of the 2nd partial in Fig. 8.6. Nevertheless, this effect is not very important for real organ pipes, because the normal motion of the jet is quite asymmetric [8.21].

4d. The relative position of a harmonic partial and the neighboring eigenmode influences the amplitude of that partial. If the harmonic frequency is close to the eigenfrequency, the partial will be amplified by the eigenresonance. A harmonic partial lying midway between two eigenmodes will not be amplified. Therefore, the stretching of the eigenmodes also influences the envelope of the partials. In the case of small stretching (narrow pipes) several partials will be amplified, while for wide pipes the 3–4th partials are located in the valley between the eigenmodes. Nevertheless, as higher partials approach the peak of the one-index-lower eigenmode, they will also be amplified. This effect can be seen in Fig. 8.1b.

5. It has been shown [8.19] that the radiated acoustic field corresponds to that of two simple sources located at the openings of the pipe. The simple sources radiate in-phase for the odd partials and out-of-phase for the even ones. The strengths are

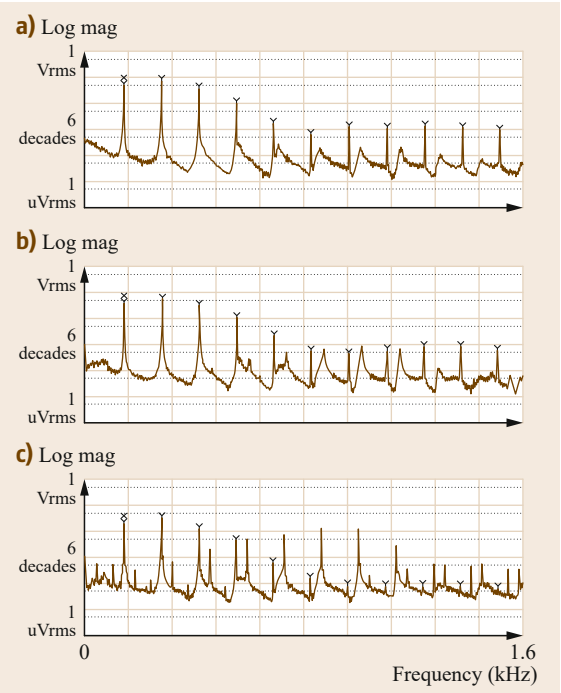

Fig. 8.8a–c Formation of the second sound of the Salicional pipe for decreasing wind pressure

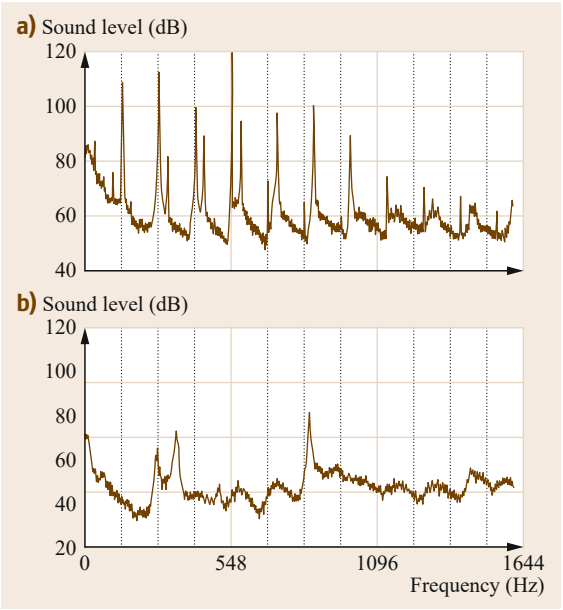

Fig. 8.9 (a) Sound spectrum of the Salicional pipe. **(b)** Mouth tone of the same pipe (the pipe sound was stopped by an absorbing termination at the open end)

different for both sources, and the two openings radiate different spectra [8.18]. The spectra of the sound radiated at the openings are different, because the standing waves in the pipe are asymmetrically located (see Fig. 8.3). Since the end correction is inversely proportional to the area of the opening [8.10, 18], the envelope minimum occurs for a smaller serial number of partial at the mouth than at the open end, in accordance with the experimental observations. That is, the spectral envelopes at the mouth and open end are always different. It may accidentally happen that the effective opening at the open end has about the same size as the mouth (for example when a tuning slot is applied). In such cases the symmetry may be restored, or the standing wave may even be shifted towards the tuning slot. Slight changes in the geometry of the openings can thus result in significant alterations of the radiated spectra. Another important parameter is the overlapping of the envelope minimum with a certain partial. It can be seen by comparing Figs. 8.1b and 8.6b that a very deep envelope minimum exists in Fig. 8.6b at the 5th partial (almost perfect overlapping), and only a slight decrease of the 6th partial in Fig. 8.1b (bad overlapping). Since the envelope minimum is shifted by certain voicing steps (for example by the change of the cutup), the voicer can influence the spectral envelope of the steady sound.

6a. Irregularities in the range of higher harmonics can be caused by the excitation of transverse resonances of the pipe. It is well known [8.10] that above the cut-off frequency of the pipe ($f > 200/d$, where d is the pipe diameter in meters) radial, azimuthal and mixed transverse modes exist. Certain pipe ranks may have harmonic partials well above the cut-off, therefore, transverse resonances can appear in the spectrum between the harmonic partials (Fig. 8.1, first transverse resonance ≈ 4.6 kHz). These resonances are excited by the high-frequency noise or edge tone at the upper lip.

6b. It has been shown [8.22, 23] that wall vibration cannot radiate sound directly. Conversely, a linear coupling exists [8.24] between the air column and the pipe wall for rectangular pipes, and also for cylindrical pipes if the pipe cross section is not a perfect circle, but slightly elliptical. In this case, wall vibrations can influence the sound radiated at the openings [8.23]. If a sharp vibration mode is close to an eigenmode or harmonic partial of the pipe sound, both modes will be coupled, which leads to a slight detuning of the corresponding sound component [8.25]. Nevertheless, such a coincidence is quite rare in practice.

7. It is very characteristic, especially for metal pipes in the $1'$ and $2'$ stops, that nonharmonic sharp

peaks occur on the sides of high-frequency partials (Fig. 8.7a). These components give a roughness and a metallic character to the timbre. It was assumed [8.23] that these additional peaks can be assigned to wall vibrations, but recent investigations revealed that this phenomenon is probably caused by the excitation of higher eigenmodes by a higher component of the edge tone. This effect can be avoided by properly adjusting the edge tone, or by reducing the levels of the higher eigenmodes by nicking (Fig. 8.7b). Similar nonharmonic peaks were produced for example by reducing the wind pressure gradually. In this case the acoustic properties of the resonator do not change, while the edge tone frequencies shift downwards. It can be seen (Fig. 8.8) that certain eigenmodes (6th and 7th) start to grow. On further reducing the pressure the pipe produces two pitches, one corresponding to the fundamental and a second one corresponding to the virtual pitch of the second series of peaks. Stopping the pipe sound by an absorbing termination the so-called mouth tone (Chap. 3) shows a sharp and strong component around the 6th eigenmode (Fig. 8.9). This component may be responsible for the excitation of the second sound of the pipe.

8. Subharmonic peaks exactly halfway between the harmonic partials can be produced by strong nonlinear coupling between sound and wall vibration. The physical mechanism of such an interaction can be found in [8.26]. The phenomenon can be understood as follows: The pipe wall, if vibrating, undergoes an elliptical deformation of the originally circular cross section. As the area of an ellipse is always smaller than that of a circle with the same circumference, the cross-sectional area of the pipe will be modulated by a double frequency. The modulation of the cross section modulates the acoustic flow in the pipe, thus a coupling occurs between the sound and the wall vibration with about half of the sound frequency. Conversely, the oscillating sound pressure generates a periodic stiffening of the pipe wall; this effect can be regarded as a time-dependent elastic constant. The effect leads to a parametric instability of the wall. Because of this nonlinear coupling the wall and the air column can oscillate at half of the sound frequency. Such an effect was observed in the acoustic laboratory of the Fraunhofer-Institute in Stuttgart [8.23] with a very thin-walled pipe. This pipe is used in a church organ, but the nonlinear vibrations are damped by means of plastic adhesive tape wrapped around the pipe at about one third length from the mouth. Removing the tape causes the nonlinear vibration to increase tremendously. The comparison of Figs. 8.10a and 8.10b clearly show this effect. However, hardly any change can be seen in the corresponding sound spectra (Fig. 8.11), although some changes are evidenced in the levels of the

higher harmonics. Subharmonic components can be seen between the fundamental and the 2nd and between the 2nd and 3rd partials.

The explanations given above show that several different mechanisms influence the steady sound of the pipe. Nevertheless, even the most complicated features could be assigned to the measurable and understandable physical properties of flue organ pipes. Certainly, this is just a synopsis; more detailed analysis instead of the short descriptions given above will be published in the near future.

8.3 Edge and Mouth Tones

Since the edge tone seems to play an important role in the attack, the characteristic properties of the edge and mouth tones will be surveyed preceding the discussion of attack transients.

The air jet emerging from the flue and hitting the upper lip produces a very characteristic sound (jet sound), which is called *edge tone* in this chapter, because the edge tone is the dominant component of the jet sound. In order to study the edge tone without the influence of the acoustic resonator so-called *foot models* were used [8.28]. A foot model is essentially a flue organ pipe without acoustic resonator; it consists of a foot, a flue, and an upper lip only. The primary excitation of the organ pipes can be studied also by reducing the sound reflection (terminating the pipe with an absorber) from the other end below the threshold of oscillation. The sound heard in this case is called *mouth tone* and its role in the attack of the flue pipes was recently extensively investigated [8.29]. In the following the most important results of the research of the authors on edge and mouth tones will be surveyed.

8.3.1 Edge Tone of a Foot Model

The sound produced by the foot model has a very interesting character. It is noisy, the amplitude fluctuates, but it does have a definite pitch. The spectrum of the edge tone clearly shows the mentioned features (Fig. 8.12). It contains at least two or three peaks, which are not harmonically related, and a broadband base line, which decreases with the frequency. In the high-frequency range ($f > 10$ kHz) other very broad maximums may occur. The presence of the peaks shows that several hydrodynamical modes can coexist in the edge tone. Several theoretical and experimental works have been published about edge tones [8.30–33], but they cannot be used directly for organ pipes. Organ pipes utilize only a very limited range of wind pressure (usually 500–900 Pa), therefore the jet velocity is also limited. However, very detailed data are needed within this limited range. Therefore, extensive investigations have been carried out in the laboratory [8.15, 28, 34] in order to determine the main parameters of the edge tone and their dependence on the mouth dimensions and pressure. The main results can be summarized as follows:

- The jet emerging from the flue is not symmetric to the vertical plane containing the flue but bends slightly towards the lower lip. The angle of deviation from the vertical direction depends on the relative position of the lower lip and the edge of the languid.

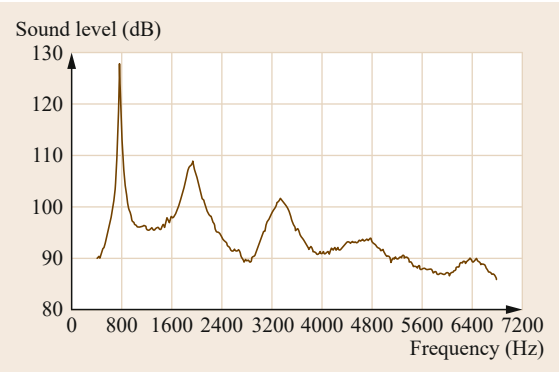

Fig. 8.12 Typical spectrum of a foot model (edge tone)

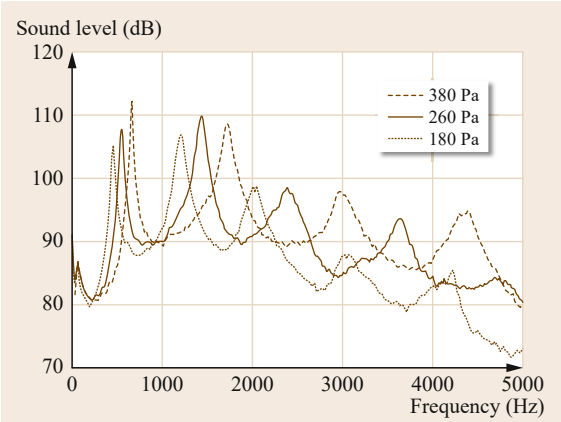

Fig. 8.13 Comparison of spectra of a foot model (edge tone) as a function of wind pressure

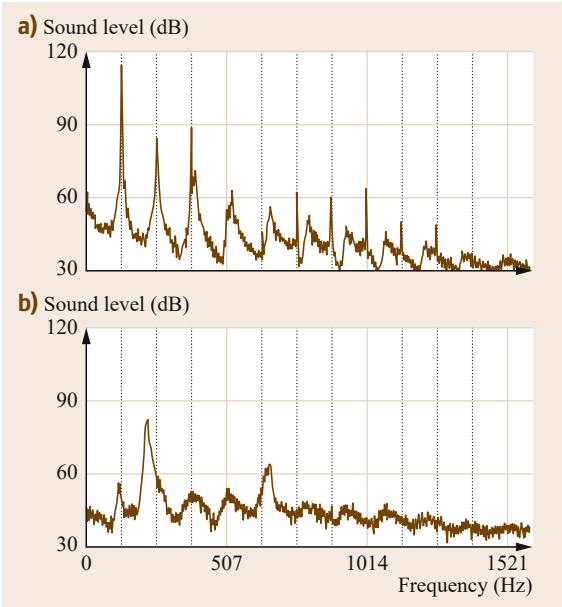

Fig. 8.14 **(a)** Sound spectrum of the Diapason pipe shown also in Fig. 8.4. **(b)** Mouth tone of the same pipe (the pipe sound was stopped by an absorbing termination at the open end)

- The jet broadens with the distance from the flue, but the angle is quite small (only 3–5°).
- The source of the edge tone is an acoustic dipole located slightly above the edge of the upper lip. The dipole character can be observed in the spatial distribution of the edge tone.
- The peaks of the edge tone spectrum move downwards in frequency when the jet velocity at the upper lip decreases (pressure decreases or the distance between the flue and upper lip increases) (Fig. 8.13).
- The peaks will be compressed with decreasing and stretched with increasing jet velocity (see Fig. 8.13). When moving downwards, more and more peaks appear, and the maximal amplitude shifts from the lowest peak to the second one.
- No jump or hysteresis of the edge tone frequency can be observed in the pressure range of the investigations.
- The build-up of the edge tone is very fast compared to that of the sound of a pipe having corresponding dimensions.
- The amplitude fluctuations are produced mostly by pressure fluctuations in the foot. Two stable flow states were observed in the foot [8.15, 28], and it is assumed that the flow randomly oscillates between them, producing quite large pressure changes at the flue. Indeed, the edge tone became more stable and the peaks in the spectrum became sharper when the flow was forced to remain in the selected flow state.

8.3.2 Mouth Tone of a Damped Pipe

When the jet hits the upper labium, an edge tone is generated. The rise time of the edge tone is very short, therefore it is already present at the mouth area well before the air column (the acoustic resonator) can enter into the game. As mentioned, the source of the edge tone is an acoustic dipole located slightly above the upper lip [8.14], thus the edge tone is immediately radiated outwards from the upper lip area. Since a dipole can be regarded as two simple sources with opposite phase, the same signal with opposite phase is radiated into the pipe simultaneously. This component, emphasized by the response of the resonator, is re-radiated by the mouth. Both components together form the mouth tone.

Mouth tones are also regularly studied in the laboratory. Their measurement is unfortunately quite difficult, because the effect of a termination of the open end with an absorber is twofold; not only will the amplitude of the reflected signal be reduced, but also the phase shift will be influenced. Reliable results can be obtained only if small phase shifts are produced by the absorber. From this point of view a low density rockwool absorber proved to be the best [8.34].

The mouth tone has a very similar spectrum to the edge tone. The only difference is that the broadband base line will be emphasized slightly by the (damped) eigenmodes of the pipe (Fig. 8.14). The subjective impression is also very similar; mouth and edge tones have the same character. The build-up time of the mouth tone is also very fast; it is comparable to that of the edge tone.

8.4 Characteristics of the Attack Transients

In the attack of the flue organ pipes three phases can be subjectively distinguished. These parts cannot be entirely separated in time, because they overlap quite broadly. Perhaps it is better to speak about three components, which start almost simultaneously, but with different rates of development. These three components can be characterized as follows:

1. *Forerunner*: This is the sound heard first. It is very difficult to describe. It may have a pitch, but sometimes no pitch can be assigned to it. Several different terms are used for this component (chiff, ping, hiss, cough, etc.). A detailed description of this phenomenon [8.29] was published recently.
2. *Appearance of a pitch*: The second component in the attack usually has a pitch close to the pitch of a higher harmonic partial. This component is very important for certain stops. For example, for several Diapason stops the second or the third harmonic can be heard preceding the fundamental, for Quintadena stops the third component is always prominent, while for narrow string stops this component often overlaps with the domain of higher (6–7th) harmonics.
3. *Onset of the fundamental*: The third parameter of the attack is the rise time of the fundamental. For stops of the flute family this rise time is very short, for stops of the string family it is very slow. As the fundamental grows certain components of the attack simultaneously become weaker.

The presence of the first two components is not compulsory in the attack. Moreover, the voicer can influence the attack very much, thus, according to his taste, he can produce faster or slower attack, more or less forerunner, brighter or more fundamental sound, etc. It is worth mentioning that sometimes one or more partials are quite strong in the beginning of the attack, but later they become weaker. Such behavior is often displayed by the fifth harmonic of the Diapason pipes.

The measurements show that the perception of the attack can be assigned to measurable properties. The attack transient of a Diapason pipe is shown in Fig. 8.15. This measurement was performed with the help of a computer program developed by the authors [8.11]. The sound was measured at the mouth of the pipe and the signal was converted to digital data by a 16-bit AD converter. A running window was shifted along the time recording, and a 256-point FFT was calculated at every step, then the levels of the harmonic partials were determined. About 250 FFT calculations were performed, then the levels of the first nine partials were displayed as functions of time. Since the frequency resolution is quite low, the method is not sensitive to minor changes in frequency. The three parts of the attack can be clearly distinguished in Fig. 8.15. The forerunner appears in every partial, implying its broadband nature (chiff). Then the partials start to grow; the fastest component is the 6th one. After a while the second will be the strongest; it dominates the attack in the 35–40 ms domain. The fundamental slowly overtakes the 2nd, which becomes slightly weaker as the fundamental rises.

The presented characteristics of the attack of flue pipes are very general, they can be found in almost all pipe sounds having been measured during the last 15 years. It can be assumed that these characteristics are related to the basic physical properties of the pipes. These relations will be investigated in the next section.

8.4.1 Physical Phenomena Related to the Observed Features of the Attack

The features of the attack can also be explained by the physical properties of the flue pipes. The reasons for the different features are summarized in Table 8.2. A more detailed description of the phenomena can be found in the references given in the last column of Table 8.2. A short explanation is given later for all items found in the second column of the Table.

1a. In order to understand the onset of the sound the events should be followed in the time domain. When the corresponding valve is opened (the key is pressed), the pressure in the pipe foot suddenly increases and, as the pressure difference drives the air through the flue, a jet is formed. As the jet

3	a) Locking of the jet to the fundamental b) Shift of the frequency to the corresponding harmonic partial	[8.37] This chapter

emerges from the flue, turbulent noise is produced by the flow. First, a pressure pulse is produced, then broadband noise appears due to the turbulence of the jet [8.14]. Both sound components are broadband, no pitch can be assigned to them. This sound is radiated directly from the mouth area without any contribution from the acoustic resonator.

1b. When the jet hits the upper labium, an edge tone, which will be transformed within a very short time to a mouth tone, is generated. Since the jet velocity increases within the first ≈ 10 ms of the attack from zero to the final value [8.37], the mouth tone cannot develop a certain pitch, its frequency and spectrum change continuously according to the jet velocity change. This sliding signal produces the special hearing sensation in the forerunner. If the rise time of the jet velocity is very fast compared to the period of the edge tone, only a short sound pulse can be observed.

2a. The eigenresonances of the acoustic resonator need about ten times longer than the nearby mouth tone component for the sound to build up. Since the effect of the weak sound components on the transversal motion of the jet is small at the beginning, the already developed mouth tone provides a larger contribution to the excitation than the still weak feedback of the acoustic resonator. Therefore, the tonal components of the mouth tone will excite the nearby eigenmodes of the air column. Since the mouth tone has several spectral components more eigenmodes could be excited simultaneously. Among these eigenmodes the highest will grow the fastest, because the rise time is smaller for higher eigenmodes than for the lower ones. This effect can be clearly observed in Fig. 8.15. It can be seen that the first excitation occurred around the 5–6th eigenmode, followed by the excitation of the 2nd eigenmode by the strongest component of the mouth tone. A well-trained ear can hear these components as a fast changing pitch in the speech of the pipe.

2b. For narrow pipes the onset of the fundamental is usually very slow. Since the higher eigenresonances have large Q-values, these higher components also need a long time to build up. Therefore, the mouth tone can be heard (and observed) between the forerunner and the onset of the sound of the resonator. A good voicer can adjust the edge tone so that a tone reminiscent of a harmonic component of the steady sound can be heard. Such voicing produces very pleasant pipe speech.

3a. The fundamental tone starts to grow also, because the reflections from the ends of the pipe amplify this component most effectively. As the signal grows in the resonator, the sound pressure and the acoustic flow at the mouth become so large that they can influence the movement of the jet. After a while the transverse movement of the jet will be locked to the fundamental [8.29], and a self-sustaining oscillation will be developed [8.10, 14]. The time needed for achieving the fully developed steady state depends mostly on the Q-factor of the fundamental eigenmode of the pipe. Since the Q is small for wide pipes (flute ranks), medium for Diapasons and high for the string stops, the duration of the attack scales accordingly (prompt attack for flutes, slow speech for the string family).

3b. The frequencies of the higher components of the sound and the pressure distribution in the pipe change during the stabilization process until the final steady state is achieved. During this process the higher components shift from the eigenmodes to the partials of the fundamental. These changes could be quite large, because the eigenmodes have their own spatial distribution which depends only on the boundary conditions at the openings (see Fig. 8.6), while the spatial distribution of the partials depends only on the fundamental standing wave. The change of the spatial phase at the openings influences the sound radiation, therefore the magnitude of the partial closest to the envelope minimum of the stationary spectrum will decrease to the steady level. In the case of Diapason pipes the minimum usually lies around the 5–6th partial [8.18], thus these components may decrease significantly during the third phase of the attack. This process may last quite long; in the middle frequency range ($\approx$ 130–260 Hz, the tenor octave) 100–120 ms stabilization times were observed.

Since the voicing adjustment can change the attack tremendously [8.16, 35, 36], the assignment of the features of the attack to measurable and understandable physical properties of the flue organ pipes is much more complicated than in the case of steady sound. A more detailed description of the research, summarized in this chapter, will be published in the near future.

8.4.2 Acoustic Effects of the Voicing Adjustment Steps

As mentioned, the voicing adjustment can influence both the steady spectrum and the attack transient very significantly. The voicing steps influence mostly the velocity of the jet at the upper labium and the volume flow through the flue. Certain steps change the end correction at the mouth and open end. Nicking (making thin cuts into the edge of the languid) decreases the broadband noise very effectively.

Since only a few papers have been published [8.16, 20] about the effect of voicing adjustments a short summary about the acoustic effect of the most important voicing steps is given as follows:

1. *Change of the diameter of the foothole/of the width of the flue*: The pressure in the foot is determined not only by the applied wind pressure but also by the ratio of the open areas at the foothole and the flue. Both the volume flow and the jet velocity at the flue can be influenced by these voicing steps. They are used mostly for adjusting the loudness of the steady sound and the speed of the attack.
2. *Knocking the languid up and down*: This step influences the direction of the jet. If the languid is knocked up/down, the jet moves outwards/inwards. Accordingly, the velocity of the jet when hitting the upper labium and amount of the air flowing into the pipe decreases/increases. Thus, this voicing step can influence the loudness of the steady sound, the speed of the attack and the steady spectrum (because of the changing asymmetry of jet motion at the upper labium).
3. *Cutting up the mouth*: This step changes the end correction at the mouth. The frequency increases and the envelope minimum of the steady spectrum is shifted upwards. Conversely, the velocity of the jet at the upper lip and the amount of air flowing into the pipe decreases. Thus, the edge tone spectrum and the pipe resonances are shifted in opposite direction. This voicing step influences the steady spectrum and modifies the order of the appearance of the partials in the attack. Therefore, this step is the most important one in adjusting the sound character of the pipe.
4. *Nicking*: The small cuts in the edge of the languid produce vertical vortex lines, which stabilize the jet and reduce the turbulence. The broadband noise in the steady spectrum decreases in the range of the higher partials. Conversely, the attack will be somewhat slower.
5. *Tuning at the open end*: Depending on the applied tuning method either the length of the pipe is changed, or the end correction is modified by this step. When a small opening (tuning slot) is used, the tuning may influence (because of the change of the location of the standing wave in the pipe) the steady spectra at the open end and also at the mouth.

Several other voicing steps are known, but the above-mentioned steps are the most important ones. Steps 1–3 obviously influence the frequency, the spectrum, and the amplitude of the edge tone.

8.5 Discussion and Outlook

Since the scope of this chapter is to give an overview of the connection between the measurable properties of the sound and the physical properties of the systems involved in the sound generation (acoustic resonator, air jet, wall vibrations), no detailed discussion has been given of particular phenomena; rather the process of sound generation in flue pipes as a whole was discussed. Nevertheless, certain facts, which are not well known or which contradict published results, have emerged.

The sound generation may be regarded as a complicated physical interaction among all of the involved systems, aerodynamic (air jet), acoustical (air column in the pipe), and mechanical (pipe wall). The result of this interaction is the sound of the pipe. This approach was to select, demonstrate, and explain the most important connections between the sound and the above three physical systems. Since more systems are usually involved and since several properties may contribute to a single observable quantity, this approach inevitably leads to an oversimplification of the problem. Still, it is believed that the approach presented in this chapter can help the reader to reach a better understanding of the sound of flue organ pipes.

Although the main features of the steady state sound of different pipes and stops are quite well known, the difference between the radiated spectra at the openings

was completely overlooked in the literature. As was shown, the size (and shape) of the opening influences not only the eigenfrequencies and the Q-factors of the pipe, but also determines the stretching of the eigenmodes and the shape of the spectrum envelope. The latter two properties are much more important for the steady state spectrum than the first two.

The appearance of nonharmonic peaks in the range of higher partials is a very characteristic property of metal pipes. Still, this phenomenon was not discussed in the scientific literature. The first information on this phenomenon was published recently [8.29], but it was regarded as a special effect of a single pipe. Moreover, the appearance of the peaks was described as difference tones of the mouth tone and fundamental. The explanation based on the simultaneous excitation of a higher eigenmode assumes that the higher components of the edge (mouth) tone are present in the steady sound. The presence of the mouth tone in the steady sound was indirectly proved in another experiment [8.38]. Applying a telescopic extension on the pipe the nominal length (198 cm) was changed in several (48) 1 cm steps in the 174–222 cm range. The driving pressure and the mouth parameters were not changed during the experiment. In this case only the acoustic resonator changes, the jet remains the same. Accepting the regenerative excitation mechanism [8.10, 27] used for describing the sound generation in flue pipes, the pipe should produce a sound with smoothly decreasing frequency. The amplitude and the spectrum should also change smoothly. The measurements have shown, that the frequency changed smoothly indeed, but in a certain range the sound became very unstable, a beating occurred, sometimes a second sound could be heard for a very short time. Leaving this domain the sound became stable again. The attack showed similar phenomena: it became very slow in the above-mentioned domain and strong beats were observed.

Another indirect proof of the presence of the mouth tone in the steady sound was presented recently [8.39]. The harmonic partials were digitally removed from the pipe sound and the remaining sound was used for listening tests. The character of the remaining sound was very similar to the mouth tone of a damped pipe.

The short explanations given for the observed properties of the attack show that several different mechanisms are involved in the attack transient of the pipe. Certain phenomena can be explained by the properties of the acoustic resonator i. e., the observed differences in the rise time of the partials are mostly determined by the differences of the Q-factors, while the gradual withdrawal of certain partials can be assigned to the shift of their frequencies from the corresponding eigenfrequency to the harmonic frequency. It is also clear, that the very beginning of the speech is dominated by the noise and edge tone produced by the jet. However, the role of the edge tone in the excitation of the pipe sound is not understood completely yet.

The effect of wall vibrations on the attack was not taken into account, because this phenomenon is extremely complicated, but plays only a secondary role in the attack. It was shown [8.13] that pipes made from very different material can be voiced to almost identical speech.

The presented observations underline that the role of the edge tone in sound generation is not yet properly understood. Detailed investigations of edge tone–pipe sound interaction will be carried out in the near future.

Acknowledgments. The contents of this chapter have in large parts been published before [8.40].

The research surveyed in this paper was supported by several foundations in Hungary (Soros Foundation, Foundation of the Hungarian Credit Bank and István Széchenyi Foundation) and in Germany (Deutscher Akademischer Ausländerdienst (DAAD), Katholischer Akademischer Ausländerdienst (KAAD)). The research could not have progressed without the generous help of organ builders and experts, including the participants of the short courses. The authors are especially grateful for the friendly support of K. Mühleisen (Organ Builder Company Mühleisen, Leonberg, Germany) and F. Frasch (Technical College for Building of Musical Instruments, Ludwigsburg, Germany)

9. Percussion Musical Instruments

Andrew C. Morrison, Thomas D. Rossing

Percussion instruments are an important part of every musical culture. Although they are probably our oldest musical instruments (with the exception of the human voice), there has been less research on the acoustics of percussion instruments, as compared to wind or string instruments. Quite a number of scientists, however, continue to study these instruments.

Over the years we have written several review articles on the acoustics of percussion instruments [9.1, 2] as well as a book [9.3]. They are also the subject of chapters in most books on musical acoustics and on musical instruments [9.4–8].

9.1 Drums

Drums generally have membranes of animal skin or synthetic material stretched over some type of air enclosure. Nowadays synthetic materials, such as Mylar (polyethylene terephthalate), are more common, although some percussionists still prefer animal skin (leather). Some type of tensioning device is nearly always included. The speed of waves on the membrane (and thus the frequency of the various modes) depends upon the tension, the thickness, and the density of the membrane. Some drums (e.g., timpani, tabla, boobams) sound a definite pitch; others convey almost no sense of pitch at all. Some drums have a single membrane (drumhead), while others include two membranes coupled together by vibrations of the drum shell and the enclosed air. The first 12 modes of vibration of a circular membrane are shown in Fig. 9.1. Above each sketch are given the values of m (the number of nodal diameters) and n (the number of nodal circles), and below it the frequency of vibration for that mode divided by the frequency of the lowest (01) mode. Mathematically, the mode frequencies of an ideal membrane are proportional to those of the mn Bessel function.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_9

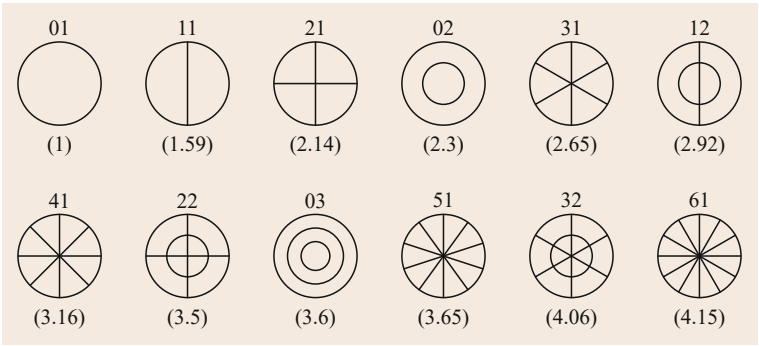

Fig. 9.1 Modes of vibration of a circular membrane

9.1.1 Timpani

The timpani or kettledrums are the most important drums in the orchestra, with one member of the percussion section usually devoting attention exclusively to them. Most modern timpani have a pedal-operated tensioning mechanism in addition to six or eight tensioning screws around the rim of the kettle. Although the modes of vibration of an ideal membrane are not harmonic, a carefully tuned kettledrum will sound a strong principal note plus two or more nearly harmonic overtones. *Rayleigh* [9.9] recognized the principal note as coming from the (11) mode and identified overtones about a perfect fifth ($f : f_1 = 3 : 2$), a major seventh ($15 : 8$), and an octave ($2 : 1$) above the principal tone. The inharmonic modes of an ideal membrane are shifted into a nearly harmonic series mainly by the effect of air loading [9.10]. Mode frequencies of a kettledrum, with and without the kettle, are given in Table 9.1.

Normal striking technique produces prominent partials with frequencies in the ratios $0.85 : 1 : 1.5 : 1.99 : 2.44 : 2.89$. If we ignore the heavily damped fundamental, the others are nearly in the ratios $1 : 1.5 : 2 : 2.5$, a harmonic series built on an octave below the principal note. Measurements on timpani of other sizes give similar results [9.11].

9.1.2 Snare Drums

The snare drum is a two-headed instrument about 33–38 cm in diameter and 13–20 cm deep. The shell is made from wood, metal, or Mylar. Strands of wire or gut are stretched across the lower (snare) head. When the upper (batter) head is struck, the snare head vibrates against the snares. The coupling between the snares and the snare head depends upon the mass and the tension of the snares. At a sufficiently large amplitude of the snare head, properly adjusted snares will leave the head at some point during the vibration cycle and then return to strike it, thus giving the snare drum its characteristic sound. The greater the tension on the snares, the larger the amplitude needed for this to take place [9.12]. Vibrational modes of a snare drum shell, with and without the drumheads, are shown in [9.12].

Table 9.1 Mode frequencies and ratios of kettledrum membranes with and without the kettle

Mode	Kettledrum		Drumhead alone		Ideal membrane
	f (Hz)	f/f_{11}	f (Hz)	f/f_{11}	f/f_{11}
01	127	0.85	82	0.53	0.63
11	150	1.00	155	1.00	1.00
21	227	1.51	229	1.48	1.34
02	252	1.68	241	1.55	1.44
31	298	1.99	297	1.92	1.66
12	314	2.09	323	2.08	1.83
41	366	2.44	366	2.36	1.98
22	401	2.67	402	2.59	2.20
03	418	2.79	407	2.63	2.26
51	434	2.89	431	2.78	2.29
32	448	2.99	479	3.09	2.55
61	462	3.08	484	3.12	2.61
13	478	3.19	497	3.21	2.66
42			515	3.32	2.89

9.1.3 Bass Drums

The bass drum is capable of radiating up to 20 W of peak acoustical power, probably the most of any instrument in the orchestra. A concert bass drum usually has a diameter of 80–100 cm, although smaller drums (50–75 cm) are popular in marching bands. Most bass drums have two heads, set at different tensions, although single-headed gong drums are used when a more defined pitch is desired. Mylar heads with a thickness of 0.25 mm are widely used, although calfskin heads are preferred by some drummers for large concert bass drums. Generally the batter or beating head is tuned to a greater tension than the carry or resonating head.

9.1.4 Tom-Toms

Tom-toms range from 20 to 45 cm in diameter, and they may have either one or two heads. Although often characterized as untuned drums, tom-toms do convey an identifiable pitch, especially the single-headed type. When a tom-tom is struck a hard blow, the deflection of the drumhead may be great enough to cause a significant change in the tension, which momentarily raises the frequencies of all modes of vibration and thus the apparent pitch. The fundamental frequency in a 33 cm tom-tom, for example, was found to rise about eight percent (slightly more than a semitone) during the first 0.2 s after the strike [9.13], resulting in a perceptible pitch glide. The pitch glide can be enhanced by loading the outer portion of the drumhead with a Mylar ring.

9.1.5 Indian Drums

Foremost among the drums of India are the tabla (north India) and mrdanga (south India). The overtones of both these drums are tuned harmonically by loading the drumhead with a paste of starch, gum, iron oxide, charcoal, or other materials. The tabla has a rather thick head made from three layers of animal skin (calf, sheep, goat, or buffalo skins are apparently used in different regions). The innermost and outermost layers are annular, and the layers are braided together at their outer edge and fastened to a leather hoop. Tension is applied to the head by means of a long leather thong that weaves back and forth between the top and bottom of the drum. The tabla is usually played together with a larger drum, called the banya or left-handed tabla. The head of the larger drum is also loaded, but slightly off center. The mrdanga is a two-headed drum that functions, in many respects, as a tabla and banya combined into one. The smaller head, like that of the tabla, is loaded with a patch of dried paste, while the larger head is normally loaded with a paste of wheat and water shortly before playing. A tabla and a mrdanga are shown in Fig. 9.2.

The acoustical properties of these drums have been studied by a succession of Indian scientists, including Nobel laureate C.V. Raman. *Raman* and his colleagues recognized that the first four overtones of the tabla are harmonics of the fundamental, and they identified these five harmonics as coming from nine normal modes [9.14]. For example, Fig. 9.3 shows how combinations of the (0,2) and (2,1) modes produce the third harmonic partial.

9.1.6 Japanese Drums

Drums have been used for centuries in Japanese temples. In Buddhist temples, it has been said that the sound of the drum is the voice of Buddha. In Shinto temples it is said that drums have a spirit (kumi) and that with a drum one can talk to the spirits of animals, water, and fire. Drums were often used to motivate warriors into battle and to entertain in town festivals and weddings [9.15]. The Japanese taiko (drum) has broken out of its traditional setting, and today's taiko bands have given new life to this old tradition. Japan's famous taiko band, the Kodo drummers, have performed in many countries of the world. Taiko bands exist in many Western countries. The o-daiko is a large drum consisting of two cowhide membranes stretched tightly across the ends of a wooden cylinder 50–100 cm in diameter and about 1 m in length. The drum, which hangs in a wooden frame, is struck with large felt-padded beaters. It is often used in religious functions at shrines, where its deep sound adds solemnity to the occasion. *Obata* and *Tesima* [9.15] found modes of vibration in the o-daiko to be somewhat similar to those in the bass drum. The tsudzumi

Fig. 9.2a,b The tabla (**a**) and mrdanga (**b**)

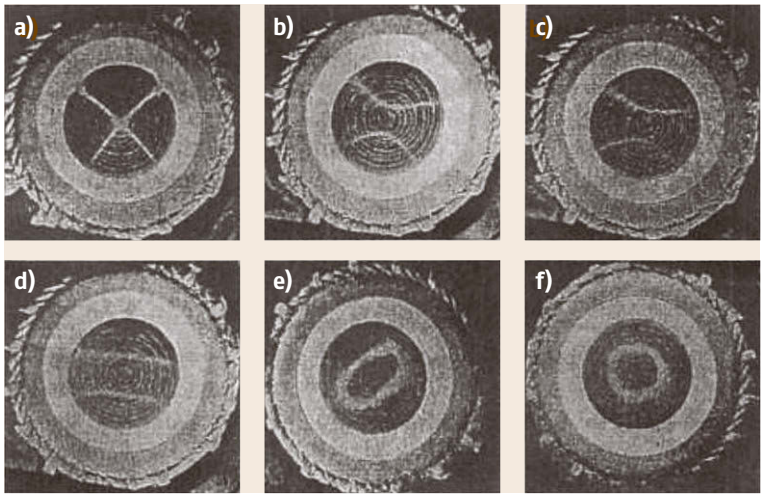

Fig. 9.3a–f Modes of vibration of the tabla (after [9.14]). **(a)** The (0,2) normal mode. **(b–e)** Combination of (0,2) and (2,1) normal modes. **(f)** The (2,1) normal mode

(or tsuzumi) is a braced drum whose body has cup-shaped ends and leather heads on both ends. A few sheets of paper wet with saliva cover an area of about $1\,\mathrm{cm}^2$ at the center of the bottom head, which tunes the modes of this head into a nearly harmonic relationship [9.16].

9.2 Mallet Percussion Instruments

9.2.1 Vibrating Bars

Bars or rods can vibrate either longitudinally or transversely. The most important vibrations in percussion instruments are the transverse bending vibrations in which internal elastic forces supply the necessary restoring force. When a bar is bent, the outer part is stretched and the inner part is compressed. Somewhere in between is a neutral axis whose length remains unchanged, as shown in Fig. 9.4.

A filament located at a distance z below the neutral axis is compressed by an amount $z\mathrm{d}\phi$. The strain is $z\mathrm{d}\phi/\mathrm{d}x$, and the amount of force required to produce the strain is $E\mathrm{d}Sz\mathrm{d}\phi/\mathrm{d}x$, where $\mathrm{d}S$ is the cross-sectional area of the filament and E is Young's modulus. This leads to a fourth-order differential equation whose solution can be found in [9.4, Sect. 2.15]. The solution leads to different modal frequencies, depending upon whether the ends of the bar or rod are free, clamped, or simply supported (hinged). The most commonly used bars in percussion instruments are bars that are free at both ends, whose relative frequencies are given by

$$f_n = \frac{\pi K}{8L^2}\sqrt{\frac{E}{\rho}}\left[3.011^2, 5^2, 7^2, ..., (2n+1)^2\right] .$$

The frequencies and nodal positions for the first four bending vibrational modes in a thin bar with free ends are given in Table 9.2.

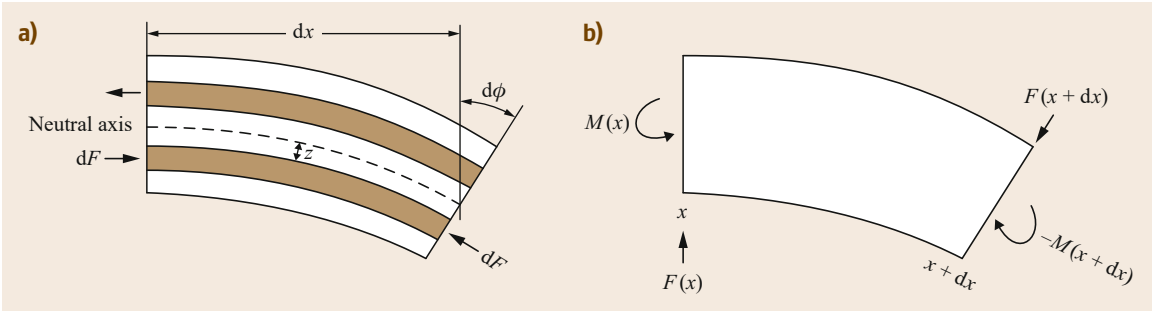

Fig. 9.4 **(a)** Bending strains in a bar. **(b)** Bending moments and shear forces in a bar

Table 9.2 Properties of transverse vibrations in a bar free at both ends

Frequency (Hz)	Wavelength (m)	Nodal positions (m from end of $1-m$ bar)
$f_1 = 3.5607\frac{K}{L}\sqrt{\frac{E}{\rho}}$	$1.330\,L$	0.224, 0.776
$2.756\,f_1$	$0.800\,L$	0.132, 0.500, 0.868
$5.404\,f_1$	$0.572\,L$	0.094, 0.356, 0.644, 0.906
$8.933\,f_1$	$0.445\,L$	0.073, 0.277, 0.500, 0.723, 0.927

9.2.2 Marimbas

In most of the world, the term marimba denotes a deep-toned instrument with tuned bars and resonator tubes that evolved from the early Latin American instrument. The marimba typically includes three to four-and-a-half octaves of tuned bars of rosewood or synthetic material with a deep arch cut to tune the overtones. The first overtone, which is radiated by the second bending mode, is normally tuned to the fourth harmonic of the fundamental in the first two to three-and-a-half octaves, after which the interval decreases [9.17]. Details of bar shapes for harmonic tuning are given by *Bork* [9.18]. Below each marimba bar is a cylindrical resonator pipe tuned to the fundamental mode of the bar. A pipe with one closed end and one open end resonates when its acoustical length is one-fourth of a wavelength of the sound. The tubular resonators emphasize the fundamental and also increase the loudness, which is done at the expense of shortening the decay time of the sound. The statement is sometimes made that the resonator prolongs the sound but that is incorrect. That impression may be conveyed when it is played with other instruments in an ensemble since the sound decay curve begins higher and may cross the background sound at a slightly later time. Some companies now make large five-octave concert marimbas that cover the range C2 to C7. In such instruments, generally the second bending mode is accurately tuned to the fourth harmonic in the first three-and-a-half octaves. The third bending mode is tuned to the tenth harmonic in the first two octaves, after which the interval decreases. The fourth mode varies from the 20th harmonic in the lowest bars to about the sixth harmonic in the highest bars [9.19]. Relative frequencies of the first four bending modes in a Malletech marimba are shown in Fig. 9.5a, while those of several torsional modes in the same marimba are shown in Fig. 9.5b. The first torsional mode frequency ranges from about 1.9 times the nominal frequency (largest bars) to about 1.2 times the nominal frequency (smallest bars).

In normal playing, the bars are struck near their centers, where the torsional (twisting) modes have nodes, and thus they will not be excited to any great extent. On the other hand, if the bars are struck away from the center, deliberately or not, the torsional modes may contribute to the timbre. Applying finite element methods to marimba and xylophone bars showed that a small curvature in the bars has very little effect on the relative frequencies of the vibrational modes. Henrique and Antunes have used finite element methods both to optimize the shape of marimba and xylophone bars and to model the sound. They employ a physical modeling approach that addresses the spatial aspects of the problem and is suitable for both dispersive and nondispersive systems [9.20]. The sound field radiated by a simulated marimba bar has been calculated by assuming the vibrating bar to be equivalent to a linear array of oscillating spheres. This sound pressure excites a monodimensional lossy tube of finite length terminated by a radiation impedance at its open end, which represents the tubular resonator. The amount of frequency decrease as the resonator is moved closer to the bar is then calculated [9.21].

9.2.3 Xylophones

Xylophones also use bars of wood or synthetic material, but the arch is not cut as deep as that of a marimba. The first overtone is tuned to the third rather than the fourth harmonic of the fundamental. The closed-tube resonators placed below the bars reinforce the third harmonic as well as the fundamental, thus producing a brighter sound than the marimba. This is further enhanced by using hard mallets.

9.2.4 Vibes

Vibraphones or vibraharps, as they are called by different manufacturers, have aluminum bars deeply arched (as in marimbas) so that the first overtone has a frequency four times that of the fundamental. The aluminum bars in vibes have much longer decay times than the wood or synthetic bars of the marimba, and so vibes are equipped with pedal-operated dampers. The most distinctive feature of vibes, however, is the vibrato introduced by motor-driven discs at the top of the resonators, which alternately open and close the tubes. The vibrato produced by these rotating discs of pulsators produces a vibrato (hence the name). The speed of rotation of the discs may be adjusted to produce a slow

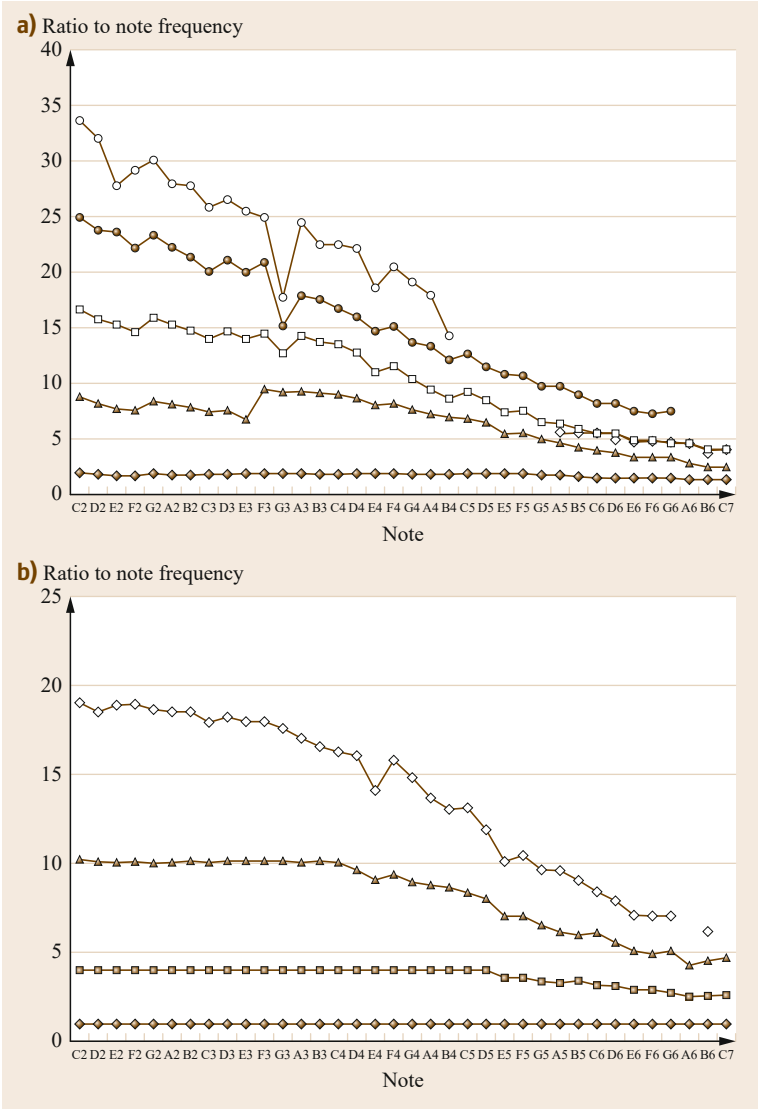

Fig. 9.5a,b Torsional modes (a) and bending modes (b) in a Malletech five-octave marimba

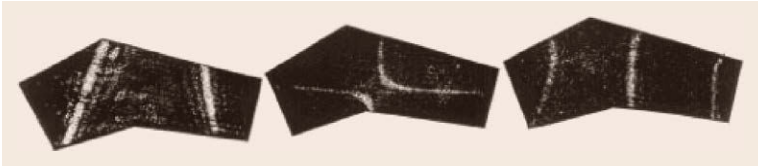

Fig. 9.6 Holographic interferogram showing vibrational modes of a jade chime stone

vibe or a fast vibe. Sometimes vibes are played without vibrato by switching off the motor. Vibes are generally played with soft mallets that produce a mellow tone.

9.2.5 Glockenspiel

The glockenspiel, or orchestra bells, uses rectangular steel bars 2.5–3.2 cm wide and 8–9 cm thick. Its range is customarily from G5 to C8, although it is scored two octaves lower than it sounds. The glockenspiel is usually played with brass or hard plastic mallets. The bell lyra is a portable version, popular in marching bands, that uses aluminum bars. Because the high overtones die out quickly, no effort is made to tune the overtones harmonically, as in the marimba, xylophone, and vibes.

Fig. 9.7 Set of 16 pyeon-gyoung (stone chimes) from the Chosun Dynasty in Korea

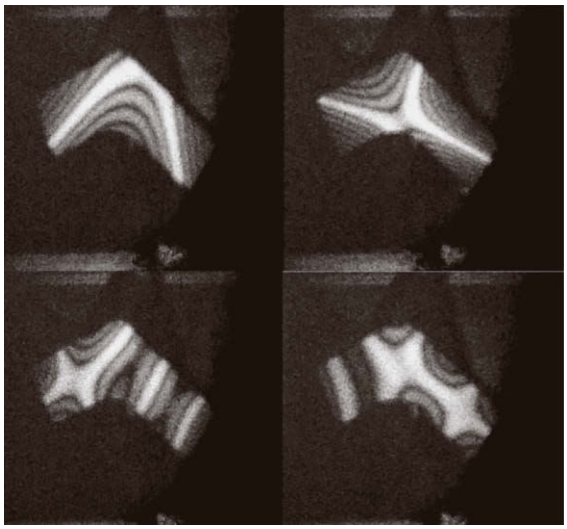

Fig. 9.8 Interferograms showing vibrational modes of a Korean pyeon-gyoung stone

9.2.6 Chimes

Chimes or tubular bells are generally fabricated from lengths of brass tubing 32–38 mm in diameter. The upper end of each tube is partially or completely closed by a brass plug with a protruding rim. The rim forms a convenient and durable striking point. The modes of transverse vibration in a pipe are essentially those of a thin bar. One of the most interesting characteristics of chimes is that there is no mode of vibration with a frequency at the pitch of the strike tone one hears. Modes four, five and six, which are near the ratios 2 : 3 : 4 in a beam or tube, appear to determine the strike tone, which is heard one octave below the fourth mode [9.1].

9.2.7 Lithophones

Lithophones are stones that vibrate and produce sound. The ancient Chinese were fond of stone chimes, many of which have been found in ancient Chinese tombs. A typical stone chime was shaped to have arms of different lengths joined at an obtuse angle. The stones were generally struck on their longer arm with

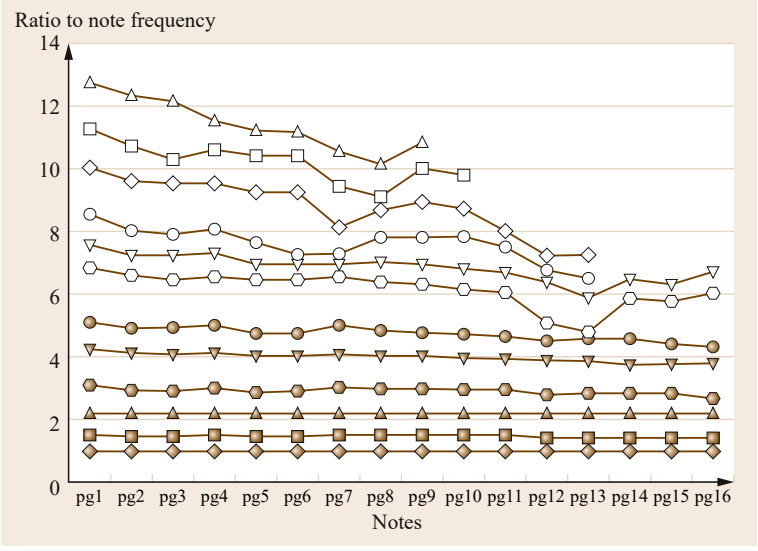

Fig. 9.9 Relative frequencies of the pyeon-gyoung stone

a wooden mallet. Sometimes the stones were richly ornamented. A lithophone of 32 stone chimes found in the tomb of the Marquis Yi (which also contained a magnificent set of 65 bells) was scaled in size, although the dimensions of the chimes do not appear to follow a strict scaling law [9.22]. In later times, the Chinese made stone chimes of jade. Holographic interferograms showing some of the modes of vibration of a small jade chime are shown in Fig. 9.6. Korean chime stones, called pyeon-gyoung, were originally brought from China to Korea in the 12th century.

A set of 16 stone chimes from the Chosun Dynasty is shown in Fig. 9.7. Unlike the Chinese stone chimes, these stones all have the same size but differ from each other only in thickness. The fundamental frequency is essentially proportional to the thickness, just as in a rectangular bar such as a marimba bar. The second mode in each stone is approximately 1.5 times the fundamental, while the third mode is about 2.3 times the nominal frequency. The fourth mode is about three times the nominal frequency up to the 12th stone, after which the ratio drops to about 2.7 [9.23]. Holographic interferograms of several modes of vibration in a pyeon-gyoung stone tuned to D♯6 are shown in Fig. 9.8. Relative frequencies of the modes in the pyeon-gyoung are shown in Fig. 9.9.

9.3 Cymbals, Gongs, and Plates

The vibrations of plates have fascinated scientists, as well as musicians, for many years. Nearly 200 years ago, *E.F.F. Chladni* published a book describing his well-known method of sprinkling sand on vibrating plates to made the nodal lines visible [9.24]. Chladni's lectures throughout Europe attracted any famous persons, including Napoleon. The nodal lines in the vibrational modes of a circular plate are not too different from those in a circular membrane, shown in Fig. 9.1. The modal frequencies are very different, however, because the stiffness of the plate contributes a substantial amount of elastic restoring force. In fact, a plate will vibrate without externally applied tension. The modes of a circular plate are often given the labels m and n, like those of a membrane, to designate the numbers of nodal diameters and nodal circles. Chladni observed that the frequencies of the various modes of a circular plate are nearly proportional to $(m+2n)^2$, a relationship that has been called Chladni's law [9.25].

9.3.1 Cymbals

Cymbals are very old instruments and have had both religious and military use in a number of cultures. The Turkish cymbals generally used in orchestras and bands are saucer-shaped with a small dome in the center, in contrast to Chinese cymbals, which have a turned-up edge. Orchestral cymbals are often designated as French, Viennese, and Germanic in order of increasing thickness. Jazz drummers use cymbals designated by such onomatopoeic terms as *crash*, *ride*, *swish*, *splash*, *ping*, and *pang*. Cymbals range from 20 to 75 cm in diameter. The strong aftersound that gives cymbal sound its characteristic shimmer is known to involve nonlinear processes [9.17]. There is considerable evidence that the vibrations exhibit chaotic behavior. A mathematical analysis of cymbal vibrations using nonlinear signal processing methods reveals that there are between three and seven active degrees of freedom, and that physical modeling will require a like number of equations [9.26]. One procedure is to calculate Lyapunov exponents from experimental time series, so that the complete spectrum of exponents can be obtained. The chaotic regime can be quantified in terms of the largest Lyapunov exponent [9.27].

9.3.2 Gongs

Gongs of many different sizes and shapes are popular in both Eastern and Western music. They are usually cast of bronze with a deep rim and a protruding dome. Tamtams are similar to gongs and are often confused with them. The main differences between the two are that tamtams do not have the dome of the gong, their rim is not as deep, and the metal is thinner. Tamtams generally sound a less definite pitch than do gongs. In fact, the sound of a tamtam may be described as somewhere between the sounds of a gong and a cymbal. The sound of a large tamtam develops slowly, changing from a sound of low pitch at strike to a collection of high-frequency vibrations, which are described as shimmer. These high-frequency modes fail to develop if the tamtam is not hit hard enough, indicating that the conversion of energy takes place through a nonlinear process [9.28].

9.3.3 Chinese Gongs

Among the many gongs in Chinese music are a pair of gongs used in Chinese opera orchestras, shown in Fig. 9.10. These gongs show a pronounced nonlinear behavior. The pitch of the larger gong glides downward

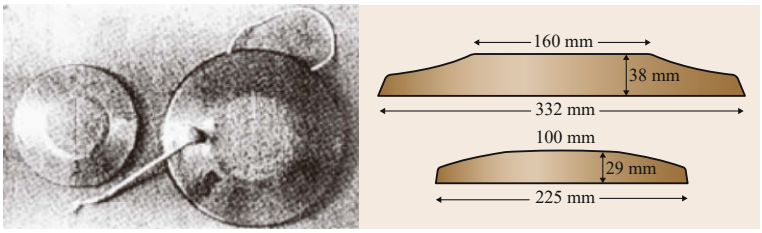

Fig. 9.10 Examples of gongs used in Chinese opera

as much as three semitones after striking, whereas that of the smaller gong glides upward by about two semitones [9.28]. Several vibrational modes of the larger gong are shown in Fig. 9.11.

In some of the modes, vibrations are confined pretty much to the flat inner portion of the gong, some to the sloping shoulders, and some involve considerable motion in both parts. When the gong is hit near the center, the central modes (178, 362, 504, 546 Hz) dominate the sound. When the gong is hit lightly on the shoulder, the lowest mode at 118 Hz is heard. The vibrations of a large tamtam were studied by *Chaigne* et al. [9.29]. They found that the nonlinear phenomena have the character of quadratic nonlinearity. Forced excitation at sufficiently large amplitude at a frequency close to one mode leads to a bifurcation with the appearance of lower frequencies corresponding to other modes. Varying the excitation frequency at constant force yielded subharmonics that were not observed at constant excitation frequency. This is quite similar to the nonlinear behavior of cymbals [9.17] [9.26].

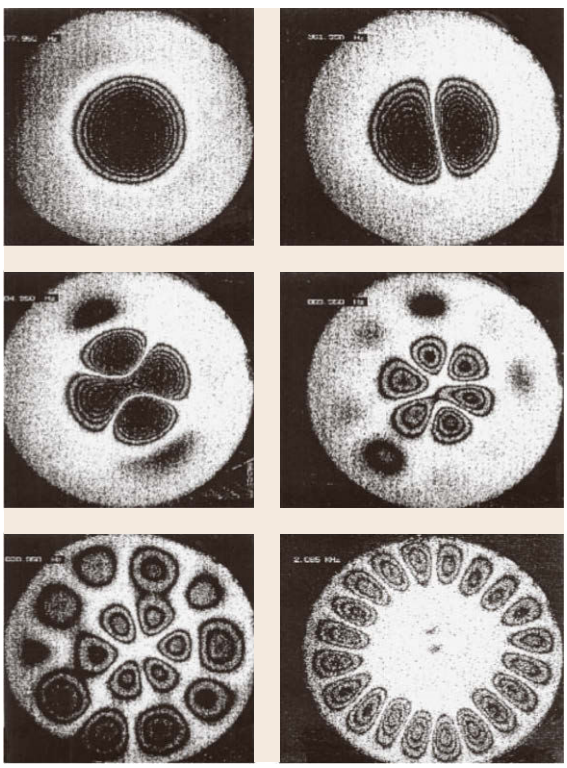

Fig. 9.11 Holographic interferograms of the modes of vibration of the larger gong shown in Fig. 9.10

9.3.4 The Caribbean Steelpan

The Caribbean steelpan is one of the most widely used acoustical instruments developed in the last 70 years. The instrument was developed on the islands of Trinidad and Tobago when local craftsman discovered methods of transforming surplus 50-gallon oil barrels into tuned drums. The Caribbean steelpan is an object of considerable acoustical study, both in its home country of Trinidad and Tobago and in the United States. Modern steel bands include a variety of instruments, such as tenor, double second, double tenor, guitar, cello, quadraphonic, and bass. Our earlier review paper [9.17] included holographic interferograms of several instruments showing how individual notes vibrate, how the entire instrument vibrates, and how the skirts of the instruments vibrate. Another piece of the puzzle, so to speak, is to understand how the vibrating components radiate sound. An effective aid to understanding sound radiation is to map the sound intensity field around the instrument. Since sound intensity is the product of sound pressure (a scalar quantity) and the acoustic fluid velocity (a vector), a two-microphone system is used. The acoustic fluid velocity can be readily calculated from the difference in sound pressure at the two accurately spaced microphones. Both the active intensity and the reactive intensity can be obtained at the desired points in the sound field. The active intensity represents the outward flow of energy, while the reactive intensity represents energy that is stored in the sound field near the instrument. While the active intensity is the most significant field in a concert hall, both active and reactive intensity fields have to be considered in recording a steelpan. Figure 9.12 shows a map of active and reactive sound intensity in a plane that bisects a double second steelpan when a single note ($F\sharp 3$) is excited at its fundamental frequency [9.30].

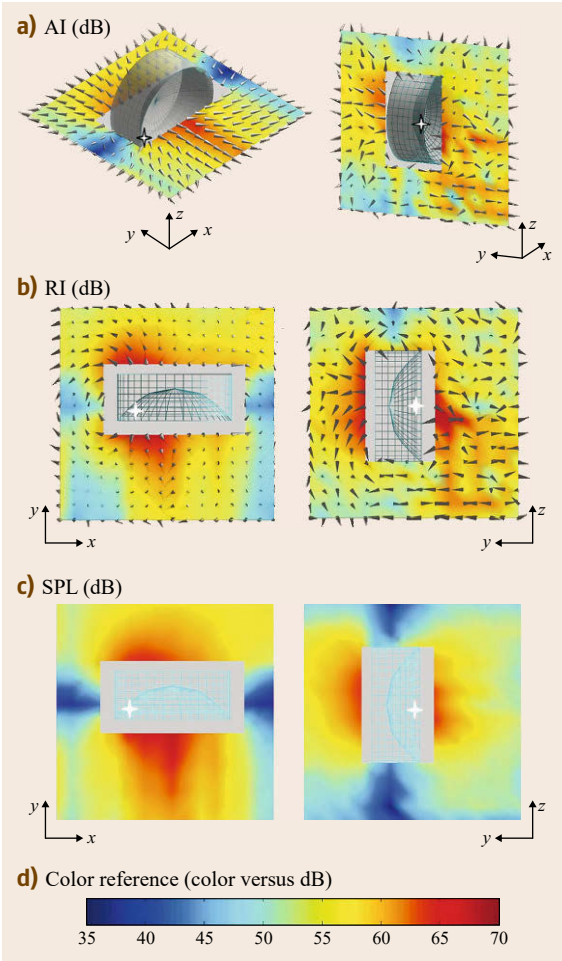

Fig. 9.12a–d Active intensity (AI) (a) and reactive intensity (RI) (b) of a Caribbean steelpan. (c) Sound pressure level (SPL), (d) color reference

9.3.5 The Hang

The Hang is a new steel percussion instrument, consisting of two spherical shells of steel, suitable for playing with the hands. Seven to nine notes are harmonically tuned around a central deep note, which is formed by the Helmholtz (cavity) resonance of the instrument body. The Hang shown in Fig. 9.13 has eight notes that can be tuned in any tonal systems between A3 and G5, including 30 tonal systems suggested by the tuners. The central note is usually tuned a fifth or fourth below the lowest note of the scale. Although it is a new instrument, many units have been shipped all over the world by PanArt, its creators. Holographic interferograms in Fig. 9.14 show the first five vibrational modes in the G3 note area of the Hang. The second and third modes are tuned to the second and third harmonics of the fundamental mode respectively [9.31].

Fig. 9.13 The Hang (image credit: Michael Paschko)

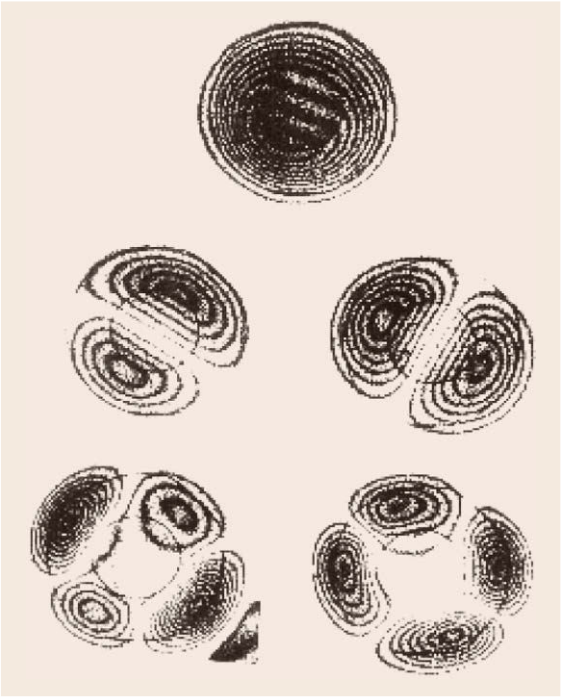

Fig. 9.14 The first five modes of vibration of the G3 note of the Hang

Figure 9.15 shows the active sound intensity in a plane 8 cm above the E4 note. The arrowheads show the direction of the sound intensity at each point in the plane, while the gray scale shows the sound pressure level. Note the sound level is greatest at the fundamental frequency, and the sound intensity is strongly upward from the note, while at the frequency of the second and third modes, considerable sound is radiated laterally.

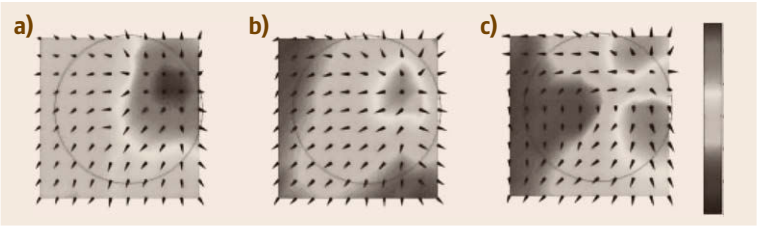

Fig. 9.15a–c Active intensity of the Hang when the E4 note is excited in **(a)** its fundamental mode **(b)** its second harmonic mode **(c)** its third mode

9.3.6 Bells

Bells have been a part of nearly every culture in history. Bells existed in the Near East before 1000 BCE, and a number of Chinese bells from the time of the Shang dynasty (1600–1100 BCE) can be found in museums around the world. In 1978 set of tuned bells from the fifth century BCE was discovered in the Chinese province of Hubei [9.32]. Bells developed as Western musical instruments in the seventeenth century when bell founders discovered how to tune their partials harmonically. The founders in the Low Countries, especially the Hemony brothers (François and Pieter) and Jacob van Eyck, took the lead in tuning bells, and many of their fine bells are found in carillons today. When struck by its clapper, a bell vibrates in a complex way. In principle, its vibrational motion can be described in terms of a linear combination of the normal modes of vibration whose initial amplitudes are determined by the distortion of the bell when struck. In practice, such a description becomes quite complex because of the large number of normal modes of diverse character that contribute to the motion. The first five modes of a church bell or carillon bell are shown in Fig. 9.16. Lines show the locations of the nodal lines. The numbers at the top denote the numbers of complete nodal meridians extending over the top of the bell and the number of nodal circles respectively. Note that there are two modes with $m = 3$ and $n = 1$, one with a circular node at the waist and one with a node near the sound bow. Thus we denote the one as (3,1♯) in Fig. 9.16. The ratio of each modal frequency to that of the prime is given at the bottom of each diagram.

When a large church bell or carillon bell is struck by its clapper, one first hears the sharp sound of metal on metal. This sound quickly gives way to a strike note that is dominated by the prominent partials of the bell. Most observers identify the metallic strike note as having a pitch at or near the frequency of the second partial. Finally, as the sound of the bell ebbs, the slowly decaying hum tone (an octave below the prime) lingers on. A new type of carillon bell, that has the dominating minor-third partial (Fig. 9.16) replaced by a partial tuned a major-third above the prime, has been developed at the Royal Eijsbouts bell foundry in The Netherlands [9.32]. The new bell design evolved partly from the use of a technique for structural optimization using finite element methods [9.33]. This technique allows a designer to make changes in the profile of an existing structure, and then to compute the resulting changes in the vibrational modes. Based on the results of the structural optimization procedure, *André Lehr* and his colleagues have designed two different bells, each having a major-third partial [9.34].

9.3.7 Handbells

Although handbells date back to at least several millennia BCE, handbells developed as Western musical instruments in the 18th century. One early use was to provide tower bell-ringers with a convenient means to practice change ringing. In more recent years, handbell choirs have become popular in schools and churches; some 40 000 choirs are reported in the United States alone. Handbells have modes of vibration somewhat similar to those of church bells or carillon bells. Hologram interferograms of a number of modes in a C5 handbell are shown in Fig. 9.17. Nodes show as bright lines, and the bullseyes locate the antinodes. In a well-tuned handbell, the (3,0) mode with three nodal meridians is tuned to a frequency three times that of the fundamental (2,0) mode.

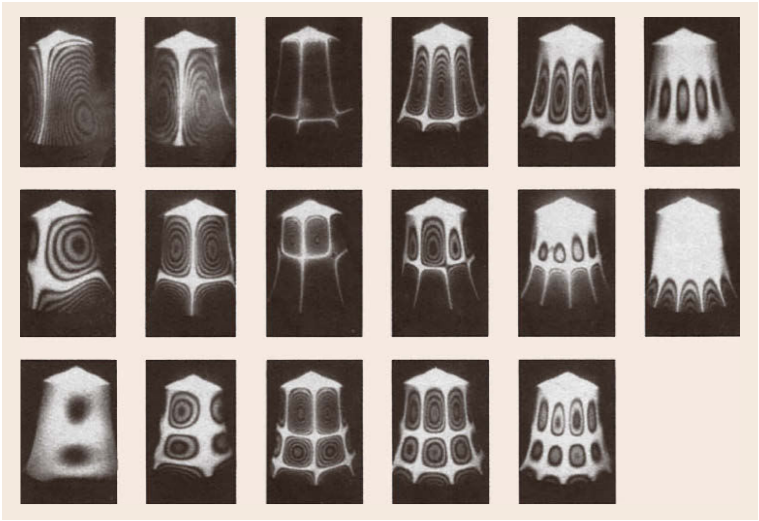

Fig. 9.17 Holographic interferograms of the vibrational modes of a C5 handbell

9.4 Methods for Studying the Acoustics of Percussion Instruments

Recent studies of the acoustics of percussion instruments have included:

1. Theoretical studies of modes of vibration
2. Experimental studies of modes of vibration
3. Sound radiation studies
4. Physical modeling
5. Studies of nonlinear behavior.

9.4.1 Finite Element and Boundary Element Methods

For all but the simplest vibrator shapes, it is difficult to calculate vibrational modes analytically. Fortunately, there are powerful numerical methods that can be carried out quite nicely by use of digital computers. These are generally described as finite element methods or boundary element methods.

9.4.2 Experimental Studies of Modes of Vibration

When a percussion instrument is excited by striking (or bowing or plucking), it vibrates in a rather complicated way. The motion can be conveniently described in terms of normal modes of vibration. A normal mode of vibration represents the motion of a linear system at a normal frequency (eigenfrequency). It should be possible to excite a normal mode of vibration at any point in a structure that is not a node and to observe motion at any other point that is not a node. It is a characteristic only of the structure itself, independent of the way it is excited or observed. In practice, however, it is difficult to avoid small distortions of the normal modes due to interaction with the exciter, the sensor, and especially the supports. Normal modes shapes are unique for a structure, whereas the deflection of a structure at a particular frequency, called its operating deflection shape (ODS), may result from the excitation of more than one normal mode [9.35].

Normal mode testing has traditionally been done using sinusoidal excitation, either mechanical or acoustical. Detection of motion may be accomplished by attaching small accelerometers, although optical and acoustical methods are less obtrusive. Modal testing with impact excitation, which became popular in the 1970s, offers a fast, convenient way to determine the normal modes of a structure. In this technique, an accelerometer is generally attached to one point on the structure, and a hammer with a load cell is used to impact the structure at carefully determined positions. Estimates of modal parameters are obtained by applying some type of curve-fitting program. Experimentally, all modal testing is done by measuring operating deflection shapes and then interpreting them in a specific manner to define mode shapes [9.35]. Strictly speaking, some type of curve-fitting program should be used to determine the normal modes from the observed ODSs, even when an instrument is excited at a single frequency. In practice, however, if the mode overlap is small, the single-frequency ODSs provide a pretty good approximation to the normal modes.

9.4.3 Scanning with a Microphone or an Accelerometer

Probably the simplest method for determining ODSs (and hence normal modes) is to excite the structure at single frequency with either a sinusoidal force or a sinusoidal sound field, and to scan the structure with an accelerometer or else to scan the near-field sound with a small microphone [9.36]. With practice, it is possible to determine mode shapes rather accurately by this method.

9.4.4 Holographic Interferometry

Holographic interferometry offers by far the best spatial resolution of operating deflection shapes (and hence of normal modes). Whereas experimental modal testing and various procedures for mechanical, acoustical, or optical scanning may look at the motion at hundreds (or even thousands) of points, optical holography looks at an almost unlimited number of points. Recording holograms on photographic plates or film (as in the holographic interferograms shown in Fig. 9.17) tends to be rather time consuming since each mode of vibration must be recorded and viewed separately. TV holography, on the other hand, is a fast, convenient way to record ODSs and to determine the normal modes. An optical system for TV holography is shown in Fig. 9.18.

A beam splitter (BS) divides the laser light to produce a reference beam and an object beam. The reference beam reaches the charge-coupled device (CCD) camera via an optical fiber, while the object beam is reflected by phase modulated (PM) mirror so that it illuminates the object to be studied. Reflected light from the object reaches the CCD camera, where it interferes with the reference beam to produce the holographic image. The speckle-averaging mechanism (SAM) alters the illumination angle in small steps in order to reduce laser speckle noise in the interferograms. Generally holographic interferograms show only variations in amplitude. It is possible, however, to recover phase information by modulating the phase of the reference beam by moving PM mirror at the driving frequency. This is a useful technique for observing motion of very small amplitude or resolving normal modes of vibration that are very close in frequency.

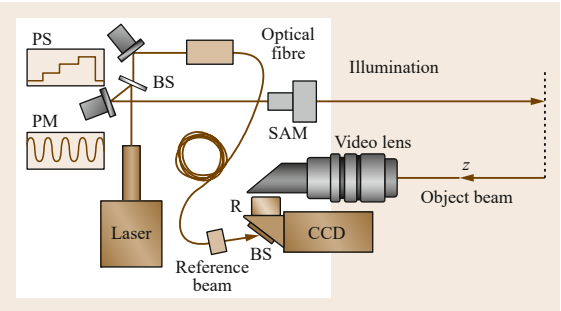

Fig. 9.18 Optical layout for a TV holography system

9.4.5 Experimental Modal Testing

Modal testing may be done with sinusoidal, random, pseudorandom, or impulsive excitation. In the case of sinusoidal excitation, the force may be applied at a single point or at several locations. The response may be measured mechanically (with accelerometers or velocity sensors), optically, or indirectly by observing the radiated sound field. In modal testing with impact excitation, an accelerometer is typically attached to a force transducer (load cell). Each force and acceleration waveform is Fourier transformed and a transfer function H_{ij} is calculated. Several different algorithms may be used to extract the mode shape and modal parameters from the measured transfer functions [9.35].

9.4.6 Radiated Sound Field

The best way to describe sound radiation from complex sources such as percussion instruments is by mapping the sound intensity field. Sound intensity is the rate at which sound energy flows outward from various points on the instrument. The sound intensity field represents the direction and the magnitude of the sound intensity at every point in the space around the source. A single microphone measures the sound pressure at a point, but not the direction of the sound energy flow. In order to determine the sound intensity it is necessary to compare the signals from two identical microphones spaced a small distance apart. The resulting pressure gradient can be used to determine sound intensity. When this is done at a large number of locations, a map of the sound intensity field results [9.30, 37, 38].

9.4.7 Physical Modeling

Synthesizing sounds by physical modeling has attracted a great deal of interest in recent years. The basic notion of physical modeling is to write equations that describe how particular sets of physical objects vibrate and then to solve those equations in order to synthesize the resulting sound. Percussion instruments have proven particularly difficult to model completely enough to be able to synthesize their sounds entirely based on a physical model. Physical modeling is complicated by their nonlinear behavior and by the strong role that transients play in their sound.

10. Musical Instruments as Synchronized Systems

Rolf Bader

Most musical instrument families have nearly perfect harmonic overtone series, for example plucked, bowed, or wind instruments. However, when considering the complex geometry and nonlinear driving mechanisms many of these instruments have we would expect them to have very inharmonic overtone series. So to make musical instruments play notes that we accept as harmonic sounds, synchronization needs to occur to arrive at the perfect harmonic overtone series the instruments actually produce. The reasons for this synchronization are different in the singing voice, organs, saxophones or clarinets, violin bowing or in plucked stringed instruments. However, when examining the mechanisms of synchronization further, we find general rules and suitable algorithms to understand the basic behavior of these instruments.

10.1 Added versus Intrinsic Synchronization

Nonlinearities contribute new aspects to the sound of musical instruments which are often considered to be the most interesting. Generally, brightness is increased, attacks are sharpened, or fluctuations are intensified when additional nonlinearities in the vibrating geometries of musical instruments appear compared to the linear case. Most listeners find an increased brightness more attractive and a sharpened attack helpful when following a melody. Fluctuations are often associated with liveliness in the tone and therefore are often preferred compared to a completely stable tone. These additional attributes of tone color are caused by a variety of effects which will be discussed below.

Conversely, musical instruments may have nonlinearities within their actual driving mechanisms. Then these nonlinearities are no longer add-ons to a linear system but are the very core of the instrument or the driving mechanism. In these cases, the sounds pro-

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_10

duced show a very complex nature with many different ways to produce the sounds. So, for example, the saxophone may be played with normal pressure producing a harmonic tone. However, it may also be played with a pressure too low to reach the stable state, thus only producing noise. Additionally, sophisticated players are also able to produce fancy sounds like multiphonics, where two, three, or even five tones are played simultaneously on the instrument, which are mostly in a complex mathematical ratio one to another. All these behaviors are caused by the same single driving mechanism which is nonlinear in nature and therefore able to produce these very different sounds. In these cases, the normal tone is often produced by synchronizing the different vibrating systems one to another, where one system tells the other in which frequencies to vibrate. Therefore, these instruments can be treated with methods known from self-organization and synergetics known from many other physical, biological, or neural systems.

When discussing linear and nonlinear behavior, taking the notions mathematically it is clear that there can only be one linear case – there is only one straight line with some slope – but there are endless possibilities of nonlinear cases – a curve may show an endless variety of different turns and twists. Linearity is present when the rule holds that if one unit is increased by a fixed amount another unit is also in- or decreased by another also fixed amount, no matter where we set the starting point. This is a simple property of a straight line. Conversely, for a nonlinear system this no longer holds. So if one adds a certain amount to one unit, another unit in- or decreases to a certain amount, too, but this amount now depends on the starting point. So an exponential function is a nonlinear curve, but also a logarithm is one. Such functions appear with large displacements of a string or with damping in musical instruments. There may be sudden jumps in the curve like the change from sticking to slipping with the violin bow attached or sliding over a string. There may also be a Gauss-shaped curve as appears with blown instruments when comparing blowing pressure and flow into the mouthpiece.

Because of this large variety of nonlinear cases only a few frameworks have been suggested to be able to explain musical instruments in general taking the nonlinearities into consideration. These ideas are discussed at the end of this chapter, focusing on different questions like mode coupling, determination of stability, or transient behavior. In the following sections, the most important examples of such nonlinear or synchronizing behavior are discussed. First, however, we provide an overview of the different instrument families and their synchronization relations.

10.1.1 Generator/Resonator Synchronization

Musical instruments are most often described as coupled systems of a generator and a resonator. In wind instruments, the labium or the reed are the generator and the tube is the resonator. With string instruments, the string generates the sound while the wooden box is the resonator. Still it is interesting to note that sometimes the generator determines the played pitch, sometimes it is the resonator. With wind instruments, generally the resonator determines the pitch so by using certain fingerings the musician can play different notes. With stringed instruments, it is the generator determining the played pitch. But not only does the role of these parts differ between instrument families, other conditions also have an effect. The overblowing of trumpets or horns is performed using a combination of generator and resonator. Reed organ pipes can be tuned by adjusting the reed but also by adjusting the tube length. When examined in greater detail, most instruments show very complex behavior when played in extreme regions as often performed in free jazz, free improvised music, or contemporary classical music using extended techniques. For example, saxophones or clarinets may play several notes at the same time using multiphonics. With the violin string, one may also play subharmonics, where the pitch is no longer determined by the string length but by the bowing force; also this mechanism may lead to bifurcations and play scratchy sounds easily.

Table 10.1 gives a rough overview of the generator/resonator behavior for different instrument families and which determines the pitch. We will discuss in more detail below the reasons for this behavior which is caused by nonlinearities in the generator and a complex coupling to the resonator.

10.1.2 Synchronizing Conditions

In synergetics several reasons are known why one oscillator is taking over – or is synchronizing – the other oscillator, and so is forcing the second oscillator into the frequencies of the first one [10.1, 2]. The simplest is a difference in system damping. If two oscillators f and g are driven by themselves with damping α and β, respectively, and both are coupled with coupling constants c_1 and c_2 like

$$\dot{f} = -\alpha f + c_1 f\, g\,, \tag{10.1}$$

$$\dot{g} = -\beta g + c_2 f^2\,, \tag{10.2}$$

then if the damping of g is much stronger than that of f like

$$\beta \ll \alpha\,, \tag{10.3}$$

Table 10.1 Generator/resonator model of musical instruments. With some instrument families the generator determines the played pitches while with others it is the resonator

Instrument	Generator	Resonator	Part determining instruments pitch
Guitar	Strings	Body	Generator
Violin	Strings	Body	Generator
Singing voice	Vocal folds	Vocal tract	Generator
Saxophone	Reed	Air column	Resonator
Trumpet	Lips	Air column	Resonator
Percussion	Mallet	Body	Resonator
Organ	Labium	Air column	Generator/resonator
Violin bowing	Bow	String	Generator/resonator
Vocal folds	Lung pressure	Vocal folds	Generator/resonator

the coupled oscillator equations simplify to

$$\dot{f} = -\alpha f + c_1 f\, g\,,$$
$$\dot{g} = c_2 f^2\,.$$

So g depends only on f and no longer upon itself and therefore g is synchronized to f, where f determines the temporal development of g.

This general finding was already discussed by *Aschoff* [10.3] for the saxophone. He finds that the saxophone tube must take over the frequency of the reed because the reed is much heavier damped than is the tube. In the following discussion of several instruments in terms of their driving mechanism, the reason for synchronization of the oscillators will become clearer and in the end we will collect the different reasons.

10.2 Models of the Singing Voice

The singing voice consists of a nonlinear driving mechanism, the vocal folds and a vocal tract filtering the impulse train produced by the larynx to vowels or transient sounds. The vocal tract is basically passive and linear, while the vocal folds are highly nonlinear. Because of this nonlinearity they are able to produce periodic sounds with a harmonic overtone structure at normal vocal fold tension and air pressure produced by the lungs. However, when leaving this normal range the vocal folds may produce bifurcations, sounds with more than one harmonic overtone series which is known as rough voice and is often desired in singing styles like Blues or Rock. The folds may also produce subharmonics used in throat singing of ethnic groups for example those in Tuva, Mongolia, or Tibet. With very low lung air pressure the folds produce noise which can still be shaped to arrive at a whispering voice.

Describing the voice in general is beyond the scope of this chapter where we want to focus on the nonlinear behavior of the vocal tract and examine how such a nonlinear system can arrive at producing a perfect harmonic overtone series. For more detailed descriptions of the singing voice see [10.4–6]. Many papers experimentally examining the vocal folds using glottography [10.7, 8] discuss them with respect to their nonlinear nature. Also fractal dimensions have been calculated to estimate the chaoticity of vocal fold vibrations, for example in [10.9]. The role of vocal fold nonlinear expressiveness is discussed in [10.10] for contemporary vocal music.

Understanding vocal fold vibration is a matter of ongoing debate. Still, over the decades of research many models have been proposed that each have pros and cons.

10.2.1 Bernoulli Effect

The first approximation used in understanding the vocal folds is the Bernoulli effect. Here a pressure gradient appears when two flows of air next to each other have different traveling speed. An example is air traveling over and under an air plane wing. The air takes longer to travel over the wing than under it. Therefore, the air above the wing is stretched or decompressed because of the increased speed, while the air below it is more compressed because of its lower speed. So below the wing there is more pressure than above the wing. As pressure is a scalar acting in all directions both pressures act on the wing. As the pressure below the wing is higher than the one above it the wing is pushed upwards and so is the plane.

The same principle holds for the vocal folds. If an air flow produced by the lungs is traveling through the folds the air stream becomes faster as the folds have a smaller area for the air to flow through. Therefore, there is higher pressure at the position of the folds than

above or below them. This causes the folds to open releasing the lung pressure. As the cycle proceeds the upper part of the folds are wide open while the lower part is narrower. Again according to the Bernoulli effect of over- and underpressure acting on the folds, the air now at the upper part of the folds have an underpressure while the air at its lower part have an overpressure. Therefore, the upper part of the lips are forced inwards to close the upper lip part again. After closing of the upper lip part the fold is again in its initial position and one cycle of oscillation has occurred. The next cycle will be started in the same way as the previous one and therefore the folds are in steady oscillation.

This very basic understanding of vocal fold vibration is still found in the more sophisticated models discussed below. Improved models are needed as this first approximation does not explain many more complex vocal fold phenomena. The most striking one is the sudden onset of a periodic motion when increasing lung pressure or lip tension. Also, a sudden change into falsetto singing is not explained by this model alone. Additionally, rough voice, subharmonics, or other bifurcations can not be explained by the Bernoulli effect alone.

10.2.2 Two-Mass Model

On the basis of the assumption of understanding the vocal folds only when splitting them into an upper and a lower part, the most prominent model in the literature today is the two-mass model initially proposed by [10.11], which has been implemented in many variations [10.12–14]. Figure 10.1 shows the basic idea. Both sides of the vocal folds are modeled with two masses, one upper and one lower one. The upper is supraglottal while the lower is subglottal. This is in accordance with the Bernoulli effect discussed above, where an over- or underpressure effect appears when the flow changes its speed; then the upper or lower fold has a different opening area. As the folds are under pressure the upper and lower folds are modeled by two strings with displacement x_1 and x_2. This is an enlargement of the Bernoulli model as it includes the vocal fold tension by adding string constants d_1 and d_2 and fold masses m_1 and m_2. When assuming both fold parts to be springs we can introduce a differential equation as follows

$$\frac{\partial^2 x_1}{\partial t^2} = \frac{1}{m_1}\left(P_1 L\, d_1 - k_1 x_1 - r_1 \frac{\partial x_1}{\partial t} - k_c(x_1 - x_2)\right), \tag{10.4}$$

$$\frac{\partial^2 x_2}{\partial t^2} = \frac{1}{m_2}\left(P_2 L\, d_2 - k_2 x_2 - r_2 \frac{\partial x_2}{\partial t} - k_c(x_2 - x_1)\right). \tag{10.5}$$

Here P is the subglottal pressure, L the folds length, and r_1 and r_2 are damping constants of the folds. Both folds are coupled with a coupling term k_c.

The model is able to produce a periodic oscillation of the folds as with normal singing. However, when varying the parameters bifurcations appear. Figure 10.2 shows bifurcations on changing the coupling constant k_c of the model, thus displaying a traditional bifurcation scenario as known from the logistic map [10.2]. The Lyapunov exponents shown in Fig. 10.2b are an indication of nonlinearities in the system and display the onset and amount of chaoticity in the regime.

Also falsetto voice transition can be explained using the two-mass model [10.15, 16]. Here the transition from chest to falsetto voice is a hysteresis loop as shown in Fig. 10.3. It takes more pressure to change from the chest to the falsetto voice then when coming back

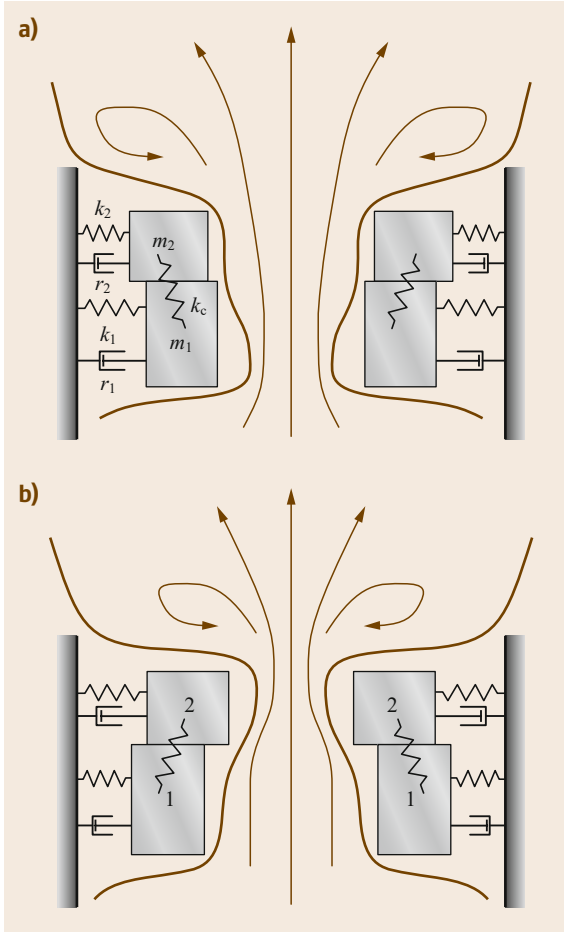

Fig. 10.1a,b Two-mass model of the vocal folds shown at two turning points of one oscillation cycle: **(a)** folds are more open at the supraglottal side, **(b)** folds are more open at the subglottal side (after [10.14])

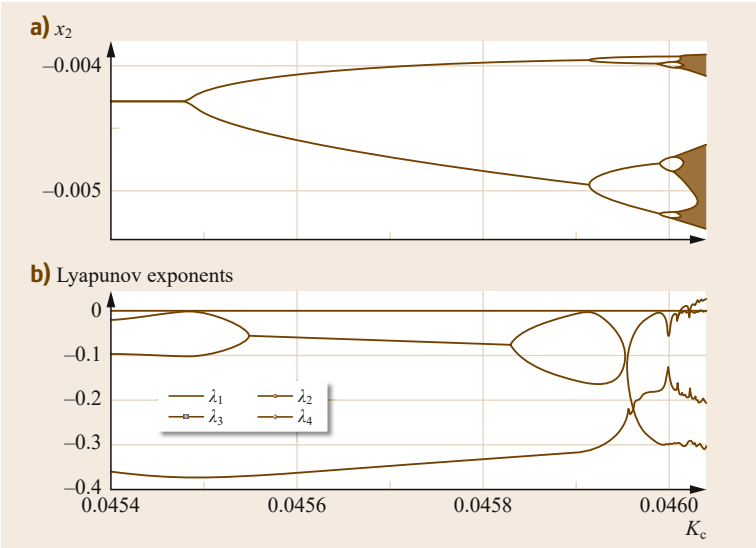

Fig. 10.2a,b Bifurcation scenario of a two-mass model of the vocal folds when varying the coupling constant between the vocal folds. From a certain region bifurcations appear and lead to an unstable rough voice. **(a)** Period-doubling at $K_c = 0.04548$ into two periodicities, followed by bifurcations with increasing K_c. At $K_c = 0.04611$ the system becomes chaotic. **(b)** Lyapunov exponents λ_1–λ_4 (*top* to *bottom* in **(b)**) calculated from **(a)**. $\lambda_1 = 0$ (bifurcated but non-chaotic oscillation) until $K_c = 0.04611$, where λ_1 becomes positive, indicating chaotic motion. $\lambda_2 = 0$ from $K_c > 0.04611$ (after [10.14])

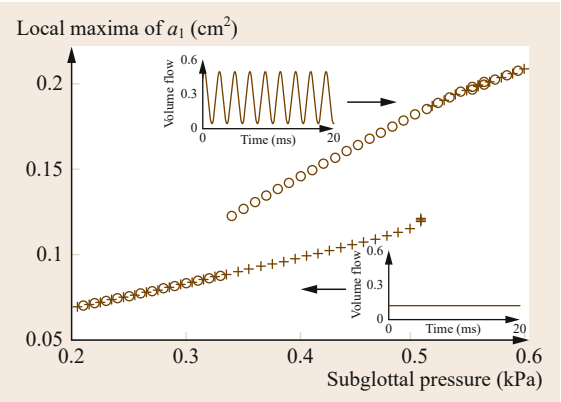

Fig. 10.3 Hysteresis loop between chest and falsetto voice. When changing from chest to falsetto a higher pressure is needed than when changing back from falsetto to chest voice

from falsetto to chest voice. This is a classical behavior of self-organizing systems which try to stay in an established regime as long as possible, stretching the boundaries of sudden phase changes to the other regime as much as possible.

So the two-mass model is able to determine sudden phase changes like tone onset and the change from chest to falsetto singing. It can also model bifurcations when the vocal folds have different tensions as discussed below.

10.2.3 Mucosal Wave Model

The two-mass model explains most of the vocal fold behavior. Still, it is a purely iterative model to which no analytical solution is known. To get an analytical understanding *Titze* proposed a mucosal wave model [10.5], which reasons that the vocal folds are basically a van der Pol oscillator like

$$m\frac{\partial^2 u}{\partial t^2} + (R - R_g)\frac{\partial u}{\partial t} + Ku = 0\,, \tag{10.6}$$

where u is the displacement of the folds perpendicular to the air stream P_s. Then m is the vocal fold mass, K its stiffness, and R its internal damping. Here P_s is acting on the folds not directly but through the relation of the open area a_1 and a_2

$$a_1 = 2L\left(u_0 + u_+\tau\frac{\partial u}{\partial t}\right) \tag{10.7}$$

$$a_2 = 2L\left(u_0 + u_-\tau\frac{\partial u}{\partial t}\right), \tag{10.8}$$

of the supraglottal and subglottal fold side, respectively. Then the pressure acting on the folds is built from the lung pressure P_s and the areas like

$$P_g = P_s\left(1 - \frac{a_2}{a_1}\right), \tag{10.9}$$

where then

$$R_g = \frac{2\tau P_s}{u_0}\,. \tag{10.10}$$

From the van der Pol oscillator an analytical solution is known with eigenvalues

$$\lambda_{1,2} = -\frac{R - R_g}{2m} \pm \sqrt{\left(\frac{R - R_g}{2m}\right)^2 - \frac{K}{m}}\,. \tag{10.11}$$

These eigenvalues have imaginary parts that are complex conjugates and therefore the attractor is a limit cycle if the real part is zero, which is the case for $R = R_g$. If $R \neq R_g$, the attractor is a focus which is either stable for $R > R_g$ or unstable for $R < R_g$. In the latter case, the driving of the folds by the air stream is greater than the internal damping of the folds and therefore the folds start moving as an unstable focus increasing the vibration amplitude. We can therefore calculate the onset pressure as

$$P_{\text{onset}} = \frac{Rx_0}{2\tau} \,. \tag{10.12}$$

10.2.4 Hopf Bifurcation

This mucosal model shows us analytically the reason for tone onset and gives estimates when this will appear. Still it arrives at an unstable limit cycle which theoretically could build up forever leading to unphysically large amplitudes. This is avoided by a Hopf bifurcation [10.17–19]. The basic idea of this formulation is to solve the equations analytically by linearizing the nonlinear equation system using a Taylor series in the neighborhood of the attractor point [10.2]. Mathematically, this is beyond the scope of this paper. Still the basic equation system is

$$\begin{pmatrix} \dot{x} \\ \dot{y} \end{pmatrix} = \begin{pmatrix} \alpha(P_s) & -\omega(P_s) \\ \omega(P_s) & \alpha(P_s) \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} + \begin{pmatrix} f(x,y) \\ g(x,y) \end{pmatrix} , \tag{10.13}$$

where P_s is the lung pressure again. On the rhs the first term is linear and the second term consists of all nonlinear terms which we neglect in the neighborhood of the attractor. The attractor has two coordinates x and y. A simpler way to understand the system analytically would be to use polar coordinates (s, θ) of radius and angle, respectively. Then a tone onset would be the transition of $s = 0$ to $s > 0$ and vice versa for a tone offset. After transformation of the equation system into polar coordinates and some math we arrive at

$$\dot{s} = dP_s s + as^3 = f(s) \tag{10.14}$$

$$\dot{\theta} = \omega + cP_s + bs^2 = g(s) \,, \tag{10.15}$$

with $d = \partial\alpha/\partial P_s(0)$ and $c = \partial\omega/\partial P_s(0)$. After examining the eigenvalues of the system four cases are possible:

- $d > 0, a < 0$: supercritical stable Hopf bifurcation
- $d < 0, a > 0$: supercritical unstable Hopf bifurcation
- $d < 0, a < 0$: subcritical stable Hopf bifurcation
- $d > 0, a > 0$: subcritical unstable Hopf bifurcation.

Bifurcation here means the onset of an oscillation so the transition from a point attractor to a limit cycle. In the terminology of nonlinear dynamics this is justified as an oscillation is expected with differential equations of second order. However, the Hopf bifurcation equation system is one of first order and therefore does not have an oscillation as a solution but an exponentiall decay. So an oscillation is not expected. Still it appears as a bifurcation of the system. As this bifurcation is appearing at a certain pressure level it indicates a sudden phase change from silence to a musical tone.

Lucero finds the vocal folds to be a subcritical unstable limit cycle. This explains tone onset and the hysteresis loop of on- and offset already discussed above. Figure 10.4 shows the results of these calculations where the pressure for tone onset needs to be higher than the one of tone offset as known experimentally.

The only problem here is that the bifurcation, the onset of the oscillation, in this system is unstable. This means that only a small change in singing would make it blow up to unreasonable large amplitudes. Therefore, one need to stabilize it by limiting the lung pressure.

10.2.5 Biphonation and Subharmonics

The singing voice has many more articulations than only a perfect harmonic pitch. Rough voice is well known to such musical styles as Blues, Rock, Metal, or Grunge. Such rough voice still has a periodicity and therefore a pitch, now with additional inharmonic components. To mention only a few, the throat

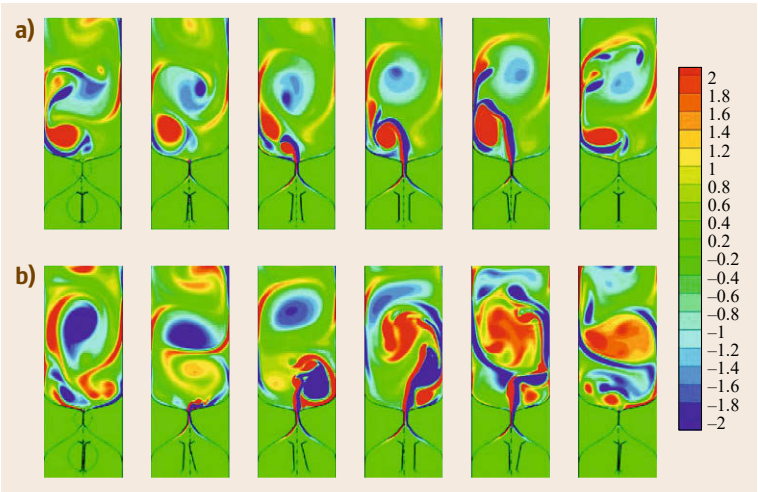

Fig. 10.6a,b Adjacent time points of a finite-element model of vocal fold flow dynamics for **(a)** a normal voice and **(b)** a voice with uneven fold tension displaying more turbulent motion with the altered folds

singing of Tuva or Tibet uses subharmonics where the singer normally performs an octave below his normal singing voice as discussed e.g., with *kagyraa* singing of Tuva [10.20]. Paul Pena, a Blues musician demonstrates the similarity of Tuvan subharmonic singing and blues howling style (CD: Paul Pena: Ghengis Blues. Six Degrees 2000). *Lee* compare Korean and Western singing in this way [10.22]. The role of vocal fold nonlinear expressiveness is discussed in [10.10] for contemporary vocal music.

These phenomena have been extensively studied using two-mass and related models [10.21, 23, 24] as well as experimentally [10.25].

The bifurcation diagram shown in Fig. 10.5 shows regions within which a stable oscillation of simple or complex integer oscillation ratios appear. Normal singing would be 1:1, throat singing would be 1:2 as an octave below. With 3:2 two tones would be present within one singer a musical fifth apart etc. The regions depend on the subglottal pressure and the relation between the vocal fold tension. These regions show sudden phase changes to other regions and are therefore stable over some parameter variations of pressure and tension relation.

A Finite-Element Model (FEM) of the air stream of vocal fold vibration [10.24] shows the turbulence appearing over the folds for two cases of symmetrical folds (both with the same tension) and asymmetrical folds. Clearly the turbulence above the folds is getting more complex with the asymmetrical case (Fig. 10.6).

In the model of *Xue* [10.24] it is interesting to see that the turbulent flow above the folds looks very much like the flow of an air stream entering a saxophone or clarinet mouthpiece. As discussed in the wind instrument part of this chapter, a laminar air stream entering a larger cavity becomes unstable and builds a first large

vortex which is the main sound source. So the next step in building a model for the singing voice could point in this direction of modeling the air flow in terms of the sound production and transition and possible reflections in the vocal tract.

10.2.6 Synchronization with Vocal Tract

Above we concentrated on the self-oscillating system of the vocal folds without taking the vocal tract or subglottal areas into account. We might simply consider the vocal tract as a resonator and not go into further detail here. Still strictly speaking the vocal tract is a tube which reflects the sound produced by the vocal folds and therefore is acting back on them. The mechanisms of a tube reacting to a fluid-driven self-sustained oscillation is discussed in more detail below with the organ. Also the organ labium is not a vocal fold. Comparing the singing voice with a saxophone we find a considerable difference. With the saxophone, the tube (the resonator) forces the reed (the generator) to go with its frequencies, as the tube is much less damped than is the reed. With the singing voice the situation is vice versa. The vocal tract (the resonator) is forced into the frequencies of the vocal folds (the generator), although again the resonator is much less damped. Still in a normal singing register the vocal tract resonance is normally above the periodicity of the vocal folds. This is reasonable as the vocal tract is shaping the voice in a formant way, enhancing higher spectral regions above the fundamental periodicity of the fold vibrations. So here we find that although the folds are more damped than the resonator, the generator takes over the vibration because its pitch is much lower than that of the vocal tract.

10.3 Harmonic Synchronization in Wind Instruments

When playing a saxophone, trumpet, or organ pipe under normal playing conditions, the played notes show a nearly perfect harmonic overtone spectrum. This is so familiar that we take this for granted. Still, when examining these instruments closer this harmonic series should not be expected at all as the instruments are highly nonlinear, show turbulence flow, uneven bores in flues and clarinets, shaped tubes like in trumpets or saxophones, a flared bell at the tube end, and other features that distort the simple behavior of a mathematical tube with a theoretically harmonic spectrum.

And indeed when overblowing a horn, trumpet, or saxophone the overtone series is never harmonic, but shows large deviations up to a third above or below the expected partial frequency. This is one of the major problems of instrument builders. Flute makers use a complex bore diameter shape over the flute length to account for the harmonic overtone series as well as for the amplitudes of the partials [10.26]. So when enlarging the bore at one point one overtone may fit better while at the same time another is deviating more. Additionally, the size and length of the finger holes change the length of the tube in a complex way and again lead to distortions of the harmonic series [10.27]. Here, over the centuries the builders established rules of thumb to arrive as closely as possible at a perfect series. The rest need to be adjusted by the player who can change playing pressure, lip tension, or the distance between the players lips and a labium to intonate the instrument correctly. With instruments of lesser quality it can be a pretty demanding task and in some cases a desired pitch cannot be reached at all.

With horns the flaring of the bell not only determines the timbre of the tone by enhancing higher partials with stronger flaring, larger bells lead to a frequency dependence of the tube end-correction. So for each frequency the tube has a considerably different length and therefore the harmonic series is no longer harmonic at all [10.28]. Although theoretically the Bessel horn, a horn with a bell flaring according to a Bessel function would again meet a perfect spectrum, when measuring the bells of existing instruments this Bessel shape is nearly never found.

Finally, the driving mechanism, the mouthpiece with reed or double reed or cavity as with brass instruments, or the labium shape and cavity with organ pipes or flues, are highly complex with a nonlinear driving mechanism. Here again we would expect a different theoretical tube end which is frequency dependent.

Still with all wind instruments within a normal playing regime the tones produced show a nearly perfect harmonic overtone series mostly far from the overtones which the instruments produce when they are overblown. This behavior is so robust that we would expect a simple mechanism to be behind it. Indeed, it is not possible to shape the overtone spectrum of one tone to a desired spectrum by changing the geometry of the instrument. At first sight this sounds very much like a synchronization or self-organization system where due to a nonlinearity in the driving mechanism as discussed below a very simple output is produced, the harmonic spectrum. So we need to discuss these instruments in detail to see if this mechanism exists and how it might work.

The fact that wind instruments leave this harmonic series when not played with enough blowing pressure, which produces noise, or with complex fingerings, which produce multiphonics, is again pointing in the same direction as a self-organized system would perform a simple output only for a certain parameter range. It then leaves the simple regime suddenly, which again is a property of wind instruments which suddenly change from noise to a tone at a certain lung pressure threshold. Also bifurcations would be expected from such a system which would be present with multiphonics played on nearly all wind instruments in contemporary, free improvised or modern classical music or free jazz. Here tutorial material teach hundreds of possible multiphonics with complex fingerings like with the clarinet [10.29].

This chapter reasons that this synchronization phenomenon arriving at a perfect harmonic series can be understood when examining the flow in the instruments, its change from laminar into turbulent flow, and its interactions with the tube and a possible reed.

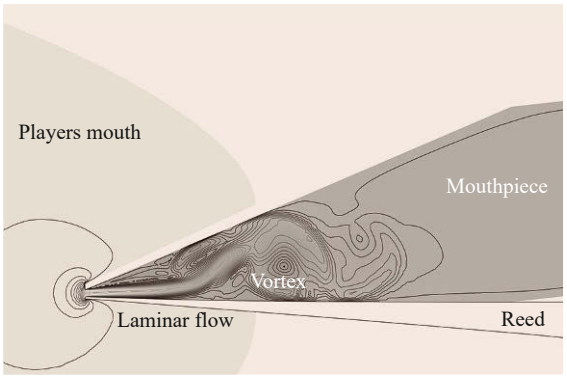
10.3.1 Navier–Stokes Flow Model

The Navier–Stokes flow equation can be used to understand the flow that appears when blowing into a wind instrument [10.30],

$$\partial_t u_i + u_j \partial_j u_i = -\frac{1}{\rho} \partial_i p + \nu \nabla^2 u_i$$
$$\text{with} \quad i = 1, 2, 3 \,. \tag{10.16}$$

It states that there is a balance of accelerations when comparing the flow velocity u and its interaction in all three directions $i = 1, 2, 3$ with the pressure p. So when the velocity changes, either in time as stated by the term $\partial_t u_i$ or in space as stated by the term $u_j \partial_j u_i$, it needs to be balanced either by a spatial change of pressure $-1/\rho \, \partial_i p$ at this point or by a viscous damping $\nu \nabla^2 u_i$ with viscosity constant ν.

Let us consider this in action in a saxophone mouthpiece as shown in Fig. 10.7. The pressure in a mouth causes a laminar flow into the mouthpiece which then becomes a large vortex. This vortex is caused by the term $u_j \partial_j u_i$, which describes a change of flow velocity between the directions. So as the laminar air stream is small it interacts with the air around it and as the air stream is freely moving in the cavity only slight differences between these interactions above and below the stream will drive it in one direction more than the other. This change of direction is exponentially increasing leading the stream to turn around itself by 360° building a vortex or eddy as seen in the figure.



10.3.2 First Vortex and Sound Production

This first vortex building is crucial for the synchronization in some ways. First, it is only caused by the nonlinear term in the Navier–Stokes equation $u_j \partial_j u_i$ and is therefore the nonlinearity in the system. If the equation was linear in this respect, so if the derivative of the flow velocity is not multiplied by the velocity of the other directions, the flow would be straight and not build a vortex.

Secondly, the vortex means that the flow does not move further in its original direction, it stops by building a vortex at a certain point. This means two things, first the flow is nearly completely dissipated within the mouthpiece and all energy traveling further into the tube is almost completely acoustic flow [10.31, 32]. Further, this also means that there is a strong spatial gradient at the point of the vortex. As discussed above, the Navier–Stokes equation is a balance of flow and pressure change. So when the flow changes strongly at a point in space the pressure changes strongly too at this point, a pressure gradient is built there. This pressure gradient is the sound source, so here the transfer of flow into acoustic energy is taking place.

In terms of the labium, the pressure gradient produced by the first vortex is experimentally shown in the case of a self-sustained oscillation at a labium in Fig. 10.8 [10.33, 34]. Here the three columns show the flow (column c)), the pressure at the upper labium side (column a)), and at the lower labium side (column b)) for adjacent time points from top to bottom over one cycle of oscillation. The sketch d) holds as a reference for all pressure plots displayed in columns a) and b). The pressure plots start at the labium tip on the left end of sketch d) and display the pressure at the different time

Fig. 10.7 Turbulent flow in a mouthpiece when driven by the pressure of the mouth. The reed is driven by the pressure difference between these two cavities. A large vortex is formed in the mouthpiece as the laminar flow from the mouth enters a large cavity (the mouthpiece) and therefore becomes unstable ◄

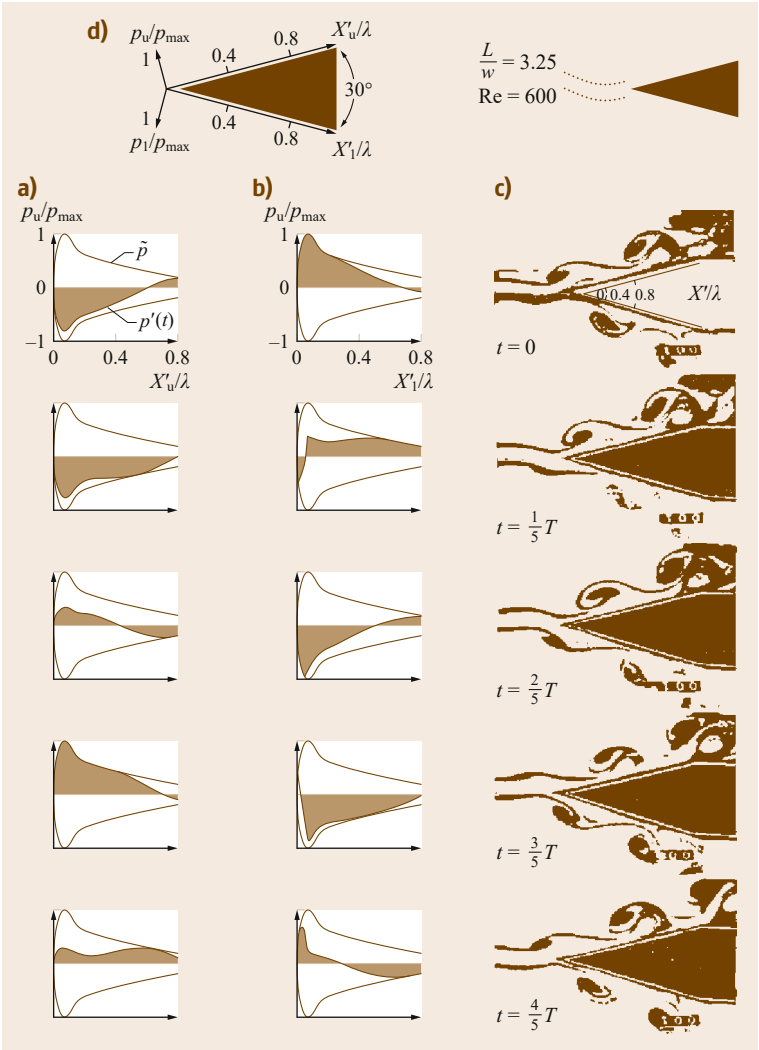


Fig. 10.8 Column **(a)** and **(b)**: pressure distribution $p'(t)$ (normalized by maximum pressure p_{max}) and column **(c)**: flow visulaization of the vortex street for pressure p_u. p_u is shown **(a)** above and **(b)** below the labium. The labium is sketched in **(d)** with labium tip at the left end and labium length as unit of oscillation wavelength λ like X'_u/λ for a flow of Reynolds number Re = 600. The rows in columns **(a–c)** are shown at five adjacent time points t over one cycle of a periodicity T (after [10.33])

points (*black area*) and the maximum pressure envelope over one period cycle (*black line*).

The point of interest for our reasoning is the strong pressure gradient at the tip of the labium shown in the pressure envelopes of the plots. This is the point where the large first vortex appears around the labium tip. So also for the labium instrument the first vortex is the point of a pressure gradient.

Now this gradient is changing fast in time according to the oscillation periodicity. So at this point at the labium, or at the vortex in the saxophone mouthpiece, a pressure impulse is produced which has a certain shape according to the geometry of the mouthpiece or labium cavity, the oscillation frequency, and the blowing pressure.

Still when using a Navier–Stokes model as discussed above we do not have any sound yet as this model is incompressible. Sound means a density change and therefore including a compressible Navier–Stokes model with a density ϱ varying over time and space like

$$\frac{\partial \varrho}{\partial t} = -\nabla(\varrho u_j) \,. \tag{10.17}$$

Using an incompressible Navier–Stokes model artificially skips the acoustics, still it is much easier to handle and therefore suitable as a first approximation. Nevertheless, the transfer from flow into acoustics is the core idea of wind instruments. It appears that the first pressure gradient at the vortex cannot move further as an acoustical pressure when using the incompressible Navier–Stokes equation as we artificially prohibit the acoustics. Still, when adding compressibility we allow the pressure gradient to continue as acoustical sound where the impulse is then traveling along the tube, is

reflected at the tube end, and then returns to the mouthpiece or labium again.

10.3.3 Phase Disturbance and Turbulent Damping

So now we have a pressure gradient or impulse traveling down the tube of the instrument. Indeed wind instruments are known to have a time series which consists of pressure impulses and are often modeled by synthesizers using rectangular-shaped oscillators. Still, as discussed above the pulse shape is very distorted when traveling down the tube. This is caused by a complex bore profile with flues, the tube shapes of saxophones or trumpets, the bell flaring at the tube end with frequency-dependent end-correction, and other aspects like finger hole size and tube thickness.

An interesting aspect is the shape of small areas of the instrument which may cause turbulent damping again because of the thin tube diameters. The acoustic flow can be fully described by the compressible Navier–Stokes equation, therefore it still remains a flow of pressure, velocity, and density fluctuations. Therefore, the acoustic pressure is interacting with the walls of the tube causing considerable damping within the tube which is affecting the playability of the instruments as well as their acoustic properties. This can only be explained by a tremendous damping caused already by only small turbulence production.

Such a case was found with bassoons in their s-shaped tube section [10.35]. Bassoon players need up to 15 kPa of lung pressure to drive their instruments, which physiologically is a challenge for the players' lungs. Therefore, reducing this pressure is highly welcome. When examining the acoustic flow through the bassoon tube, it appeared that for acoustic flow through s-shaped tubes where the pressure needs to change direction, turbulence appears in the tube which increases the onset threshold for playing on the instruments. By changing the geometry of the shape the onset playing pressure could be decreased.

A theoretical model for understanding turbulent damping is the k-ϵ Reynolds-Averaged Navier–Stokes model [10.30]. This was applied to a flute and compared to a normal incompressible Navier–Stokes model to account for the damping appearing through turbulence when blowing into the flute [10.36]. The efficiency of a flute is low where only about 3% of blow energy is entering the tube as acoustic energy. Then again only about 2% of these 3% is transmitted into the room as sound pressure making the flute a very low sounding instrument [10.37]. In a Finite-Element Reynolds-Averaged Navier–Stokes model it could be shown that when modeling the flute in-blow without taking turbulence into consideration the amount of energy entering the flute tube is about 50% while when modeling the instrument with turbulence it is only about 3% leading to a realistic model.

Therefore, most damping in the tube of wind instruments seems to be caused by turbulence, although there the acoustic energy traveling through the tube is transferred into flow again and then dissipated. So strictly speaking there is no fundamental difference between flow and acoustics and the compressible Navier–Stokes equation is able to account for both as well as for their coupling.

10.3.4 Triggering of New Impulse and Phase Alignment

So when the pressure impulse produced at the labium or in the mouthpiece has traveled through the tube and returns to the generator its phases are greatly disturbed. If this impulse would simply be reflected at the generator and travel back into the tube the resulting overtone spectrum of a tone would not be harmonic at all but would reflect the distorted series of overblown tones on the instrument. So a synchronization of the phases of the impulse needs to occur at the labium or in the mouthpiece to align these phases again leading to a harmonic series. The literature suggests two main approaches to this synchronization.

Models like van der Pol oscillators, as discussed in some detail in the section on the vocal tract (Sect. 10.2.3), are suitable for synchronizing organ pipes [10.38, 39]. These were applied to a slightly different problem of synchronizing two pipes. The synchronization occurs due to an energy transfer between the frequencies so that slower or decayed phases are pushed and faster phases are decayed in such a way that the phases are aligned again. This is reasonable in the case of two organ pipes coupling through space and is an effect that is known by organ builders and used to increase tuning stability of organs in regard to temperature fluctuations in churches due to weather conditions, which would otherwise detune the organ considerably.

The other model assumes that the returning impulse only triggers a new impulse, which is built in the generator [10.36]. So in saxophones the returning impulse moves the reed up or down, depending on whether the returning pressure is an under- or overpressure. Then the inflow of air into the mouthpiece changes and therefore the first vortex changes, too. This vortex then produces a new pressure impulse from scratch without taking the old one into account. As this new impulse is built in exactly the same way as the last one the synchronization is perfect and this new impulse then travels

down the tube again. So in this model the disturbance of the returning impulse can have any shape, as the returning impulse is either damped in the mouthpiece or radiated into the surrounding air via the labium. It need not be phase aligned again to arrive at a harmonic overtone series. It only triggers a new impulse and therefore can have any kind of distortion.

The trigger model is supported by the reed system to be a pure valve system. So although the impulse sent out from the mouthpiece has a rich harmonic overtone series, the reed moves almost completely in a sinusoidal manner without any harmonic overtones. The reed behaves like a simple valve opening or closing and is not contributing any harmonics. Therefore, the returning impulse can only trigger the fundamental periodicity as the reed is not reacting to the higher harmonics of the returning impulse.

Also the robustness and stability of the synchronization can be explained by the trigger model more easily. Aligning the phases of highly distorted returning impulses is complex and would be much more unstable and unreliable. Indeed, under normal playing conditions all wind instruments show this synchronization of partials almost completely, suggesting a very simple reason is behind this synchronization.

So when considering the reasons why, in a system of coupled oscillators, one oscillator takes over the other oscillator, in terms of its frequencies, with labium instruments it appears that the strong turbulent damping at the labium leads to the labium oscillator being heavily damped, while the tube is only weakly damped, and therefore the tube takes over the labium oscillation. With reed instruments the reed is much more damped than the tube and therefore here it is the reed taking over as already discussed by *Aschoff* [10.3].

10.3.5 Synchronization Condition

So we might generally say that the slaving of the generator by the resonator is due to the resonator being much less damped than the generator. Still, as we have found with the singing voice this might not always be the case and in this system, although the generator is damped more than the resonator, the generator prevails as its pitch is much lower than that of the resonator. A saxophone reed has a lowest eigenfrequency of about 1 kHz when attached to the mouthpiece. While playing this lowest eigenfrequency doubles to about 3 kHz [10.36] and therefore is greatly above the resonator frequency. Therefore, here both conditions, that of a heavier damping as well as a higher pitch, leads to a slaving of the reed by the tube.

With organ pipes the self-sustained oscillation of the labium is tuned to about the resonance frequency of the tube. Therefore, here the situation is not as simple and although we have perfect synchronization between the two it is not straightforward to say who synchronizes whom to what extent.

10.4 Violin Bow–String Interaction

Many musical instruments are bowed, like the violin, viola, cello, or double bass, but also the Indonesian *rebab*, the Chinese *erhu*, the Indian *esjay*, and hundreds of other instruments around the world. There are also some rare friction instruments which are played by rubbing over a surface, like the bowed glasses or the *lounuet*, a rubbed wooden block found in New Ireland, or bamboo tube zithers like the *kting ga-un* from Thailand [10.40]. The mechanism of bowing is a highly nonlinear one where the bow or a rubbing finger is alternatively sticking and slipping over the string or over a surface like glass or wood. The nonlinearity in this interaction is the strong and sudden change in the function of force of the bow acting on the string. A linear force function would only linearly change with bowing pressure where doubling the pressure would double the force of the bow acting upon the string. However, when bowing the force changes from being very strong during the sticking phase to a rather light force during the slipping phase, where the bow is only gliding over the string.

The system also shows all aspects of a self-organizing system [10.36, 41]. First, over a wide bowing pressure and velocity parameter range, it stays in the same regime, a periodic Helmholtz or sawtooth motion where the periodicity is determined by the string length. Adding to the string periodicity is a small effect from the bowing pressure, where higher pressures decrease the pitch slightly, which is known as the flattening effect. The system also shows sudden phase changes at certain pressure values either entering a subharmonic or a bifurcation regime with scratchy and noise sounds. In the subharmonic regime, the pitch is determined no longer by the string length but by the playing pressure, which in terms of synergetics can be described as a change of the ordering parameter from string length to bowing pressure. In the bifurcation regime, multiple periodicities appear which are again stable over a certain parameter range only to then suddenly shift into another regime with again inharmonic partials. Finally, the shifts between the regimes, like the Helmholtz and the subharmonic or the bifurcation regimes, show hystere-

sis loops where entering one regime needs a different playing pressure to coming back to it.

Historically, bowing was first prominently considered by *Raman* [10.42], who argued that when we hear a violin tone of constant amplitude there needs to be an energy balance between input energy supplied by the bow and sound energy radiated into space. When calculating the energies he used the velocities of bowing and string and therefore many later considerations took string and bow velocity as their starting point [10.43–46].

Another approach is to consider displacement of strings and bow first and discuss the system in a time-dependent manner, which was proposed by *Güth* [10.47]. He is especially concerned with initial transients and describes them as small initial impulses traveling along the string when the bow is not in a steady state but still struggling to achieve a regular periodicity. Models using finite-differences to model the system have the same argument because such models include displacement, velocity, and acceleration in a time-dependent manner. Theoretically there can be no fundamental difference between the models as displacement and velocity are directly connected via integration and differentiation. Still both viewpoints, that of velocity and that of displacement were leading to different models explaining the stick/slip interaction and the conditions leading to a stable sawtooth motion.

10.4.1 Bowing Force Model

Figure 10.9 shows the force function f over the string velocity v [10.48, 49]. The bow velocity in this plot is where the curve has its infinite slope and crosses the horizontal axis. If the bow is sticking to the string both velocities, that of the bow and that of the string, are the same and therefore the curve is in the region of the infinite slope. The slipping phase is displayed as the region left of the infinite slope. There the string velocity is less than the bow velocity. The three lines with constant slopes and intersections v_h, v_r, and v_c point to three different relative bow velocities. v_r and v_c are both extremes crossing $f(v)$ twice, v_r relates to the maximum force point. v_c is parallel to v_r, touching the rising curve of the force function only once. Conversely, v_h crosses $f(v)$ three times, indicated by the points. The region between v_r and v_c is a region of arbitrariness, where the system is still stable and will continue with its basic motion. If this region is left, either above v_r or below v_c, the stability is left and the system will no longer show sawtooth or Helmholtz motion. In other words, the normal Helmholtz regime of playing appears over a larger region of bowing pressure, not just with only one single bowing pressure value. This is crucial for playing violin, as only the Helmholtz regime produces a harmonic pitch depending upon the fingering enabling normal violin playing.

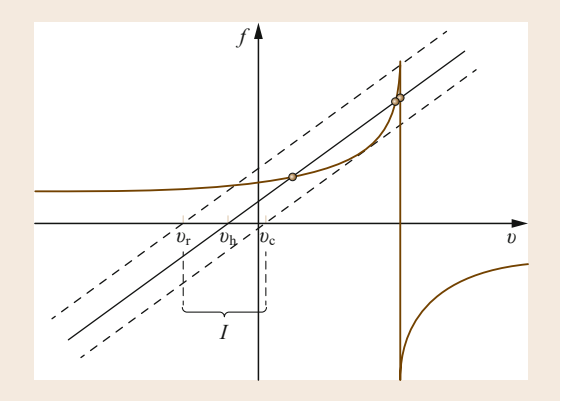

Fig. 10.9 Force f of the bow acting on the string depending upon the string velocity v. The positive force corresponds to the sticking phase, the negative force to the slipping phase. The point of sudden change is at the bow velocity v_h. The three slopes determine the region of ambiguous velocity-force dependency

10.4.2 Stick–Slip Condition Model

Another proposal is to model the string by introducing conditions for the bow to enter sticking or slipping in regard to the string [10.36, 50]. Such conditions can easily be introduced in a finite-difference time domain model (FDTD).

With displacement $f(x,t)$, damping D, the speed of sound c, and adding the bowing force $F(x,t)$, we have for the differential equation of the string

$$c^2 \frac{\partial^2 f(x,t)}{\partial x^2} - D\frac{\partial f(x,t)}{\partial t} - \frac{\partial^2 f(x,t)}{\partial t^2} = F(X,t)\,, \quad (10.18)$$

with the following stick-to-slip conditions:

- If the restoring force of the string at the bow point is higher than the bow force acting on the string or
- if the velocity of the string is higher than the bowing velocity

then the bow will tear-off the string.

If the second case is present we are in the stable regime of periodic sawtooth or Helmholtz motion. In the first case, a totally different string behavior appears, a subharmonic regime as discussed below.

10.4.3 Bifurcations and Subharmonics

Subharmonics and bifurcations have been widely studied with violin bowing [10.51, 52]. When leaving this

region of normal sawtooth motion by in- or decreasing the bowing pressure too much, two other regimes are reached:

- If the bowing pressure is larger than a threshold, a subharmonic regime is reached, where the played pitch depends on the bowing force.
- If the bowing pressure is smaller than a threshold, a bifurcation regime is reached, where inharmonic sounds are produced.

Subharmonic playing also produces normal pitches, still much lower than normal violin tones could be played. Bifurcation regimes produce noisy sounds and are more easily produced by reducing the amount of rosin on the bow leading to a low-volume, high-pitched noisy sound.

Figure 10.10 shows the time series for all three regimes. It was produced by a finite-difference solution of the string equation driven by a bow with constant velocity and linearly in- and decreasing bowing pressure. The pressure starts at $p = 0$ at the very left, increases up to the point of maximum amplitude in the middle of the plot, and linearly decreases again to become $p = 0$ again at the very right. Figure 10.11 shows a correlogram of this time series. A correlogram is like an autocorrelation of an autocorrelation of a time series, displaying only harmonic overtone series. Therefore, this plot displays the produced pitch of the time series.

The basic properties of bowing are shown in both plots:

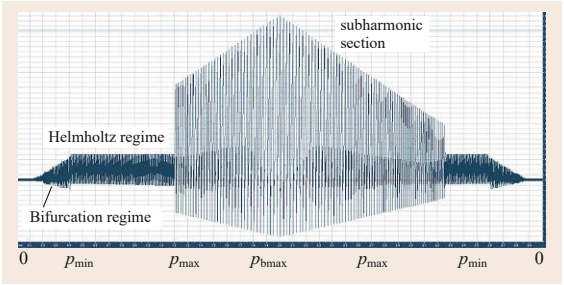

Fig. 10.10 Amplitude time series of the violin string/bow simulation, which was taken at the bridge point of the string, where the sound is transmitted to the radiating violin body; bowing pressure (*horizontal axes*) versus amplitude (*vertical axes*). The bowing pressure was increased from $p_b = 0$ to $p_b = p_{b\,max}$ linearly and then again linearly decreased to $p_b = 0$ again. The time series shows clear phase changes at certain pressure values. The Helmholtz regime is reached at p_{min} and becomes the subharmonic regime at p_{max}, which shows a more stable behavior with decreasing than with increasing pressure, a kind of hysteresis effect (Fig. 10.11). The bifurcation regime with lower pressure values than the sawtooth region also decreases amplitude and starts again at a certain threshold

- At the beginning with low pressures a complex bifurcation regime exists, as discussed below.
- Then at a sudden bowing pressure threshold a stable Helmholtz or sawtooth regime begins.
- Again at a certain threshold a subharmonic regime appears. As can be seen in the correlogram, the pitch of the played tone is strongly and linearly changing with linear increase of the bowing pressure. Also, the amplitudes in- and decrease linearly.
- The threshold at which the sawtooth regime is changing to a subharmonic regime is higher than the return threshold from subharmonic to sawtooth behavior. This is a typical hysteresis where an established regime tries to maintain itself as long as possible.
- During an increase of bowing pressure within the Helmholtz regime in the correlogram the pitch of the tone is slightly decreasing. This so-called 'flattening effect' of bowing is caused by the increased velocity difference between string and bow so as to tear-off the bow from the string with increased bowing pressure.

The bowing regime where the bowing pressure is too low to produce a sawtooth motion is very complex. Figure 10.12 shows the fundamental pitches during small subregimes within this bifurcation regime. These subregimes are again stable for a very small pressure region.

Overall, bowing is a very complex mechanism which, because of this complexity leads to a very simple output, a constant periodicity. This periodicity in the

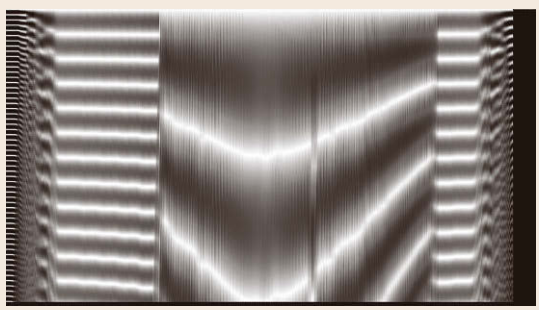

Fig. 10.11 Correlogram of the time series data of Fig. 10.4; bowing pressure (*horizontal axes*) versus fundamental frequency 100 Hz–20 kHz, linear scale (*vertical axes*). The different regimes can clearly be distinguished (see the caption for Fig. 10.10). The Helmholtz region shows a nearly constant fundamental frequency with a slight decrease of frequency known as the flattening effect. The subharmonic region clearly shows the dependence of the fundamental frequency on the bowing pressure. The bifurcation region shows small regions of constant fundamental frequencies between which phase changes occur

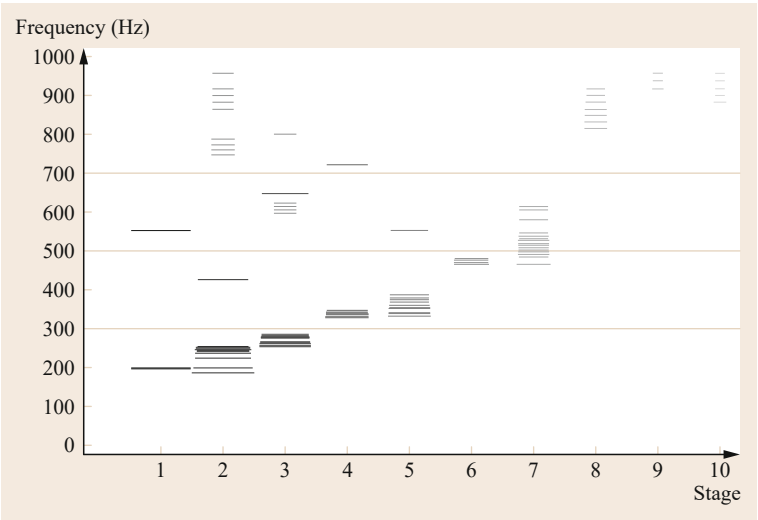

Fig. 10.12 Bifurcation scenario of the bowed string under the threshold pressure value needed to establish the Helmholtz regime (*Stage 1*); data from simulation

normal playing region has a fundamental pitch caused by the string length which only then makes normal violin playing by using fingerings possible at all. This mechanism also holds over a certain bowing pressure region making playing more convenient. Still, when leaving a certain pressure region the behavior of the system is very different, where the played pitch is determined by the bowing pressure itself. In contemporary forms of music these additional features of bowing are used to play low pitches on instruments which are normally not able to produce such low sounds.

10.4.4 Synchronization Condition

The reason for synchronization in the bow/string system and why sometimes the string and sometimes the bowing pressure determines the pitch becomes clear when using the stick–slip condition model. If the bow force is above a certain threshold, the damping of the string is too large to still be able to tear-off the bow from the string and therefore it no longer determines the pitch. Violin strings need to be damped much more than, e.g., guitar strings, for the system to work as the energy of the bow into the string must not survive more than one cycle around the string. Otherwise, the old traveling waves from previous tear-offs would disturb the present tear-off process and therefore a regular sawtooth motion would not be possible. Therefore, here the system which is damped less becomes more prominent and determines the pitch of the whole system.

10.4.5 Synchronization of Organ Pipes

Also synchronization may take place between musical instruments. Not many investigations have been carried out in this regard, those that have mainly deal with coupled organ pipes. This coupling between organ pipes standing next to each other or the coupling of organ pipes near a wall results in frequency synchronization between pipes [10.38, 39, 53]. Figure 10.13 shows the synchronization of a pipe and a loudspeaker standing next to it in relation to distance. *Abel* et al. use a van der Pol oscillator model to understand the synchronization assuming phase-locking when the pipes and frequencies are close enough. Varying these parameters leads to a d'Arnold tongue behavior, where with decreasing distance the range of frequency differences between the pipes where synchronization occurs is increasing in a nonlinear way.

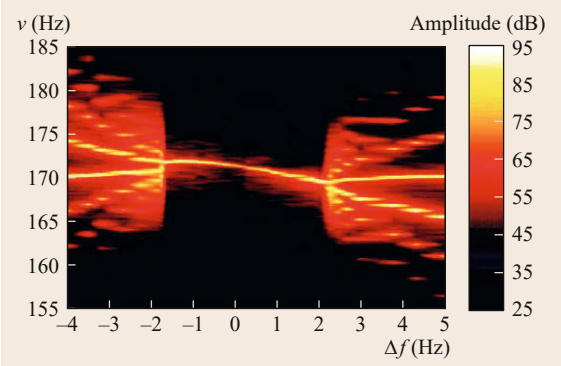

Fig. 10.13 Synchronization of an organ pipe and a loudspeaker standing next to it as the speakers frequency changes. Sharp onset and offset thresholds appear starting and ending the synchronization. Also the sidebands appearing in the nonsynchronized regions disappear during synchronization. (Reprinted with permission of [10.38]. Copyright 2006, Acoustical Society of America)

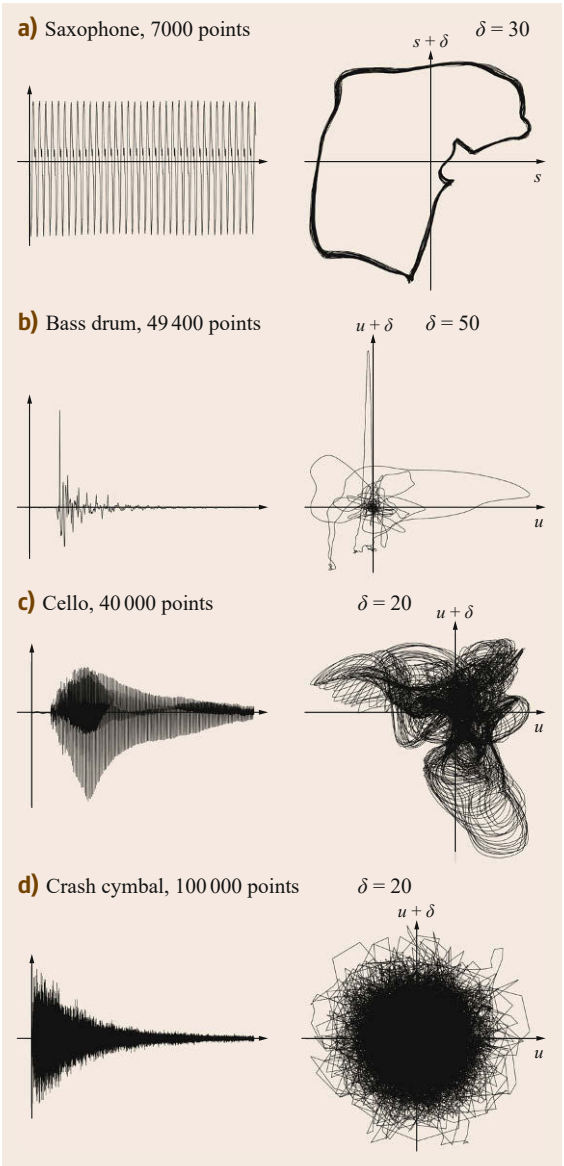
10.5 Fractal Dimensions of Musical Instrument Sounds

The term fractal is most often associated with self-similarity. The most common example is a snow flake which is complex in structure but is built following one simple rule of replacing lines in the geometry by stars, which then also have lines which are then once again replaced by stars ad infinitum. Then there is a self-similarity while operating on different levels of a scale. If there is one simple rule holding for all levels then the complex geometry can be explained by one simple construction rule. Also, as this rule holds for all levels of a scale from large to small, there is a scaling law characterizing the structure.



Still, the terms fractal and fractal dimension are derived from a mathematical standpoint. The relation between the length of a line r and the volume of a body C has the relation

$$C = r^D \,. \tag{10.19}$$

Here D is the dimension which for ordinary bodies has values of $D = 1, 2, 3$ and so is one-dimensional, two-dimensional, or three-dimensional. Now when writing this equation for the dimension we have

$$D = \log_r C = \frac{\log C}{\log r} \,. \tag{10.20}$$

So if there is a relation between the logarithms of a parameter C with changing r, the dimension is calculated by a fraction and may therefore be called fractal. Also as D may be different from an integer, a fractal dimension may have any value. Plotting this relation means using a log / log plot as both parameters C and r are present as logarithms. The fraction in such a plot means a slope and therefore we can say that the fractal dimension of a system described by $C(r)$ with changing r is the slope of a log / log plot.

When using measured data for such a structure, like when using a musical sound, of course this definition only makes sense when this slope is constant over a wide range of r. Then the time series is characterized by a fractal dimension. Such calculations have been performed for multiphonics of wind instruments [10.54], biphonations of the voice [10.9], initial transients for musical instrument sounds [10.36], or analyzing musical pieces of contemporary music [10.55].

There are many kinds of fractal dimensional calculations, a box-counting dimension, an information dimension, a correlation dimension, etc. which are shown to result in the same fractal number [10.2]. Still, the calculations are different where the fractal correlation dimension was built for time series and it is therefore often used with musical sounds. Still, other dimensions

Fig. 10.14a–d Four examples of musical sounds displaying their time series $s(t)$ on the left and their pseudo phase plots with different delays δ on the right in a two-dimensional embedding. **(a)** Limit cycle of a quasi steady state of a saxophone tone, **(b)** fixed point of a bass drum sound recorded with an accelerometer at the resonance membrane, **(c)** attack and decay of a cello tone with hard attack at the beginning and released bow, **(d)** a crash cymbal of a drum kit ◄

may be used for other purposes, like an information structure for musical onset detection [10.36].

10.5.1 Pseudo Phase-Space

All calculations of fractal dimensions start with the pseudo phase plot [10.56]. Here a one-dimensional time series $X(t)$ is embedded in an n-dimensional space by a delay variable δ

$$X(t) = \{x(t), x(t+\delta), x(t+2\delta), \ldots, x(t+\delta)\}\,, \tag{10.21}$$

with embedding dimension n.

Figure 10.14 shows four examples including a saxophone, a bass drum, a cello, and a crash cymbal in their time series and phase plots. The saxophone tone is shown in its quasi steady state only where the stable periodicity produces a limit cycle attractor. Still, the cycle shows deviations which is the quasi of the quasi steady state, where small amplitude and frequency deviations are displayed. The bass drum is a percussive sound showing strong amplitudes at the beginning of the sound and a fast decrease producing the knot at the axis origin. The cello tone is displayed with an initial transient with low amplitudes and additional inharmonic frequency components to the basically harmonic overtone structure. This plot shows a limit cycle but with very different cycle amplitudes and again the knot at the origin where the tone starts and ends. The crash cymbal has many inharmonic overtones, therefore coming close to a noise sound. Here no limit cycle is present and we have a chaotic attractor.

Phase plots can also be used to display the development of sound in detail. Figure 10.15 shows attractors at adjacent time points of a soft saxophone sound Fig. 10.15a, a violin sound with a hard attack Fig. 10.15b, and a Cambodian metalophone (*roneat deik*, Fig. 10.15c). All plots are normalized to the maximum amplitude of each plot. This ignores the amplitude decay of the sounds over time and therefore displays more details. The soft attack of the saxophone starts with noise at 0 ms, after which only slowly does a stable limit cycle with many deviations appear. The violin sound has a scratchy beginning with many inharmonic components shown at the beginning to then reach a very stable limit cycle. The last plot at 6000 ms shows the string still vibrating after bow release from the string. The *roneat deik* has an inharmonic structure and like the crash cymbal in Fig. 10.14 above begins with a noise-like attractor. After a while the higher harmonics have attenuated leaving basically the fundamental frequency vibrating where then a stable oscillation appears with only some inharmonic partials left.

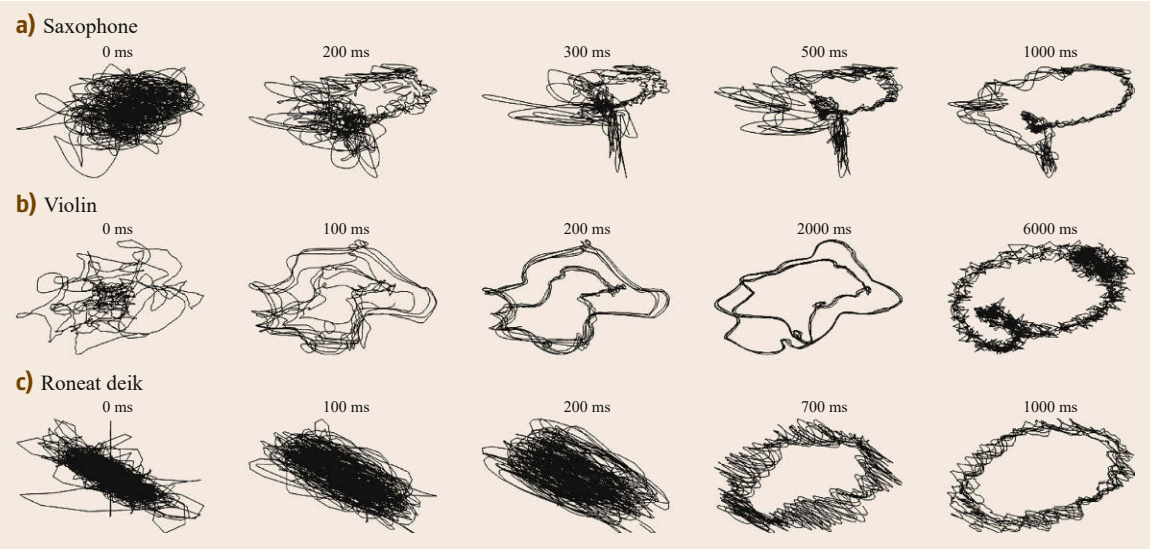


Fig. 10.15a–c Time development of phase plots of a saxophone tone with a soft attack (**a**), a violin tone with a hard attack (**b**), and a Cambodian metalophone (*Roneat deik*) (**c**) with an inharmonic overtone spectrum. The saxophone starts with noise and is only slowly reaching a quasi steady state. The violin sound has a scratchy beginning but is reaching a stable state, the 6000 ms plot displays the string after bow release. The Cambodian *Roneat deik* has an inharmonic overtone structure and therefore a chaotic plot which enters a cyclic motion when the higher harmonics have decayed and only the fundamental is still strong

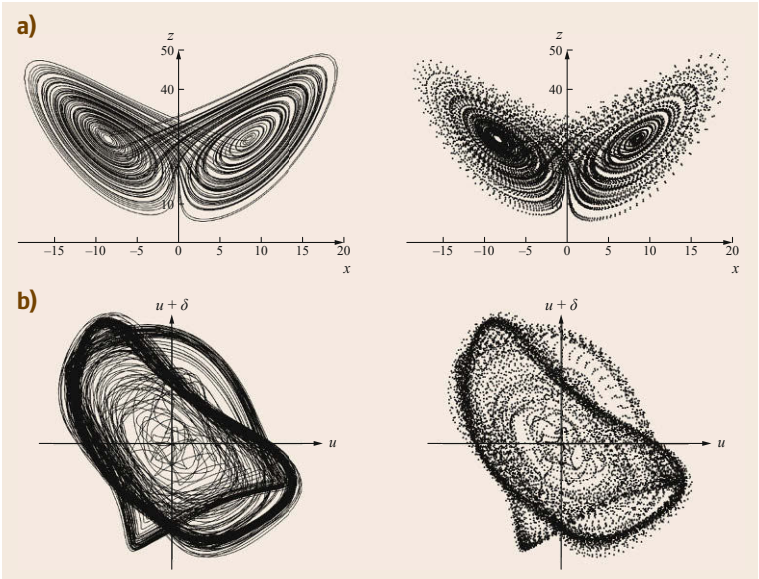

Fig. 10.16a,b Comparison of trajectories (*left plots*) and single point sets (*right plots*) of a quasi steady state and a transient attractor, **(a)** Lorenz attractor (x/z plane) as a quasi steady state attractor, **(b)** sinusoidal transient of first 100 Hz then 180 Hz with overall rising amplitudes

10.5.2 Fractal Correlation Dimension

So the pseudo phase plots display the fundamental behavior of musical tones very well and are therefore a reasonable starting point for further calculations. Here only the fractal correlation dimension is discussed as it is the one most widely used and numerically equivalent to all other dimensions.

Starting from the n-dimensional embedding X as discussed above to calculate a fractal dimension we need to have a parameter $C(r)$ changing with a scaling r. Here first all distances between two points X_i and X_j in the n-dimensional space are calculated. Then r is a maximum distance for which we count how many distances $C(r)$ are below r like

$$C(r) = \frac{1}{N^2} \sum_{i \neq j} H(r - |X_i - X_j|) \,. \tag{10.22}$$

Here, $H(x)$ is the Heaviside function with

$$H(x) = \begin{cases} 0, & \text{for } x \leq 0 \\ 1, & \text{for } x > 0 \end{cases} \,. \tag{10.23}$$

Then the correlation dimension is again the fraction of the logarithms of $C(r)$ and r like

$$D = \frac{\ln C(r)}{\ln r} \,. \tag{10.24}$$

If D is constant over a wide range of r then a general scaling law appears in the sound characterized by the fractal dimension value D.

Musically this makes great sense as the correlation was developed to count the number of dynamic subsystems of a system. It appears that a subsystem as taken by this algorithm is a harmonic overtone structure no matter how many overtones there are as long as they are all in harmonic relation 1 : 2 : 3 : . . . Another harmonic overtone series raises the dimension number by one as do all inharmonic components by themselves as they may be interpreted as a new subsystem which may consist of only one partial. Also large amplitude fluctuations raise the fractal correlation dimension by one. The correlation dimension starts with the normalized phase plot and therefore does not consider the overall amplitude of the sound at the time slice the phase plot is constructed of. This amplitude may be added later to account for it, still it is convenient to have both parameters separated at first, the chaoticity or complexity as displayed by the fractal dimension and the loudness of the sound.

So the algorithm behaves like this:

1. If only one harmonic overtone spectrum is in the sound, $D_C = 1$ no matter how many overtones are present.
2. Each additional harmonic overtone spectrum raises D_C to the next integer.
3. If only one inharmonic sinusoidal is added, D_C raises to the next integer making it suitable for detection of additional single inharmonic components.
4. Large amplitude fluctuations lead to a rise in D_C.
5. As the absolute amplitude is normalized, D_C does not depend upon amplitude.
6. If a component is below a certain amplitude threshold it is no longer considered by the algorithm.

Table 10.2 Fractal correlation values and length of the initial transients for a Tsuji classical guitar with a cedar top plate and rosewood body. In the literature, it is sometimes stated that the fractal correlation dimension can only calculate steady states and not initial transients. This is not quite the case as can be seen when comparing a standard attractor, the Lorenz attractor of $D = 2.05$ with a transient sound of a clarinet changing a note as displayed in Fig. 10.16. Both phase plots show two attractors where we expect both to be $D = 2$. Indeed, the clarinet attractor is at $D = 2$. The difference between both attractors is that the trajectory of the Lorenz attractor travels a small amount of cycles on the left attractor then moves to the right and after some cycles there it moves back again. The clarinet attractor first stays at one attractor and then moves completely to the second one as this is the next tone played. However, the correlation dimension does not know about the temporal development of the trajectory as it is only taking all distances of the points into consideration. Therefore, to be precise when displaying the phase plot only the points should be displayed and not the temporal development between the points. Both cases are displayed in Fig. 10.16.

10.5.3 Initial Transients

So the fractal correlation dimension is very suitable for calculating the complexity or chaoticity of initial transients of musical instrument sounds. Table 10.2 shows the fractal dimensions of guitar tones of one guitar for the high e, h, g, and d-string for three volumes, fortissimo, mezzoforte, and piano, and two articulations *apoyando* (hard attack) and *tirandu* (soft attack). The dimensions are up to $D \approx 5$ meaning that four loud additional frequencies are added to the basically harmonic overtone series of the tone. The dimension does not

depend on volume or articulation very much which is expected when taking the physics of the guitar into consideration [10.36, 50].

Table 10.3 shows the mean values for three classical guitars for the two articulations. The *Lauenhardt & Kobs* has the smallest values and the *Tsuji* guitar has the highest value for *apoyando*. The subjective evaluation of guitar builders and experts in relation to these three guitars correspond to this finding concerning parameters like loudness or presence of the three instruments. Indeed, the inharmonic components of the guitars are perceived as a *knocking* at the tone onset which makes the sound more prominent or present. Therefore, higher values of fractal dimension of initial guitar transients point to a higher perceptual presence.

Further investigations with other instruments confirm this finding in general [10.36]. Violins and wind instruments have a wider range or articulations and therefore a wider distribution of fractal dimension values where hard violin attack sounds may have a dimension up to eight.

10.5.4 Mirliton

Also multiphonics [10.54] or the sound of mirliton, instruments where one finger hole is covered by a thin membrane [10.57] show a higher fractal dimensionality. Although not perfectly understood yet, mirliton instruments, as well as some multiphonic saxophone or clarinet sounds often show sidebands next to harmonic partials like

$$f_{n,m} = \frac{1}{(1+m)} n f_0 \pm m f_m \quad \text{with} \quad n = 1, 2, 3 \quad \text{and} \quad m = 0, 1, 2, 3 \ldots , \tag{10.25}$$

where f_0 is the fundamental frequency of the tone, nf_0 are its partials, f_m is a modulating frequency, and mf_m are the deviations around the harmonic partials with sideband frequencies decreasing around the harmonics.

Table 10.3 Mean and standard deviations for the two articulations for the three guitars

	Tsuji	Zander	Lauenhardt & Kobs
Apoyando			
Mean	2.9	2.5	2.0
Standard dev.	0.75	0.93	0.56
Tirandu			
Mean	2.5	2.6	2.3
Standard dev.	0.83	1.3	0.65

This leads to a rough and inharmonic sound with higher fractal dimensions. Figure 10.17 shows the time development of a Chinese *dizi* flute with the membrane unattached (first tone) and the membrane attached (second tone). Clearly the fractal dimension with the rougher sound of the attached membrane rises in general as well as with articulation.

10.5.5 Musical Density

The fractal dimension may also be used when investigating art music of the 20th century like free jazz, free improvised music, contemporary classical music, or sound-based music like Techno or Dance music. In many of these styles the temporal development of musical density is a prominent composition parameter as well as a prominent perception parameter with sound textures where no melodies, phrases, or cadenzas are present. As the perception of density is perceived instantaneously by listeners it needs to be considered by composers and musicians alike in these genres.

As an example, Even Parker's solo saxophone piece *Broken Wing* was calculated in terms of its fractal dimension [10.55] as shown in Fig. 10.18. Even Parker uses extended techniques of saxophone playing like complex tongue movement at the reed, multiphonics, and related techniques to arrive at an often nonharmonic tone production. The piece is perceived as starting with a low sound event density, then gradually increasing this and after reaching a maximum gradually becoming sparser again and finally ending in a low event density. The plot represents exactly this behavior for the per-

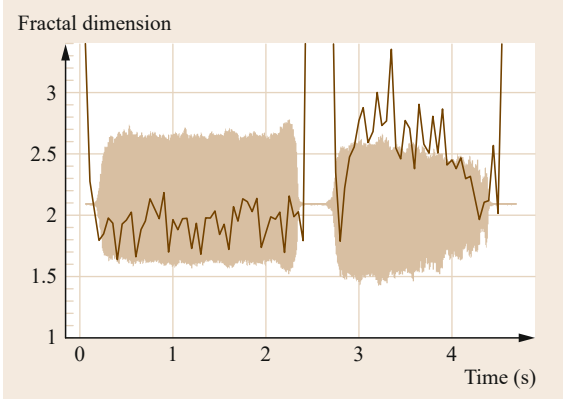

Fig. 10.17 Fractal dimension of two sounds of a Chinese *dizi* flute of same pitch, first played normally by closing the mirliton hole completely, second played as mirliton. The fractal dimension of the rough mirliton sound is considerably higher than with normal playing. Sections in between are noise with very high fractal dimensions

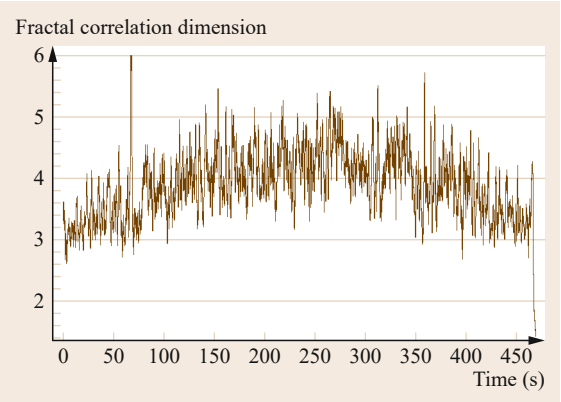

Fig. 10.18 Fractal dimensions of Even Parker's saxophone solo piece *Broken Wing* using extended techniques for saxophone tone production. One can clearly see the in- and decreasing behavior of the perceived density of the piece over 460 s ◄

formance and is therefore in very good correspondence with the event density musical feature for the whole musical piece.

So the fractal dimension displays many musical features:

- *Musical density* as often used in free improvised, electronic, contemporary classical, or experimental music where this parameter is crucial both for composition and perception of pieces.
- *Chaoticity of initial transients* as a measure of perceived presence and loudness of the musical tones.
- *Counting of the numbers of voices* in a musical texture as with homophonic or polyphonic music of all styles from Jazz, Rock, Metal, Techno, non-Western, or classical music.

10.6 General Models of Musical Instruments

Now, after our review of the main instrument families and their synchronization methods, we will sum the findings into general models to understand the phenomena. This general view has a top-down character and may not explain all details of the instruments at first. Still, the models can provide insight into basic aspects of synchronization.

10.6.1 Phase-Locking

As mentioned in some detail especially in the wind instrument section, the different frequencies or modes in an instrument have frequencies that do not match a harmonic overtone spectrum precisely and may deviate from it considerably. So one way of explaining synchronization is in terms of an energy transfer between the modes due to nonlinearities especially in the generator region. Then modes that are too slow can be pushed to catch up with faster modes and modes that are too fast can be drawn back to arrive at mode-locking and synchronize the phases.

One such general model proposed for wind and string instruments suggests a coupled equation system for modes [10.58]. Although a detailed description of the math is beyond the scope of this paper, the basic reasoning is that for displacement x_i and harmonic n_i of mode i driven by a force $F(\dot{x}_j)$ with eigenvalue λ_j like

$$\ddot{x}_i + k_i\dot{x}_i + n_i^2 x_i = \lambda_j F\left(\dot{x}_j\right) . \tag{10.26}$$

there is a solution that is a modification of the standard solution as we expect the amplitudes a_i and frequencies ω_i of the modes to change over time by phase Φ_i like

$$\dot{a}_i \sin\left(\omega_i t + \Phi_i\right) + a_i\dot{\Phi}_i \cos\omega_i t + \Phi_i = 0 . \tag{10.27}$$

Using only terms that slowly vary with ω, which are only considered here as only these are able to synchronize adjacent frequencies, we arrive at estimations of the amplitude and phase variations using

$$\langle\dot{a}_i\rangle = \frac{\lambda_i}{\omega_i}\left\langle F\left(\dot{x}_j\right)\cos\left(\omega_i t + \Phi_i\right)\right\rangle - 0.5k_i a_i , \tag{10.28}$$

$$\left\langle\dot{\Phi}_i\right\rangle = -\frac{\lambda_i}{a_i\omega_i}\left\langle F\left(\dot{x}_j\right)\sin\left(\omega_i t + \Phi_i\right)\right\rangle + \frac{\left(n_i^2 - \omega_i^2\right)}{2\omega_i} , \tag{10.29}$$

where the $\langle\rangle$ denotes that only slowly varying terms have been used. Now mode-locking is present when

$$qj = pi , \tag{10.30}$$

and

$$qn_j \approx pn_i , \tag{10.31}$$

with $p, q = 1, 2, 3, \ldots$ When assuming a nonlinear coupling function $F(\dot{x}_j)$, we arrive at the equation for mode-locking

$$p\left(n_i + \dot{\Phi}_i\right) = q\left(n_j + \dot{\Phi}_j\right) = pi\omega . \tag{10.32}$$

Here a common frequency ω holds for two modes n_i and n_j and its harmonics p and q when $\dot{\Phi}_i$ and $\dot{\Phi}_j$ are

appropriate. So as stated above, the phase changes slow down or speed up the modes and therefore lock them together to a common frequency.

Coupled systems of van der Pol oscillators also belong to this category as found with the singing voice. Similar models for musical instruments have been proposed in the literature, either a general view [10.59], or specifically for organ pipes [10.38], percussion instruments [10.60], and the singing voice [10.11].

10.6.2 Force Function Model

Another approach is a model that assumes a nonlinear generator and a linear resonator and has been proposed for violin–bow interaction, but was also proposed to hold for wind instruments [10.48, 49]. This model has already been discussed above in the bow–string section. The basic idea is that a force function of nonlinear nature is driving a system where the energy sent out by the generator (bow or mouthpiece) is traveling through a resonator (string or tube) and when returning is shaped by the force function again. Because of the nonlinear nature of this force function a regular motion appears which at first would also be present in a linear driver as no nonlinear distortion in the string or tube is assumed. Still, in addition to regular oscillation other regimes like subharmonics or double-slip or scratchy sounds can occur with violins when a parameter, the bowing or blowing pressure, reaches a certain threshold.

This model has analytical power because of the nonlinear driving mechanism, although in many cases the nonlinear function is not trivially found.

10.6.3 Impulse Pattern Formulation (IPF)

Another model sees musical instruments in terms of impulses starting from one system like a string, which travels through the instrument and interacts with the initial system again in a nonlinear way [10.36, 61]. This nonlinearity is found mainly in the damping taking into account the findings for musical instruments that in a coupled oscillator system the one with less damping forces the other into its oscillations. This model results in a logistic map with coupling constant α

$$g(t) = g(t_-) - \ln \frac{1}{\alpha} g(t_-) \,, \tag{10.33}$$

where a system g at different times $g(t)$ and a previous time $g(t_-)$ are interacting in an iterative way. The logarithm comes from assuming an exponential decay for the traveling wave due to damping. This damping may be the turbulent damping of a vortex as in wind instruments, the damping of a reed, or it might also be the damping of a wave traveling in wood.

This model can easily be enlarged to a multiple oscillator system where one system sends out an impulse which is then reflected at multiple points, like a string sending its energy to the top plate which is then transferred to the ribs, back plate, enclosed air, etc. Such a multidelayed version is

$$g(t_+) = g(t) - \ln \left[\frac{1}{\alpha} g(t) - \sum_{k=1}^{n} \frac{\beta_k}{\alpha} \mathrm{e}^{g(t) - g(t_{-k})} \right], \tag{10.34}$$

where β_k is the k-th impulse damping at the $t_{-k\text{-th}}$ step before the time step t with n+1 back-traveling impulses.

A stability analysis of the two systems shows that in a system of only one sending oscillator and one reflection point, as with wind instruments or bow-string interaction, a full bifurcation scenario appears as shown in Fig. 10.19.

Still, when using the multidelayed system and inserting the reflection strength found with a guitar these multiple reflection points stabilize the system and bifurcation and noise are no longer present as shown in Fig. 10.20.

This could explain why in stringed instruments where the string forces the body into its vibrations with all possible playing strengths a stable oscillation appears and no bifurcations, sudden onsets, or noise can be produced like with wind instruments or other systems with only two oscillators. The stability of a stringed instrument system is taken for granted and explained as a simple linear generator/resonator system. However, when investigating all instrument types such a simple relation is no longer present and therefore it is important to also find a reason for the stability in string–body interactions.

10.6.4 IPF and Initial Transients

An IPF system is also able to estimate the basic behavior of the initial transient of instruments as shown in Fig. 10.21. Taking different view points of a guitar, like the string, top plate, back plate etc. the impulse pattern as calculated by the IPF matches the basic behavior of the guitar parts as calculated by a finite-difference time domain (FDTD) method of the whole guitar body shown on the right of the figure. The FDTD displays the time series of the parts in every detail, while the IPF only shows the development of the impulses for the wave shapes to be added later if needed. It appears that the general length and complexity of the initial transients of both, FDTD and IPF, are very similar.

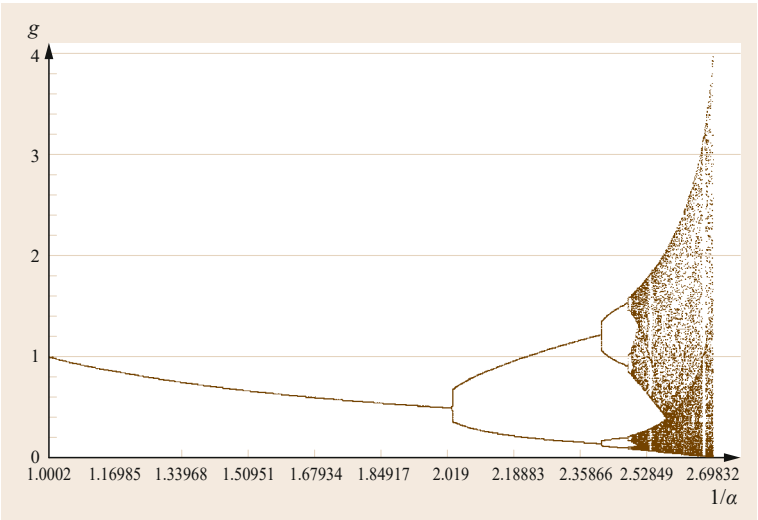

Fig. 10.19 Bifurcation scenario of the impulse time interval equation of one time point acting upon another time point for different values of $\frac{1}{\alpha}$, converged after the initial transient

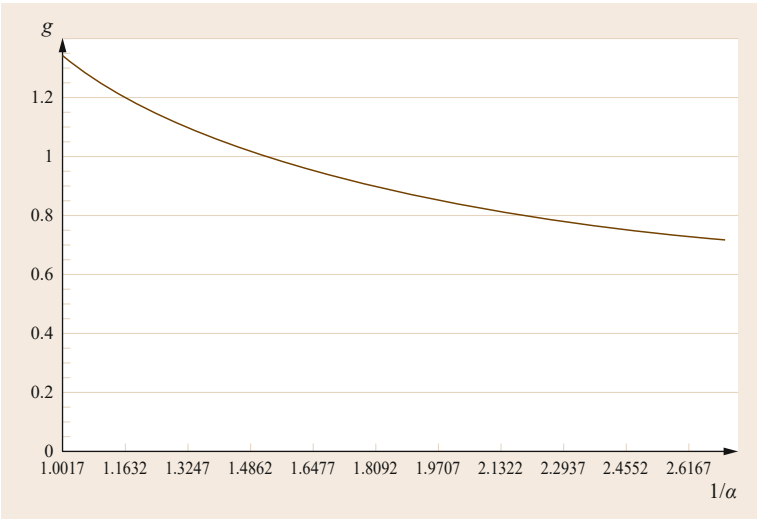

Fig. 10.20 Bifurcation scenario for the multilayered back-impulse equations with four back impulses ($n = 4$). Here $\beta_1 = 0.2$, $\beta_2 = 0.1$, and $\beta_3 = 0.05$. $1/\alpha$ is varied from $1 < 1/\alpha < 2.7$

Therefore, the IPF seems to be able also to explain the initial transient behavior of different guitar parts. As it does not display the whole time series but only the impulse development it is able to give more insight into the general behavior of these parts than the more complex time series.

10.6.5 Synchronization Conditions

We are now able to summarize the conditions for synchronization as found with musical instruments. Two of these conditions are known from synergetics and self-organization, the third one is found with the multidelayed system of stringed instruments of the IPF type.

The conditions for synchronization are:

- The less-damped system forces the more strongly damped system into its vibrations.
- The system with lower frequency forces the one with higher frequency into its oscillation.
- The lower dimensional system forces the higher dimensional system into its periodicity.

The three general types of synchronization summarized above of phase-locking, force function, and impulse pattern handle these conditions in different ways. Phase-locking formulations take damping and frequency relations into consideration. They can also include higher dimensional systems by coupling more equations, but this is often demanding in terms of finding a solution. The force function methods again consider damping and frequency but do not formulate higher di-

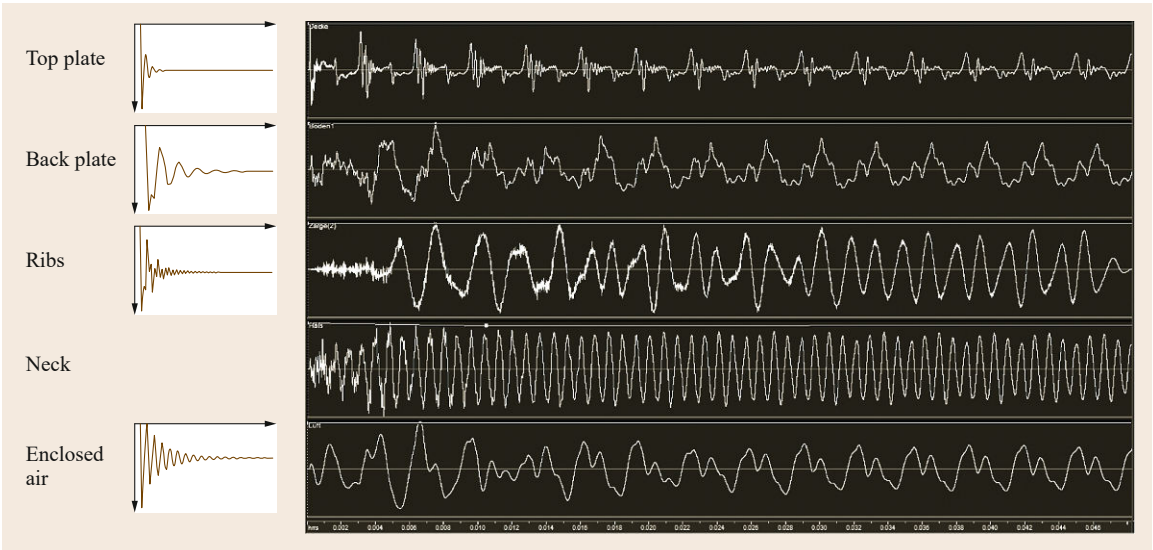

Fig. 10.21 Comparison between a finite-difference time domain (FDTD) model of a complete guitar geometry for the different guitar parts in its initial transient phase (*left*) and the impulse patterns calculated by a multiple-delayed system for the respective body parts (*right*). Note that the FDTD results are time series while the IPF series are the development of impulses without detail on the wave shapes. The FDTD and the IPF correspond very well in terms of length and complexity of the initial transient phase. (For details see [10.36])

mensional problems. The IPF takes all three into consideration. It also calculates the wave fronts or impulses and therefore is able to display the basic skeleton of initial transients. Still, it does not produce a time series at first which needs to be constructed later using an impulse shape, like a sawtooth, rectangle, sinusoidal etc.

10.7 Conclusions

Synchronization is perceptually important and hardwired in the human cochlea [10.62]. The reason for this might be evolutionary although this is just speculation. The self-sustained oscillation of the vocal folds is a highly efficient way of producing a tone as it synchronizes the otherwise broadband noise into single frequencies therefore reducing entropy considerably. These frequencies stand out above environmental noise and are therefore a very efficient way to communicate. So a harmonic overtone structure might be considered as a by-product of the attempt to efficiently produce loud sounds. Still then it is appropriate for the human ear to adapt to harmonic spectra as they are mainly produced by humans or animals which need to concern us more than inharmonic spectra of environmental ambient sounds like produced by wind or water. Indeed we find, e.g., in research of noise perception that noise of a tonal quality disturbs us much more than broadband noise. Also tonal music has been used to simulate intelligent beings in some ethnic groups such as spirits or animistic creatures [10.63]. From this viewpoint musical instruments imitate intelligent life because of their harmonic structure and might therefore be considered as a *universal language*. Also it is interesting to see that many musical instruments use a similar driving mechanism like that of the vocal folds which can be modeled in a similar way.

The converse may also be argued. Musical instruments have been used for the last 40 000 years [10.64] and one might expect even before that time. If the time span musical instruments exist would even be so large as to become salient in terms of evolutionaly changes, the precise fit of the human ear to musical sounds might also be an adaptation of the cochlea and auditory pathway to musical instruments. Then music would be part of our nature and therefore it would not be astonishing to find that it is such a prominent feature in practically all ethnic groups around the world.

All these assumptions are purely speculative in nature. Still, it is interesting to see how important it is for musical instruments to arrive at a perfect harmonic overtone spectrum, which is not at all self-explanatory, and where much effort is put into instrument building to achieve such a synchronization.

11. Room Acoustics – Fundamentals and Computer Simulation

Michael Vorländer

In room acoustics analytical formulas and computer simulations can be used to predict the acoustics of spaces, not only in terms of reverberation but other perceptual aspects, too, which are related to the perception of music or speech. In this context the room impulse response is the function of main interest. It can be measured by using sophisticated instrumentation and signal processing, or it can be simulated with computer models. In the process of auralization the data and signal processing enables one to listen into the simulated rooms in order to interpret the sound in the room aurally. In real-time implementation, this is a valuable extension of the technique of virtual reality.

Room acoustics is a well-established field with fascinating links to architecture and music. Knowledge concerning sound propagation in spaces, its physics and its effects on perception, is widely available. Efficient design tools are available, too, and experience with solutions for various applications is the basis for daily work in acoustic consulting. After all, room acoustic design and consulting is a quite straightforward process. This statement is true if elementary design rules and creation of acceptable room acoustic conditions are respected. Acceptable acoustic conditions, however, are not always given in rooms for speech and music, because standards and guidelines in room acoustics are not taken into account properly in the first phase of architectural design.

When it comes to requirements for excellent acoustic conditions, the picture is different. In prestigious projects the acoustic conditions need to fulfill high standards. What are these standards? In ISO 3382 [11.1] definitions and guidelines are given for the measurement and interpretation of room acoustic quantities. In famous textbooks, the most well known by *Beranek* [11.2] and *Barron* [11.3], we find a huge amount of data for concert halls and opera houses, and these data indicate target values and tolerance ranges for successful acoustic designs. Computer methods can help to optimize the design. Auralization, which is the most recently developed tool in room simulation, can provide audible results rather than numbers. Thus, an intuitive interface is provided, which allows the designer to experience the sound and its character.

In this chapter, the history and fundamentals of room acoustics are briefly summarized, the state of the art re-visited, and open questions discussed. These questions are related to crossdisciplinary research of classical room acoustics in combination with psychoacoustics and the technology of virtual reality.

11.1 Fundamentals of Sound Fields in Rooms

For a complete understanding of sound propagation physics we require a wave theoretical approach. Accordingly, a physically correct description and interpretation in enclosed spaces starts with the solution of the stationary wave equation with boundary conditions. For harmonic excitation

$$p = \hat{p}\mathrm{e}^{\mathrm{i}\omega t}\,, \tag{11.1}$$

the Helmholtz equation

$$\Delta p + k^2 p = 0 \tag{11.2}$$

is solved by using specific wave numbers, the eigenvalues k_n with the eigenfrequencies

$$f_n = \frac{c}{2\pi} k_n \tag{11.3}$$

for each eigenfrequency a characteristic distribution of the sound pressure in the room occurs. In a rectangular room, for example, with the dimensions $L_\mathrm{x}, L_\mathrm{y}, L_\mathrm{z} (V = L_\mathrm{x} L_\mathrm{y} L_\mathrm{z})$ and with hard boundaries ($R = 1$) these eigenfunctions (also called *modes*) are

$$p_{lmn}(x,y,z) = 8\hat{p}\cos\left(\frac{l\pi x}{L_\mathrm{x}}\right)\cos\left(\frac{m\pi y}{L_\mathrm{y}}\right) \times \cos\left(\frac{n\pi z}{L_\mathrm{z}}\right) \tag{11.4}$$

with l, m, n positive integers, and the eigenfrequencies

$$f_{lmn} = \frac{c}{2}\sqrt{\left(\frac{l}{L_\mathrm{x}}\right)^2 + \left(\frac{m}{L_\mathrm{y}}\right)^2 + \left(\frac{n}{L_\mathrm{z}}\right)^2}\,. \tag{11.5}$$

This principle holds for any room shape although the eigenfrequencies cannot be calculated in a comparably easy way. In general the number of eigenfrequencies in an interval between 0 and f drastically increases with f^3, while the density of eigenfrequencies within frequency bands increases with f^2.

$$\frac{dN_\mathrm{f}}{df} \approx 4\pi V \frac{f^2}{c^3} \tag{11.6}$$

Sound fields in rooms are usually excited with broadband and transient signals such as speech, music, or noise. Therefore, the total field is a rather complex superposition of eigenfunctions. With losses, damping constants, δ_ν, can be introduced, and the superposition reads

$$p(\boldsymbol{r}_0, \boldsymbol{r}) \propto i\omega \sum_\nu \frac{p_\nu(\boldsymbol{r}_0)\, p_\nu(\boldsymbol{r})}{K_\nu\left(\omega^2 - \omega_\nu^2 - 2\mathrm{i}\delta_\nu\omega_\nu\right)} \tag{11.7}$$

with ν, in short, denoting any combination of l, m, n, and the vectors $\boldsymbol{r}_0$ and $\boldsymbol{r}$ the positions of the source and the receiver, respectively. K_ν are constants depending on the relative amplitudes of the modes.

This function, the so-called *stationary room transfer function*, is a series of overlapping modes (Fig. 11.1). With increasing frequency the overlap of complex sound pressure becomes more and more dominant. The result at a specific frequency crucially depends on the relative phases of the modes involved. Furthermore, the relative phases depend on the complex reflection factors, on the speed of sound in the room (depending on temperature and humidity), and on the exact positions of source and receiver. This data is (a) not known precisely, and (b) it may slowly vary in time, for example the room itself may vary slightly simply in response to persons moving around. After all, according to the pioneering work by *Schröder* [11.4] and *Kuttruff* [11.5], the overlap range above the Schroeder frequency

$$f_\mathrm{Schroeder} = \sqrt{\frac{c^3}{4V\bar{\delta}_\nu}} \tag{11.8}$$

is quasistochastic. The room transfer function cannot be used as a basis for evaluation of the quality of the room response. It can be shown that the specific fine structure of the stationary room transfer function contains nothing but an estimate of the reverberation time (see below).

Typical Schroeder frequencies are given in Table 11.1.

Because of the stochastic nature of the transfer function it is useless to apply wave models for this frequency range. The apparently exact result is not relevant for actual transient excitation signals because the stationary case cannot be excited with these too short signals. For

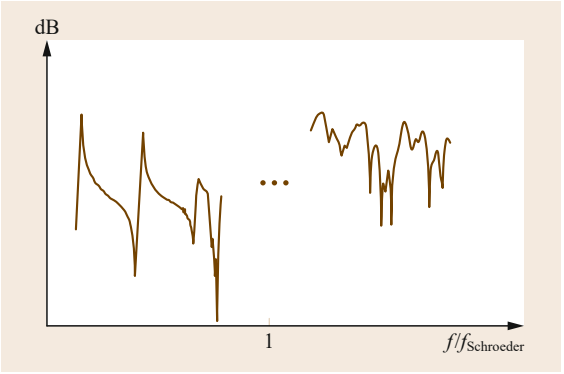

Fig. 11.1 Magnitude of a stationary room transfer function

Table 11.1 Typical Schroeder frequencies

Room	Volume (m^3)	$f_{Schroeder}$ (Hz)
Classroom	500	64
Auditorium	5000	32
Concert hall	50 000	16

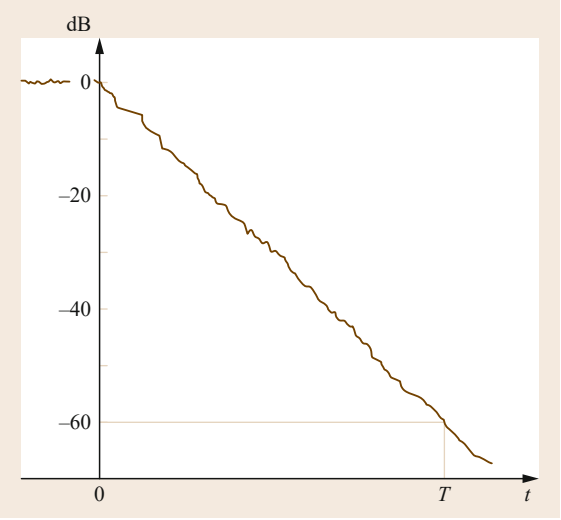

Fig. 11.2 Decay curve of a room

not too small rooms ($V > 500\,m^3$) these facts apply to basically the whole audio frequency range.

For interpretation of sound perception in rooms and for application in architectural design, another concept is required, which allows derivation of a set of quality metrics related to psychoacoustic effects in rooms such as reverberation, loudness, clarity, localization, spaciousness, etc. This is achieved by introducing a physical concept for the time domain and by interpreting the propagation of sound by geometrical propagation of rays rather than of waves.

Wallace Clement Sabine created the first scientific approach to understanding the acoustics of performance spaces. His famous *collected papers* [11.6] form the basis for room acoustics which we are still using today. The inter-relation between reverberation and volume and absorption was clarified and explained empirically. A little later, in the 1930s, *Norris* [11.7] and *Eyring* [11.8] presented a theory with more correct factors in the equations, which today, of course, are known as Sabine's and Eyring's reverberation time equations.

The reverberation time is defined as the time elapsed for a sound decaying by 60 dB after shut-off of a signal (Fig. 11.2).

With W denoting the acoustic power of a point source, the intensity I of a ray determined at a distance r is proportional to the squared sound pressure

$$I = \frac{W}{4\pi r^2} \propto p^2 \,. \tag{11.9}$$

With the assumption of incoherent rays, n of them add to

$$I = \sum I_n \,. \tag{11.10}$$

The assumption of incoherence would be violated in the case of stationary signals. Here, however, we assume broadband transient signals. Using this basic concept, statistical room acoustics can be introduced.

11.2 Statistical Room Acoustics

The basic assumption of statistical room acoustics is the existence of a *diffuse* field. In room sound fields this does not exist perfectly but the approximation is a very good guess. In a diffuse field, the angles of incidence at a receiver point are uniformly distributed in 3-D space. With this assumption it can be shown that the energy density at all positions in the room is constant, and all boundaries of the room (walls, floor, ceiling) are irradiated uniformly from all directions.

A ray with intensity I_0 is traced in a room with volume V and surface area S. It contributes to the energy density, w, with

$$e = e_0 = \frac{I_0}{c} \tag{11.11}$$

$$w = \frac{\sum e}{V} \,. \tag{11.12}$$

The expectation value of the time between two wall collisions is $1/\overline{n}$, with

$$\overline{n} = \frac{cS}{4V} \tag{11.13}$$

denoting the mean reflection rate.

11.3 Reverberation

For the derivation of the reverberation time formula we assume a room with uniformly distributed and directional-independent absorption. A diffuse field exists in the room. The sound field is modeled by rays filling the whole space, traveling at the speed of sound and bouncing between the boundaries (Fig. 11.3). Each ray initially has an energy e_0. At a boundary reflection it loses a portion of $(1-\alpha)$, so the remaining energy after the first reflection is $e_0(1-\alpha)$. Accordingly, after n reflections during time t the ray energy is

$$e(t) = e_0\,(1-\alpha)^{n(t)} = \frac{W}{4\pi c^3 t^2}\,(1-\alpha)^{n(t)}\,. \quad (11.14)$$

The expectation value of the number of reflections per time unit is (11.13)

$$n(t) = \overline{n}t\,. \quad (11.15)$$

The expectation value for the number of rays arriving at a receiver at time t during a time interval Δt is [11.9]

$$\Delta N = \frac{4\pi c^3 t^2}{V}\Delta t\,. \quad (11.16)$$

This leads to the energy density at a receiver point

$$w(t) = \frac{\sum e(t)}{V} = \frac{W\Delta t}{V}\,(1-\alpha)^{\overline{n}t}\,. \quad (11.17)$$

Re-arranging this equation for t and inserting, for the reverberation time T, a decay of 60 dB (i. e., a decay of $w(t)$ by a factor of 10^{-6}) leads to the famous Eyring reverberation formula

$$T = \frac{24\ln(10)}{c}\frac{V}{-S\ln(1-\alpha)} \approx 0.16\frac{s}{m}\frac{V}{-S\ln(1-\alpha)}\,. \quad (11.18)$$

For small absorption coefficients $\alpha \approx -\ln(1-\alpha)$ it can be simplified to

$$T \approx 0.16\frac{s}{m}\frac{V}{S\alpha}\,. \quad (11.19)$$

This equation is known as the Sabine equation. It holds for the large majority of ordinary rooms and performance spaces. Exceptions are spaces of complex geometry or any other special case in which no diffuse field can be expected. This may apply to coupled rooms, long or flat spaces, for example.

In the case of nonuniform absorption the reverberation formula must be modified by introducing the mean absorption coefficient or the equivalent absorption area, A, for N subsurfaces.

$$\overline{\alpha} = \frac{A}{S}, \quad A = \sum_{i=1}^{N} S_i\alpha_i \quad (11.20)$$

In the particle model, the sound can be attenuated by wall absorption but also by attenuation in the air. Sound traveling over a distance $x = ct$ is affected by an intensity loss of $\exp(-mct)$. Thus, the reverberation formula can be further extended to

$$T_{\text{Sabine}} \approx 0.16\frac{s}{m}\frac{V}{S\overline{\alpha}+4mV} = 0.16\frac{s}{m}\frac{V}{A_{\text{Sabine}}+4mV}\,, \quad (11.21)$$

$$T_{\text{Eyring}} \approx 0.16\frac{s}{m}\frac{V}{-S\ln(1-\overline{\alpha})+4mV} = 0.16\frac{s}{m}\frac{V}{A_{\text{Eyring}}+4mV}\,. \quad (11.22)$$

It should be noted, however, that the reverberation formula in Sabine's or Eyring's notation are approximations. The underlying assumption of a diffuse field is a theoretical model, which exists in rooms only in approximation. The interpretation of the equivalent absorption area A also leads to the possibility of considering it in relation to the mean logarithmic reflection loss, to the linear reflection loss, or just to the term in the denominator which expresses the losses associated with the boundaries. This factor A also appears in the solution of the sound level in stationary excitation.

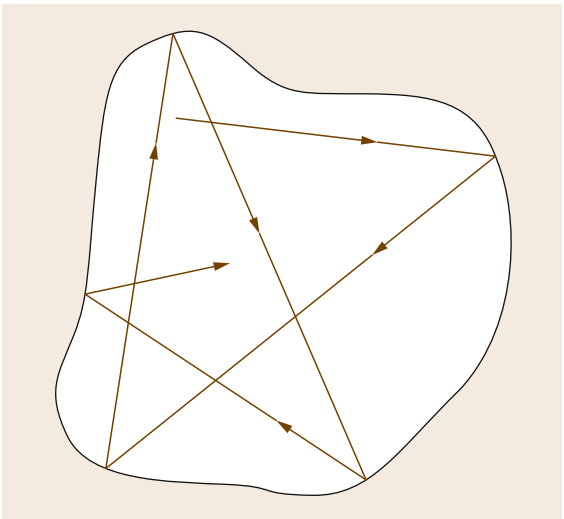

Fig. 11.3 Free paths between subsequent reflections

11.4 Stationary Excitation

In the case of a stationary sound power source the exponential energy propagation over time (11.14) must be integrated in order to calculate the total energy in the room. The energy balance is given by the steady state between the energy injected by the power source and the energy losses in the boundaries and the air. In this way the integration can be performed easily, and after normalization with the source sound power W it yields

$$w_{\text{diffuse}} = \frac{4W}{cA} e^{-\frac{A}{S}} . \tag{11.23}$$

This energy density can be compared with the energy density of the direct sound w_{direct}, observed at a distance r from the source

$$w_{\text{direct}} = \frac{W}{4\pi c r^2} . \tag{11.24}$$

The distance in which the direct and the diffuse field are equal is called the reverberation distance

$$d_{\text{rev}} = \sqrt{\frac{A}{16\pi}} . \tag{11.25}$$

The basic findings illustrate the influence of room volume and absorption on the perceived sound. This is actually the basic experience while listening in a room. Humans can estimate the room size and the state of the room interior (fully furnished, empty, etc.) very well. When it comes to more specific aspects of sound perception in rooms, however, the sound incident on the listener must be studied in more detail and in particular in dependence of the position of the source and the receiver.

11.5 Room Impulse Responses

In the 1950s, the *fine structure of reverberation* became the focus of interest. *Lothar Cremer*, in the first edition of his pioneering book [11.10], illustrated sound reflections using geometric constructions of rays and image source, a methodology which is still one of the standard methods in room acoustics today. He had identified the importance of reflections, their series of arrival, their density, and their global late decay. With these findings and with the availability of instrumentation for impulse response measurement, acoustic consulting was put on a scientific basis. From the 1950s, consulting firms could rely on a deeper understanding of sound fields and could advise architects accordingly. The basis is the room impulse response as illustrated in Fig. 11.4.

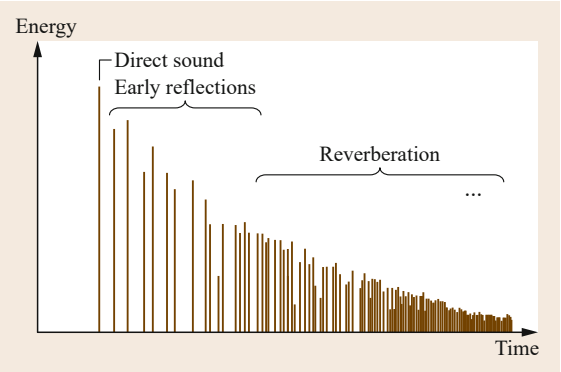

Fig. 11.4 Typical energy room impulse response

According to the concept of geometrical acoustics the reverberation is generated by subsequent sound reflections at the boundaries. A human listener in the room therefore perceives not just the direct sound but a series of delayed and attenuated reflections. They are delayed due to detours through the room and they lose energy due to the spread of the spherical wave behavior and to boundary absorption and air attenuation.

If the sound source emits a very short pulse, the room response contains a series of pulses, the density of which quadratically increases with time while their strength decreases quadratically in time and exponentially due to repeated absorption. Eventually, the energy decay integrated over short time intervals is an exponential function (11.17).

Concerning perception, the first component (the direct sound) determines the source localization. This effect is called the *law of the first wavefront* [11.10], or the *precedence effect* [11.11]. The reflections that arrive not later than 50–80 ms after the direct sound are perceptually very important. They support the loudness, a certain source widening by localization blur and they create the sensation of clarity in music perception. The reflections that arrive later than 80 ms are interpreted as reverberation. They create an impression of the room size and of the so-called listener envelopment (LEV; spatial impression). A strong reflection that significantly exceeds the exponential trend of the reverberation tail is considered an *echo*, which is usually a dramatic room defect.

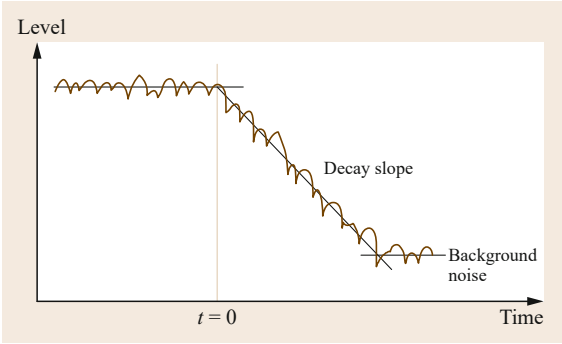

Fig. 11.5 Typical level versus time curve by using a switch-off of a random noise signal

The function of energy versus time depends on the positions of the source and the listener. The exponential envelope of the reverberation tail may be constant throughout the room but this does not at all hold for the early part.

11.5.1 Room Acoustic Measurements

In classical reverberation time measurement a noise source (loudspeaker excited with random noise) is switched on for a time sufficient to obtain an excitation in steady state. Then the source is switched off, and the decay of the sound level is observed.

As seen from Fig. 11.5, the stationary level (11.23) and the decay time (11.18) are obtained from the stationary excitation level and from the slope after switch-off. Statistical signal characteristics require averaging over several excitations until a stable and smooth mean decay curve appears.

In modern digital measurement methods, however, it is possible to obtain the room impulse response as a primary deterministic result. The reverberation time is calculated by postprocessing (Fig. 11.6). This approach requires more sophisticated equipment and signal processing but it is much more effective and theoretically more elegant.

According to *Schroeder* [11.12], the expected decay resulting from an infinite number of averages in one particular observation point may be obtained by processing the impulse response between the excitation signal (loudspeaker) and the observation point (microphone) directly and without tedious averaging.

This situation can be accounted for with a known impulse response $h(t)$, between source and receiver. When a room is excited by stationary white noise for a time sufficient to obtain stationary conditions and the noise is thereafter switched off at time $t = 0$, the ex-

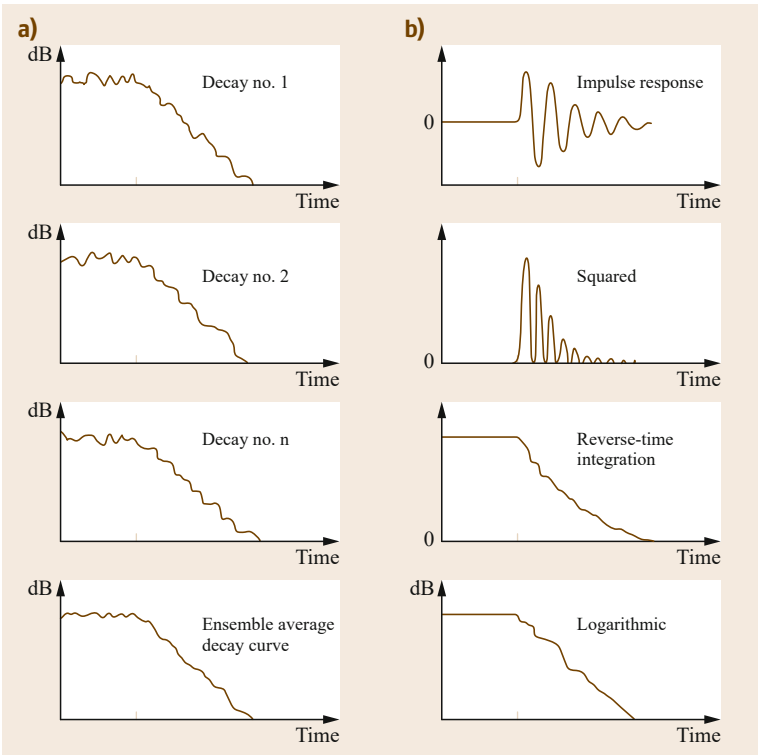

Fig. 11.6a,b Classical versus impulse response method. **(a)** In the classical method the expected decay is found by ensemble averaging of a number of individual decays based on noise excitation. **(b)** By application of the impulse response method the expected decay is found by postprocessing of the impulse response

pected level at any time $t > 0$ will be

$$L(t) = 10 \log \left[N_0 \int_t^\infty h^2(\tau) \mathrm{d}\tau \right], \qquad (11.26)$$

where N_0 is a constant specifying the signal power per unit bandwidth of the excitation signal.

Various methods may be applied to obtain the impulse response $h(t)$ or the transfer function $H(\omega)$ (which is linked to the impulse response by Fourier transformation). All such methods may be used if they are able to demonstrate reliable results within normal measurement conditions, i. e., conditions that are linear and time-invariant.

When an octave-band or fractional-octave-band filter is a part of the measured system, (11.26) will describe the expected decay according to the classical method for the applied filter band. Accordingly, the level plot can be evaluated for determination of the reverberation time.

The dynamic range necessary for reverberation time measurement is very high. As for level measurements, the upper limit for the time integral in (11.26) shall be limited in order to reduce the contribution from unwanted noise.

$$L(t) = 10 \log \left[N_0 \int_t^{t_2} h^2(\tau) \mathrm{d}\tau \right] \qquad (11.27)$$

Usually t_2 is set to the time where the level of the exponential decay in the impulse response $h^2(t)$ is equal to the extraneous background noise level. Different methods are described in the literature to compensate for the noise and the truncation in the integration interval [11.13]. If an evaluation range of 30 dB is used, and T30 is to be measured, the decay curve must be evaluated from linear regression between an upper limit of −5 dB and a lower limit of −35 dB. To add a safety margin and to avoid a truncation error, −40 or −45 dB dynamic range is required to ensure an undistorted decay curve down to −35 dB. Other definitions for reverberation time measurements are T20, T40, etc.. The early decay time (EDT) is evaluated from the initial part of the decay between 0 and −10 dB.

With strategies for subtracting the noise floor it is possible to extend the evaluation range. Estimation of the noise floor energy C can be performed by taking the first part of the impulse response, before the direct sound, or the late part which should show a constant short-time average energy. In this case, (11.27) changes to

$$L(t) = 10 \log \left[N_0 \int_t^{t_2} h^2(\tau) \mathrm{d}\tau + C \right], \qquad (11.28)$$

with C denoting the energy of the noise contribution. This procedure, however, requires manipulation of the impulse response with some arbitrarily chosen parameter. If the noise content remains in the measured response, backward integration will lead to a curved decay of two slopes. But even in this case the correct decay slope can be extracted, by using a nonlinear regression, as shown by *Xiang* [11.14].

All measurement methods can be based upon a common scheme of impulse response and transfer function determination. In the following part of this chapter, the fundamentals of modern impulse and correlation techniques are described.

The room is excited by a deterministic signal $s(t)$, and the impulse response $h(t)$ is calculated from the response to this excitation, $g(t)$. In modern digital methods the excitation signal is usually distributed over a longer period of time to facilitate high total energy. This procedure will enhance the dynamic range and reduce the influence of extraneous noise. Most of the methods may be described as FFT (Fast Fourier Transform), de-convolution, or correlation techniques applied to the measurement and processing of the impulse response. Usually results in building acoustics are expressed in one-third octave or octave bands. These filters can be included in the excitation signal, or in the signal processing of the received response.

The signal path expressed in the time domain reads (Fig. 11.7)

$$g(t) = s(t) * h(t) = \int_{-\infty}^{\infty} s(\tau) h(t-\tau) \mathrm{d}\tau \,. \qquad (11.29)$$

Exactly the same expressed in the frequency domain reads

$$G(\omega) = S(\omega) \cdot H(\omega) \,. \qquad (11.30)$$

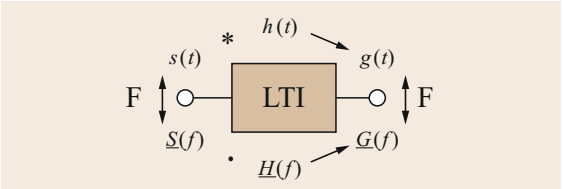

Fig. 11.7 Signal transmission through a linear time-invariant (LTI) system

While the key equation of a formulation in the frequency domain is

$$H(\omega) = \frac{G(\omega)}{S(\omega)} , \tag{11.31}$$

the same can be expressed in the time domain by so-called *de-convolution*

$$h(t) = g(t) * s^{-1}(t) \tag{11.32}$$

with $s^{-1}(t)$ being the signal with the inverse spectrum $1/S(\omega)$. $s^{-1}(t)$ is also called the *matched filter*. If $S(\omega)$ is a white spectrum, (11.32) can also be re-arranged into

$$h(t) = g(t) * s(-t) = \int_{-\infty}^{\infty} g(\tau)s(t+\tau)\mathrm{d}\tau , \tag{11.33}$$

which means that $h(t)$ is obtained from crosscorrelation of $s(t)$ and $g(t)$.

Obviously, the three equations above are absolutely equivalent for broadband white excitation signals. Differences, however, can be found in characteristics of the signal in relation to the capability of the components of the measurement chain and in relation to sensitivity against nonlinear distortions of time variances.

It is worth mentioning that the equations must be programmed in discrete form and be represented in the memory of a computer with a finite length. The integration will be read as summation, and the limits of the summation are finite. Accordingly, the excitation signal must have a certain length: a period. Now, if a repetitive excitation signal is used, the spectrum of the excitation will consist of narrow spectral lines where the distance between adjacent lines Δf will be given as the inverse of the time for one repetitive period T_{rep}

$$\Delta f = \frac{1}{T_{\mathrm{rep}}} . \tag{11.34}$$

In order to ensure that all modes of the room are excited the repetitive period must not be shorter than a certain fraction of the reverberation time for the room being measured. If, for example, the decay time of the impulse response is significantly larger than one period of the signal the tail of the impulse response appears as equivalent noise overlap in the subsequent periods. This effect is called *time aliasing*, and is similar to *frequency aliasing*, which happens if spectra are measured with too low a sampling rate. To be on the safe side, $T_{\mathrm{rep}} > T$ should be chosen.

The periodic nature of the source signals, however, offers a very big advantage. A repetition of the signal should give exactly reproducible results, measured and compared from one period to the next. This allows for the application of synchronous averaging, a procedure which reduces the effective background noise level by 3 dB per doubling of the number of averages. The reason is that the exactly repeated periods of the test signal add up *in phase* while the background noise is not correlated between the different periods and adds up energetically only. This averaging process is an advantage of deterministic signals in general. The gain in signal-to-noise ratio, with N denoting the number of averages, is $\Delta_{\mathrm{av}} = 10 \log N \mathrm{dB}$.

11.5.2 Digital Measurement Techniques

The three methods for determination of impulse responses expressed in (11.31)–(11.33) are described in more detail in this section.

The *FFT technique* is based on spectral division. There are two variants, the first of which uses any excitation signal, possibly from an arbitrary stationary noise source, and the other uses a deterministic source signal which is synchronized with the A/D sampling. Some traditional FFT analyzers operate with asynchronous noise sources.

With an asynchronous signal source the complex transfer function defined by (11.31) can be computed using the cross- and autocorrelation spectra between input and output channel, for instance from

$$H(\omega) = \frac{S^*(\omega)G(\omega)}{S^*(\omega)S(\omega)} = \frac{\Psi_{SG}(\omega)}{\Psi_{SS}(\omega)} \tag{11.35}$$

With deterministic and repeatable excitation, however, the measurement is straightforward and uses the formulation in the frequency domain. The input and output signal are measured simultaneously, transformed by FFT, and processed by complex division to obtain $H(\omega)$ (11.31). The most important requirement is that the source signal must have sufficient energy in the whole frequency range. Weak signal-to-noise ratios may cause errors in the spectrum division. Any broadband sweep, time-stretched pulses, or pseudorandom noise can be used.

After processing the spectrum division in the frequency domain, the impulse response is calculated finally by inverse Fourier transformation (Fig. 11.8).

The construction of a constant-envelope sweep with arbitrary spectral distribution, for instance, is possible when the group delay's inclination, or in other words, its derivative, is proportional to the expected energy $|H(\omega)|^2$ at each frequency [11.15]. For a discrete FFT spectrum, this means that the group delay has to increase according to

$$\tau_{\mathrm{G}}(\omega) = \tau_{\mathrm{G}}(\omega - \mathrm{d}\omega) + C \cdot |H(\omega)|^2 \tag{11.36}$$

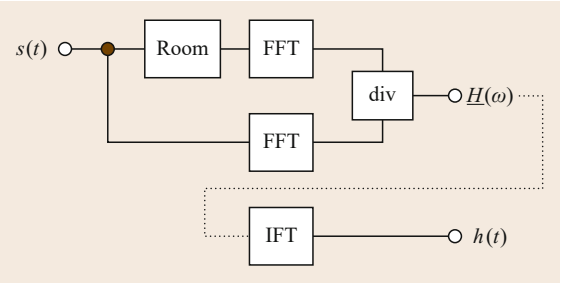

Fig. 11.8 Typical 2-channel FFT instrument

following a recursive structure of $\tau_G \to \tau_G(\omega - d\omega)$ in the FFT spectrum, and C denoting a normalization constant composed of the sweep's length divided by its total energy (ω_s is the sampling frequency)

$$C = \frac{\tau_G(\omega_{end}) - \tau_G(\omega_{start})}{\int_{\omega=0}^{\omega_s/2} |H(\omega)|^2} . \tag{11.37}$$

This type of signal is known from traditional sweep measurements and the tuned narrow-band filter. However, processing is much more sophisticated compared to the traditional narrow-band technique and it is possible to obtain the complex transfer function and accordingly the impulse response. The result is processed by a *matched filter* for de-convolution in the time domain (11.32). The matched filter is the excitation signal in reverse order

$$s^{-1}(t) = s(T_{rep} - t) . \tag{11.38}$$

An important point and a significant advantage of the sweep is that the problem of time aliasing can be significantly reduced by cyclic shift of the signal and extension by inserting *zeros*. The matched filter is then treated accordingly in the reversed way. Furthermore, *Müller* [11.15], *Farina* [11.16], and *Dietrich* [11.17] discussed the fast simultaneous measurement of the linear transfer function and nonlinear indicators like distortion products. Procedures for signal processing in the swept-sine technique can also be formulated in the frequency domain. If the matched filter convolution is performed by FFT, this technique is similar to the 2-channel FFT technique, but the differences (and disadvantages) can be found in the periodicity and the cyclic processing.

Another technique, the maximum length sequence (MLS) technique, became popular in the 1990s. The technique is a a special form of correlation measurement for obtaining impulse responses of LTI systems according to (11.32). The room is excited by a stationary MLS signal $s(t)$, and the output signal $g(t)$ is processed by crosscorrelation with the excitation signal.

Maximum length sequences are a special kind of correlation signal useable in the technique described above. The sequences are periodic binary pseudostochastic signals with an autocorrelation function almost identical to a periodic Dirac pulse. They are generated by use of a shift register with feedback loops. The exact feedback procedure is given by number-theoretical prescriptions [11.18].

The procedure of the MLS technique can be summarized as follows. The LTI system is excited with a stationary periodic sequence. In order to avoid time aliasing the period must be larger than the impulse response of the system as given, for instance, by the reverberation time. Crosscorrelation is used to extract the impulse response from the measured sequence.

$$\begin{aligned} &[s_{MLS}(t) * h(t)] * s_{MLS}(-t) \\ &\quad = s_{MLS}(t) * s_{MLS}(-t) * h(t) \\ &\quad = \Psi_{ss}(t) * h(t) . \end{aligned} \tag{11.39}$$

The important advantage of maximum length sequences is the availability of a fast correlation algorithm, the so-called *fast Hadamard transformation*, FHT. More elaborate investigations are found in *Rife* et al. [11.18], and practical aspects are discussed in [11.19].

11.5.3 Perception-Based Parameters Obtained from Impulse Responses

The subjective impressions were correlated with the physical properties of room impulse responses. One of the first observations concerning early reflections was made by *Thiele* [11.20] in 1952, who provided the basis for objective descriptors of the early-to-late energy integral ratio (*Deutlichkeit*). This was finally possible with the availability of multichannel equipment in anechoic rooms. Today, we consider the concept of early decay time as well known. This finding was given by *Vilhelm Jordan* [11.21] who discovered the relationship between early reverberation and subjective reverberance. Furthermore, during this period there were also studies on correlation of subjective impressions and objective parameters. Numerous publications appeared from research groups led by *Erwin Meyer* et al. [11.22–26].

In the following some of the quantities are introduced which were tested in laboratory environments, and applied in measurements in halls. The integrals are taken over the sound pressure impulse response $h(t)$, of the room with regard to particular source and receiver positions. It should be noted that the squared response $h^2(t)$, is proportional to the energy density.

Strength

$$G = 10\log\frac{\int_0^\infty h^2(t)\mathrm{d}t}{\int_0^\infty p_{10\,\mathrm{m}}^2(t)\mathrm{d}t} \tag{11.40}$$

with a reference to the sound pressure of the sound source used in a free field in 10 m distance, p_{10}^2.

Speech Intelligibility: Deutlichkeit

$$D = \frac{\int_0^{50\,\mathrm{ms}} h^2(t)\mathrm{d}t}{\int_0^\infty h^2(t)\mathrm{d}t}\,. \tag{11.41}$$

Transparency of Music, Clarity

$$C_{80} = 10\log\frac{\int_0^{80\,\mathrm{ms}} h^2(t)\mathrm{d}t}{\int_{80\,\mathrm{ms}}^\infty h^2(t)\mathrm{d}t}\,. \tag{11.42}$$

Apparent Source Width (ASW)

$$LF = \frac{\int_5^{80\,\mathrm{ms}} h_\infty^2(t)\mathrm{d}t}{\int_{0\,\mathrm{ms}}^{80\,\mathrm{ms}} h^2(t)\mathrm{d}t}\,, \tag{11.43}$$

with p_∞^2 denoting the squared sound pressure impulse response obtained with a gradient (dipole) microphone.

Listener Envelopment, Late Lateral Strength

$$LG = 10\log\frac{\int_{80}^\infty h_\infty^2(t)\mathrm{d}t}{\int_0^\infty p_{10\,\mathrm{m}}^2(t)\mathrm{d}t}\,. \tag{11.44}$$

11.5.4 Music Perception and Architectural Design

At the beginning of the 1970s many modern concepts for *good* room acoustics related to performance of classical music, opera, and speech in theaters were proven in theory and accepted as best practice. At that time, however, many halls were designed with modern architecture and construction methods. Usage of open concrete, mostly large flat and smooth surfaces, large and wide halls, particularly fan-shaped halls were preferred. And some of these halls did have their critics, although reverberation time, sound level, and clarity were found to be around the right order of magnitude.

James West [11.27] stated in 1966 that concert halls with good acoustics (Musikvereinssaal Vienna and Boston Symphony Hall) have a small width-to-height ratio. In 1968, *Harold Marshall* [11.28] confirmed that spatial impression is created by side wall reflections which are particularly strong in narrow halls. In the early 1970s, *Michael Barron* [11.29] in Southampton and *P. Damaske* and *Yoishi Ando* [11.30] in Göttingen identified the importance of lateral reflections as being underestimated. They pointed out the relevance of early lateral reflections for spatial impression. It affects the precision of source localization and gives an impression of diffuse sound incidence. Spatial impression still today is the most difficult component of multidimensional hearing in rooms (*Hörsamkeit*).

A fan-shaped hall shows indeed a lack of early lateral sound. A consequence was to implement side walls with segments of tilted angles, terraces, or vineyard areas, in order to split side wall reflections and to direct them to the audience at lateral angles.

After the 1970s, acousticians and architects could rely on quite stable and complete knowledge of the general principles of room shape and its effect on early and late reflections. The first issue of the book by *Heinrich Kuttruff*, published in 1972, already contained state-of-the-art knowledge of room acoustics [11.31]. Thereafter, although further detail could be added the general insight into room acoustics was complete.

It is interesting to note that the findings in room acoustic research were directly reflected in the hall shapes built. *Jürgen Meyer* [11.32] evaluated 157 halls with a seating capacity > 1000. He pointed out that the majority of room shapes were rectangular, fan-shaped, hexagonal, or arena style. Thus, hall shape has a large bearing on acoustic performance. Many details such as surface corrugations, stage, balcony and reflector design are important as well, as well as consideration of the directional radiation of musical instruments.

Finally, an extended issue of the international standard ISO 3382, *Measurement of the reverberation time of rooms with reference to other acoustical parameters* was developed and published in 1996 [11.1]. It not only contained guidelines for measuring reverberation time in auditoria but definitions of the other room acoustical criteria listed above.

11.6 Computers in Room Acoustics

The introduction of computers in acoustic measurements enabled the use of sophisticated impulse response measurement techniques for both real-room measurements and scale models. Impulse responses could be measured with high reproducibility and, thus, comparability. The first ISO 3382 already contained a hint that broadband excitation and postprocessing should be applied to obtain impulse responses [11.1].

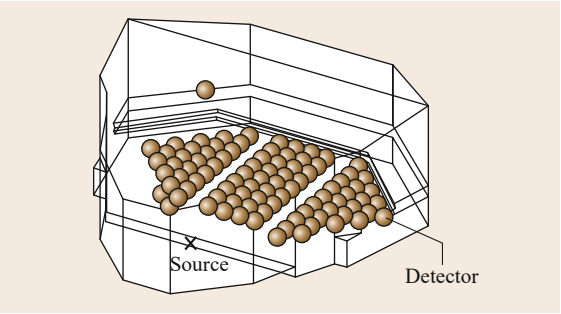

Fig. 11.9 Computer model of a room with a source (×) and a set of receivers (*brown spheres*)

Use of computers in room acoustics progressed greatly after 1985, during a period corresponding to the development of simulations. This development brought them to a level that allowed their application in consulting. Independently, *Dirk van Maercke* in Grenoble [11.33] (the first software listed was originally developed as EPIKUL at KU Leuven), *Michael Vorländer* in Aachen [11.34], *Bengt-Inge Dalenbäck* in Gothenburg [11.35], and *Graham Naylor* and *Jens Holger Rindel* [11.36] in Copenhagen worked on algorithms for simulating room acoustics on the basis of architectural CAD input data. These and other programs are still being used with success today. Round-robin tests [11.37–39] showed their efficiency and as well the limits of computer simulation of room acoustics. This led, among other findings, to the definition and implementation of scattering coefficients [11.40] in simulation methods. Similarly to observations in real sound fields with purely specular reflections (rooms with large flat concrete walls), it was noted that artificial decays based on purely specular models sound unnaturally cold and contrasted.

In room acoustic computer simulation a geometric model of the room is built using polygons (Fig. 11.9). The polygons are the portions of planes which form the room boundaries. Sound sources and receivers are considered to be small compared to wavelengths. The computer algorithm consists of equations of linear algebra for solving the problem of intersection of rays (vectors) with polygons (planes). The method is used for calculation of ISO 3382 criteria such as reverberation time (T), early decay time (EDT), definition (D), clarity (C80), center time (CT), lateral energy fraction (LF), or for auralization. The latter means that the computer results are reproduced binaurally through the D/A converter in the sound card.

Two principles are typically implemented, ray tracing and image sources. They are complementary in their pros and cons. Today, simulated room acoustics are applied in various fields with great success. Their well-developed algorithms help to create realistic acoustics during architectural planning. Acoustic simulation tools are also used for designing sound reinforcement systems in churches, stadiums, train stations, and airport terminals.

It is important to highlight the differences in the physical meaning of ray tracing and image sources. Ray tracing describes a stochastic process of particle radiation and detection. Image sources are geometrically constructed sources that correspond to specular paths of sound rays. Often, image sources are constructed by using rays, beams or cones, via a kind of ray tracing. Nevertheless, they are still *image source models*. The fundamental difference between image sources and ray tracing is the way contributions in impulse responses are calculated. Ray tracing only yields low-resolution impulse response data like envelopes in spectral and time domains. Image sources (classical or via tracing rays, beams, cones, etc.) may be used for exact construction of amplitude and delay of reflections with narrow-band resolution depending on the filter specifications for wall reflection factors, for instance.

11.6.1 Image Sources

We assume smooth walls which reflect the sound waves specularly with a reflection coefficient of one. In this case the sound paths between sources and receivers are unique solutions and use virtual (image) sources. This approach also solved the wave equation. In the case of reflection coefficients < 1 the approach is a quite good approximation. The main problem in this case is the assumption of plane-wave reflection coefficients in contrast to the spherical wave reflections in the precise wave approach. After all, the approximation is sufficiently correct if the source and the receiver are not closer to the boundaries than a few wavelengths.

Firstly, for a given room they must be constructed. The original source is mirrored at all wall polygons. In Fig. 11.10, the image source S_1 is created by constructing a perpendicular line between the source, S, and wall 1 and by continuing to the same distance behind the wall. The same is done for all walls. This yields the first-order image sources. With those the mirroring is continued to achieve the second-order image source, and so on. The order of an image source deflects the order of the reflection, i. e., the number of walls which were hit during the propagation between the sound source and the receiver.

Secondly, an audibility test must be performed. The result depends on the receiver position, and it is required for identification of the meaningful image sources. Each source is considered as the last element of a chain of image sources. At its indices we can identify

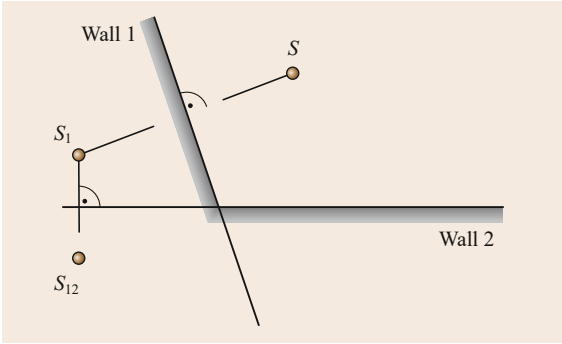

Fig. 11.10 Image source construction

the walls which were sequentially hit during the sound propagation in the room. This sequence must be physically consistent so that free lines of sight are present between the subsequent points on the polygons where the walls are hit.

A sequence of an i-th-order image source has i indices

$$S \to S_{n_1} \to S_{n_1 n_2} \to S_{n_1 n_2 n_3} \to \ldots \to S_{n_1 n_2 \ldots n_{i-1}} \to S_{n_1 n_2 \ldots n_i} \,. \tag{11.45}$$

The possible number of permutations and thus the image source number, N_{IS}, to be constructed for a room with n_{w} polygons is

$$N_{\mathrm{IS}} \approx (n_{\mathrm{w}} - 1)^{\overline{n}t} \tag{11.46}$$

with $\overline{n}t = i$ denoting the order of image source involved up to a time t in the impulse response (11.15). Of this extremely large number of image sources, however, just a very small portion is actually audible. To check this, the audibility test is introduced as follows (Fig. 11.11). We consider an example in a 2-D plane.

We start the process by checking S_{12} exemplarily. The receiver point, R, is connected to S_{12}. Its last index (no. 2) denotes the last wall (no. 2) involved in the sequence of reflections. If the intersection point, P_{12}, of the straight line connecting $R - S_{12}$ is located in the wall polygon no. 2, it's correct. Then we proceed by connecting the intersection point with the mother source of S_{12}, i. e., S_1 (the one with the same set of indices except the last). If the intersection point, P_1, of the straight line connecting $P_{12} - S_1$ is located in wall polygon no. 1, it's correct. As soon as one intersection point is located outside the polygon, the source is found to be inaudible. This applies in the example to S_{21}, because P_{21} is not inside polygon 1. This means that this reflection path is blocked by the room edges or by an obstacle in the room (in the case of concave rooms).

Accordingly, the core subroutine of the image source algorithm is the point-in-polygon test. It is crucial that the audibility is checked for the actual receiver

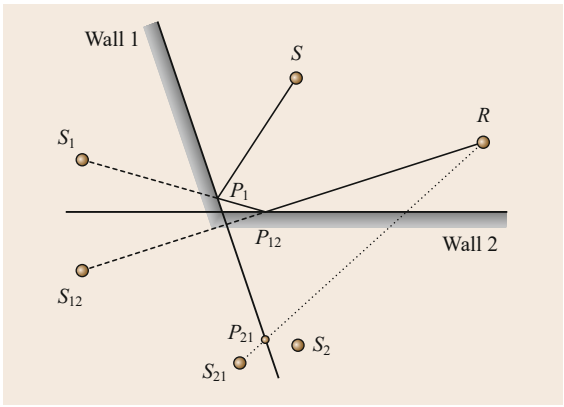

Fig. 11.11 Image source audibility test for the sources S_{12} and S_{21}. S_{21} is inaudible at R

position. Generally, image source cannot be excluded, except for constraints in the room geometry and imaging zones built by the polygon edge [11.41].

The audible image sources are postprocessed to account for their contributions to the impulse response in terms of amplitude and delay. The following factors influence the contribution of the image source number j (j is the sequence of wall reflections represented by $n_1 n_2 \ldots n_i$, see (11.45)).

$$\underline{H}_j = \frac{\mathrm{e}^{-jkr_j}}{r_j} \underline{H}_{\mathrm{source}}(\theta, \phi) \underline{H}_{\mathrm{air}}(r_j) \times \mathrm{HRTF}(\vartheta, \varphi) \prod_i^{n_j} \underline{R}_i \tag{11.47}$$

In this equation, $\underline{H}_j$ is the complex spectral component of the image source j. It contains the delay expressed in phase lag, the amplitude of spherical wave spread, the source spectrum expressed by the sound pressure radiation in source coordinates (θ, ϕ), the air attenuation over the traveled distance r_j, the spatial listener sensitivity expressed by the head-related transfer function in receiver coordinates (ϑ, φ), and the multiplied complex reflection coefficients $\underline{R}_i$ of the walls involved. Usually, however, the reflection coefficients are considered to be real-valued and taken from $R = \sqrt{1-\alpha}$.

The impulse response obtained by using image sources may look like the example shown in Fig. 11.4. The temporal resolution in the impulse is just limited by the precision of the distance between the image source and the receiver, which is a pure construction of straight lines. The accuracy in the impulse response in terms of the temporal series is very high. The accuracy of the amplitudes of the reflections depends on the input data used for the walls and the medium, the source, its directivity, and the listener head-related transfer function (HRTF).

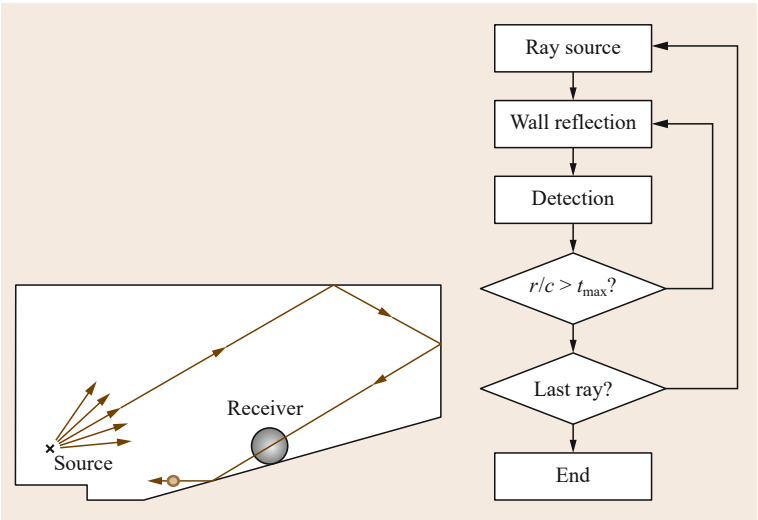

Fig. 11.12 Ray-tracing example and algorithm flow diagram

However, because of the problem of the rapidly growing computational effort, the image source algorithm is applicable to low reflection orders only. The long computation time means it is not useful for calculation of the reverberation tail. A very serious shortcoming is the prerequisite of pure specular reflections. So, the image source algorithm is a good choice for calculating the early specular part of the impulse response precisely.

11.6.2 Ray Tracing

Obviously there remains the problem of calculating the late part of the impulse response and the scattered and diffracted components. A well-established method in this respect is stochastic ray tracing (Fig. 11.12). The goal is to estimate the impulse response envelope over short time intervals without aiming at the exact fine structure formed by reflected, scattered, and diffracted sound. This approach is justified in the regime of reflection overlap within reasonable intervals of human temporal perception abilities. This statement simply means that humans cannot perceive the specific fine structure, so that an approximation by a statistical approach is sufficient. It is crucial, however, that the temporal, spectral, and spatial envelopes are correct. The corresponding averages are usually taken over 10 ms, critical frequency (or one-third octave) bands, and 5°, respectively.

In ray tracing, it is assumed that a sound source emits rays or particles at $t = 0$. In the following, the concept of a *particle* is used, which is in line with the wave-particle dualism of wave physics, too. It is crucial that numerous particles are emitted, and the results obtained are interpreted as a statistical mean of events. Events in this respect are reflections and detections are receivers, for example. Each particle is traced during its run through the room. The mathematics for this is quite similar to that described above for image source: vector algebra and intersections of vectors with planes are the basis, and the point-in-polygon test is the most relevant part.

Each time a particle hits a wall polygon, the collision point and the angles of the incident vector with the plane are calculated. Then the reflection is modeled by inverting the vector direction following a specular reflection, or by a random scattering process. In the latter case Lambert's law is often applied, which states that independent of the incidence angle the reflection angle is distributed according to a cosine function.

Absorption is modeled by reducing the energy by a factor of $(1-\alpha)$. The stop criterion of tracing one particle is defined by the maximum time in the impulse or by using a minimum energy. Absorption modeling can also be implemented by randomly deleting the particle if a random number $z \in [0, 1]$ is smaller than the absorption coefficient α. After the stop criterion is reached or the particle is deleted, the next particle is emitted from the source. This way the sound radiation into the full space, for example omnidirectionally, represented by some 10 000 particles is modeled. The particles are registered at receivers by counting the energy and arrival time.

The temporal resolution is limited by the fact that a finite number of particles are traced. Late reflections are thus represented just by a few particles, or just by one. The probability of later reflections represented by a particle is less than one. Therefore, the impulse response is not meaningful but randomly sparse. This is, by the way, a phenomenon similar to the effect of background noise limiting the meaningful temporal range of the impulse response.

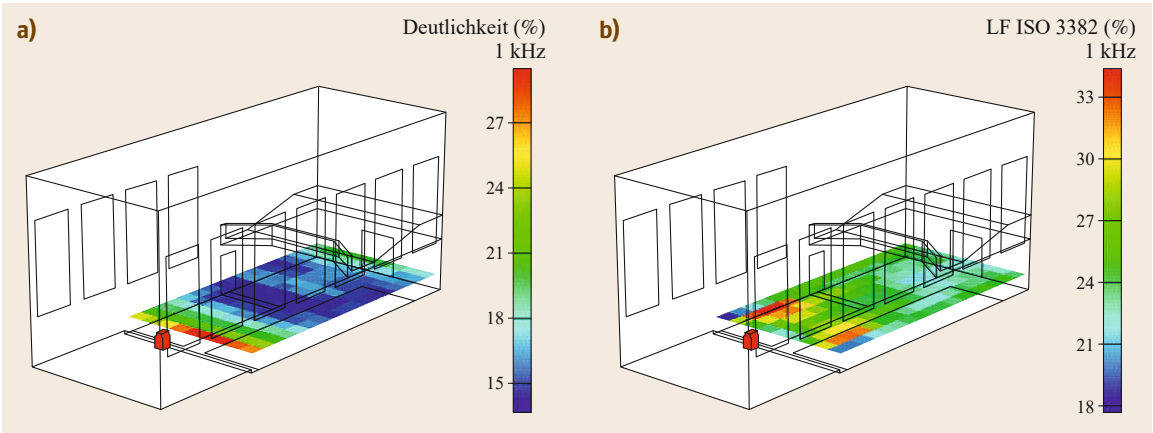

Fig. 11.13a,b Postprocessing of ray-tracing results into color maps of the ISO 3382 criteria D50 **(a)** and lateral energy fraction **(b)**

11.6.3 Hybrid Models

Because of the contradictory advantages and disadvantages of ray tracing and image sources an effort was made to combine the advantages in order to achieve high-precision results without too much complexity or computation time. Either ray tracing or similar algorithms such as radiosity were used to overcome the extremely high calculation time inherent in the image source model for simulation of the late part of the impulse response (adding a reverberation tail), or ray tracing was used to detect audible image sources in a kind of *forward audibility test*. The idea behind this is that a ray, beam, or cone detected by a receiver can be associated with an audible image source. The order, the indices, and the position of this image source can be reconstructed from the ray's history by storing the walls hit and the total free path. Hence the total travel time, the direction and the chain of image sources involved can be addressed to the image source. Almost all other algorithms used in commercial software are in a way dialects of the algorithms described above, and they differ in the way the mixing of the specular with the scattered component is implemented. The specific choice of dialect depends on the type of results wanted, particularly in terms of accuracy, spatial, and temporal resolution.

11.6.4 Wave Models

The boundary element method (BEM) and the finite element method (FEM) are also well-known algorithms in acoustics. In FEM, the field space for the acoustic problem must be discretized into suitable volume elements. Such mesh models are also available in the time domain, for example the finite-difference time-domain method (FDTD). Recent algorithmic implementations made use of the fact that FDTD requires updates of one mesh node at the actual time step just from the neighboring nodes at the last time step. Accordingly, the processing can be parallelized to a great extent, and the advantage of parallel computing leads to acceleration of the simulation by orders of magnitude.

The same speed increase was demonstrated for the acoustic radiance transfer method, which is based on discretization of the room boundaries and formulation of the integral radiation functions between the surface elements [11.42]. This method is very similar to the analytic approach of the energy radiosity method [11.31], but it can be extended to account for reflection phases and diffraction effects. Furthermore, significant parallel processing can be used due to the basically independent computation of algorithmic subroutines.

Actually high-speed wave model algorithms can exceed the Schroeder frequency. But the physical relevance of wave modeling above the Schroeder frequency is doubtful due to the stochastic nature of the pressure field. Therefore, all algorithms described above yield very similar impulse responses when it comes to perception.

The perception of room acoustics can best be assessed by listening to the results rather than by comparing color maps of ISO 3382 criteria (Fig. 11.13).

11.7 Auralization

The principle of auralization is illustrated in Fig. 11.14. It shows the basic elements of sound generation, transmission, radiation, and reproduction [11.43].

As soon as the interface between source signal and the propagation path is clearly defined, the acoustic situation can be projected into a model of signal processing. Provided the transfer functions of the elements are known by calculation or measurement, the signal transmitted in the room is processed by convolution (Fig. 11.15). The transfer function is accordingly the transfer function of a *filter*, and its representation in the time domain is nothing but the room impulse response $h(t)$.

This looks simple at first sight, but the task involves creation of a filter representing as many as possible features of the real signal path or multiple paths. To illustrate this task in more detail, some examples are given in the following sections. It is clear, however, that the requirements on the signal representation (bandwidth and sampling rate, for instance), on the accuracy of the data given, on the transmitting system, and on the quality of the audio reproduction system might be quite specific. Perception of sound signals has multiple dimensions, some of which are listed below:

- Kind of sound generation
- Direction of the event
- Movement of the source
- Own movement, environment (kind, shape, and size of the room).

The auralization filter must cover all relevant aspects of the specific case.

Impulse responses for auralization purposes must be generated with a temporal resolution adequate for the sampling rate of the test signals. A standard audio sampling rate of 44.1 kHz is usually used. In room acoustics, music or speech may be sampled at half that rate which still enables signals to be used with frequency components up to 10 kHz. This upper limit is also typically the limit of knowledge of absorption coefficients. Accordingly, the time resolution of the impulse response is less than 50 µs, which illustrates the demands on the simulation. Conventional ray tracing cannot be used since the statistical approach requires temporal histograms. The number of rays would be much too high if the (very small) time intervals must be filled with reflections. Conversely, image source algorithms are well qualified, at least up to a certain length of the impulse response.

It is clear that auralization involves binaural hearing. It's true that monoreproduction gives an impression of the simulated sound, but a very important feature of hearing in rooms is then omitted. In binaural technology, interaural delay and diffraction around the head are elementary parameters. Assuming linear sound propagation, both are included in the HRTFs or in corresponding HRIRs (head-related impulse responses). HRTF data are usually measured with probe microphones and a group of test subjects, or they can be measured with dummy heads.

Because of the fact that the later part of the impulse response doesn't need to be created with the same accuracy as the early part hybrid methods are often tried with a separation of the simulation into two or more steps. This is justified by the low energy contained in the late part and by masking. In auralization tests with running speech or music the later part of the reverberation tail is masked and noticeable only with impulsive or rhythmic signals. The early part is considered important up to a length of some hundred milliseconds at most. Methods for simulation of exact binaural impulse responses are described above. The fine structure in the late response is stochastic and can be taken, for instance, from a stochastic sequence of Dirac pulses. Octave band filters and summation enable transition into narrow-band or broadband sound pressure signals.

The appropriate playback arrangement is either headphone presentation or free-field reproduction with

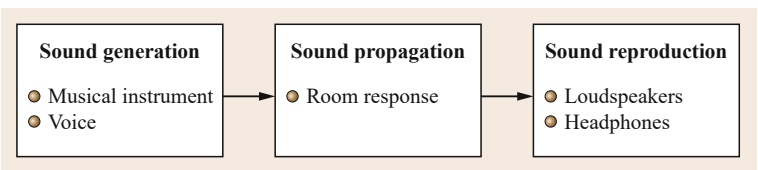

Fig. 11.14 Principle of auralization

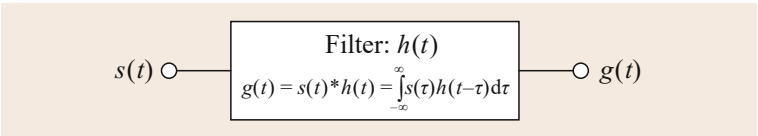

Fig. 11.15 Convolution of signal $s(t)$ with a room impulse response $h(t)$

loudspeakers and crosstalk cancelation. The equalization of the headphone or the loudspeakers is extremely important if the sound localization and spatial impression are to be created correctly. However, binaural technology has been well investigated and can be applied for these purposes.

11.8 Current Research Topics

Room acoustics is still not a solved problem. In spite of the standards and design tools there is still a need for research and transfer of knowledge to other engineering disciplines. Still too many meeting rooms, classrooms, auditoria, offices, train or metro stations, and airports have unacceptable acoustic conditions. Some recent research activities are described in the examples below.

11.8.1 Room Acoustics and Psychoacoustics

Densil Cabrera et al. asked why reverberance must be based on a level decay rather than on a loudness decay [11.44]. Time-dependent loudness also includes spectral masking as the temporal effects of cochlear sound processing. Models from psychoacoustics are available [11.45] and have already been adopted in a standard [11.46].

In fact, their loudness decay rates are well correlated with subjective reverberance. Furthermore, loudness decays can include signal properties if the decay curve is not derived from the impulse response but from signals convolved with impulse responses. Accordingly, the reverberance can be expressed in two aspects: (a) the sound reverb in signal transients and its effect on the signal modulation and (b) the decay after the final chord.

Concerning binaural aspects, hearing models of binaural processing are a powerful tool to evaluate localization, diffuseness, and spaciousness. Based on the Jeffress model of cross-correlation [11.47], diverse model approaches exist (*Lindemann* [11.48], *Dau* [11.49], *Breebaart* [11.50], *van Dorp Schuitman* [11.51], among others) and those will be used increasingly in room acoustic research.

11.8.2 Room Acoustic Measurements

A rather new field of research is the evaluation of measurement techniques (typically application of ISO 3382) concerning measurement uncertainty. The measurement uncertainty can then be compared with the just-noticeable differences (JND) in order to identify the significance of results. With the framework of the Guide to the expression of uncertainty in measurement (GUM) [11.52] it is possible to investigate the sources of errors influencing a measurement result and to specify the quantitative influence of each source of error on the overall uncertainty. In room acoustics, placement and directivity of dodecahedron loudspeakers were found to be crucial, as well as microphone and dummy head specifications [11.53, 54].

The relation between the subjective impression and in situ diffusivity at listener positions is an old problem and had already been described in the 1950s by Thiele. Directivity diagrams (*hedgehog plot*) illustrate the distribution of distinct specular and smooth diffuse sound incidence. But measurement of a detailed directional distribution is tedious and uncertain when it comes to specification of highly directional microphones. An innovative approach was introduced by Lokki and Pätynen at Aalto University in Helsinki, who use a loudspeaker orchestra which can provide reproducible situations on the stage as concerns the source positions and the directional radiation. Furthermore, they analyze the impulse responses with microphone arrays and spatial decomposition in order be able to reproduce virtual orchestra sounds for listening tests and sensory evaluations [11.55].

11.8.3 Virtual Room Acoustics

The basic algorithms of computer models were developed in the 1990s. Also at that time, the importance of scattering was recognized, thus leading to implementation of hybrid models. Their main feature is that deterministic specular components in the impulse responses are calculated separately from stochastic (diffusely scattered) parts. Both parts are combined in the end. It is important to mention that the physical sound field can be separated into those two parts as well. Auralizations using such kinds of hybrid model are in perceptive aspects close to recordings. To quantify the differences and to understand the reason for differences, though, is subject to research.

Besides the development of algorithms describing the physical sound propagation in rooms, many ideas from the field of computer graphics were also applied to room acoustic modeling, such as space partitioning or other methods to speed-up the algorithmic kernel for finding the ray intersection point with polygons. Because of severe differences of (narrow-band) light propagation in contrast to broadband sound propaga-

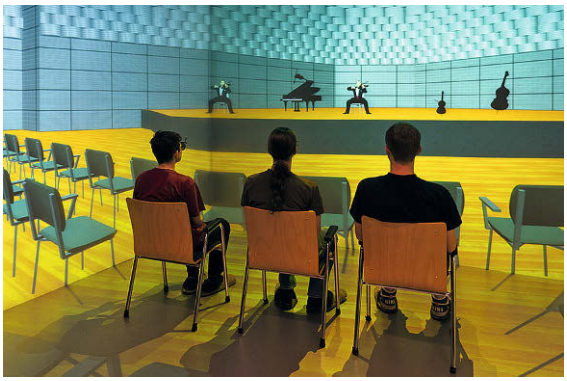

Fig. 11.16 Audiovisual real-time simulation of concert hall acoustics (photo by Peter Winandy)

tion and differences in the ratio of room and object sizes in comparison to wavelengths, the algorithms used for creation of computer images cannot be applied in room acoustics. Nevertheless, data management and dynamic object handling developed in computer graphics makes real-time auralization possible (acoustic virtual reality) (Fig. 11.16).

In a consortium of the Universities of Berlin, Aachen, Ilmenau, Oldenburg, and the Negev, Israel, several aspects of perception in room acoustics, and furthermore recording and reproduction of spaces is being investigated from various viewpoints [11.56].

The research group followed a coordinated effort to improve the complete signal chain from the numerical modelling, the data acquisition within numerical or real sound fields, the coding and transmission to the electro-acoustic reproduction by binaural technology or by sound field synthesis. A novel approach for the comparative evaluation of simulated environments did not only perceptively validate all improvements along the signal chain; it also allowed an evaluation of the plausibility and/or the authenticity of virtual room acoustic environments as a whole. Moreover, it brought forth better physical measures to predict the qualities of natural acoustic environments as well.

Another very interesting auralization project was presented by Woszczyk in 2009. *Virtual Haydn* [11.57] involved seven historic pianos, which were reconstructed by highly renowned artisans. They were played in nine virtual rooms created to represent rooms from Haydn's time, i. e., rooms in which Haydn could have played.

11.8.4 Array Technologies in Room Acoustics

The development of linear, circular, and spherical arrays for 3D sound field analysis inspired many investigations in room acoustics. Arrays are used for spatial decomposition and beamforming, thus for decomposition of complex sound fields into plane or spherical waves. Those waves of course stem from reflections. The advantage is that not only the temporal and spectral cues of room sound fields are captured, but their directional distribution as well. And apart from the possibility of multichannel sound recording, this technique is very interesting for analysis of room sound fields and reflection patterns.

One of the first findings with linear arrays was that clarity, C80, is very sensitive to small changes in the microphone position. If impulse responses are evaluated for adjacent array microphones just a few centimeters apart, clarity data differ more than the just noticeable difference [11.58]. This would indeed mean that the subjective impression of clarity differs significantly within an area of one concert hall seat. This does not match the listening experience at all, and accordingly the definition of the clarity index creates a too sensitive result.

The next example is application of the concept of wave field analysis (WFA), to room acoustics. In this way, rooms can be compared in regard to their wave propagation patterns [11.59], which gives a valuable insight into the spatial wave incidence and, thus, the amount of distinct specular wave fronts and diffuse components.

11.9 Final Remarks

In room acoustics, several dimensions of the overall listening impression were identified which show a good correlation with corresponding objective measurement data. It can be summarized that the three most important factors (loudness, reverberance, and spatial impression) explain most of the statistical variance when comparing the acoustic conditions in auditoria. Aspects of scattering and diffusivity and their relation to surface design are still under investigation, as well as robust descriptors of stage acoustics.

Apart from the definition of the most relevant perceptual factors, another crucial point is the listener's sensitivity to changes in a sound field in regard to those subjective aspects (just-noticeable differences) and to the robustness and significance of measurement results.

Cooperation of room acoustics with psychoacoustics and audio engineering will stimulate more ideas and innovation in research and concert hall design.

Room acoustics today is far from being black magic. Instead, there is a strict scientific interdisciplinary concept which will be further developed. Methods, knowledge, and guidelines from classical room acoustics will also be used for other purposes than acoustics in performance spaces, such as for train stations or airports, factory halls and offices.

Signal Pr Part B

Part B Signal Processing

Ed. by Jonas Braasch

This book section deals with signal processing techniques from the perspective of computational systematic musicology. Recent developments in the field have opened up major opportunities for researchers with technical backgrounds to pursue new ways of analyzing music using digital signal processing techniques. Traditionally, the primary work of systematic musicology focused on the manual analysis of music scores. In classical music, where the field of musicology originates from, the concept of work is based on music scores. While the score defines the work of a composer, the performance of these works is considered interpretation and thus of secondary interest. In contrast, the concept of work for many non-Western music genres as well as pop music and jazz is mainly defined through the actual sound of a performance or recording. Different rock bands, for example, use exactly the same chord progression, but the sound of these progressions is so unique that one often can tell the song before the singer starts. One cannot understand the fundamentals of this culture by just analyzing scores, and signal processing techniques are now used as an objective method to analyze the tempo, tonality, and timbre of this music, among many other features.

The underlying music analysis tools, which were introduced to better understand music, have meanwhile found their way into the music industry. Music streaming services use them to classify songs according to user preferences to maintain a competitive edge. The shift from storing music on individual media (e.g., vinyl, CDs) to large databases makes big data analyses possible, as media can now be accessed digitally. Instead of analyzing a few works by hand, general musical trends can be investigated by automatically analyzing a very large corpus of work using batch processes.

Meanwhile, signal processing tools are seeing an increased use in investigations of classical music as well, because there is an emerging focus on understanding the interpretation of works. This trend has to do with the fact that the historic body of classical music works no longer grows, and many major compositions have been analyzed multiple times. In contrast, the practice of interpreting these works is still a developing culture, leading to new opportunities to analyze works.

Moreover, signal processing methods have become important in organology, the science of musical instruments. It is common practice to develop a mathematical model of a musical instrument in order to understand how it operates and understand why certain trends occur. In this book section, we will cover one-dimensional approaches, where the acoustic propagation is simulated along one axis, for example along the resonator of a wind instrument, as well as three-dimensional methods, where the sound can travel across all three spatial dimensions.

Most chapters in this section deal with acoustical analysis methods, but techniques to process or synthesize sounds are also covered. Historically, systematic musicology has solely worked with passive methods, where the researcher merely observes his or her object of study. Meanwhile active research schemes have become more popular; for example, in Simha Arom's approach to experimental ethnomusicology he performs together with indigenous musicians to examine if his theories hold up to a practical test. Digital signal processing and synthesis methods can be instrumental in active research methods, for example in the virtual recreation of a historic music performance in a concert venue that no longer exists. This can be accomplished using wave field synthesis techniques in order to understand why the composer chose a given instrumentation in this venue.

The book section is organized as follows:

Chapter 12 covers the fundamentals of music studio technology. It deals with the whole studio production chain from capturing the signals using different microphone techniques, storing them on various analog and digital media, to different methods of playing back the signals using standard loudspeaker arrangements. In addition, the chapter outlines the complex signal processing techniques in studios that formed the artistic sound concepts of popular music. Practical introductions to digital signals, cables and connectors, and music synthesizers complete this reference on studio technology.

Chapter 13 deals with delay lines and digital waveguides. Both methods are used to understand sound propagation along a one-dimensional axis. This chapter covers the fundamentals including finite impulse response (FIR) filters, linear interpolation, sound reflection, lossy wave propagation, and comb filter effects. After explaining mathematical fundamentals, the chapter focuses on the acoustic simulation of a plucked string instrument by simulating the acoustic behavior of a damped string that is terminated at both ends after being plucked in its initial state.

Chapter 14 gives a mathematical introduction to the fundamental concepts of convolution, Fourier analysis, and cross-correlation. All three concepts are important signal processing methods used to analyze and synthesize sound. Convolution is used to simulate the transformation of a signal by a linear time-invariant acoustical system, Fourier analysis is used to understand how a signal behaves in terms of frequency, and

cross-correlation is used to compare the similarity of two systems.

Chapter 15 describes signal processing methods used to separate individual sound sources from a mixture. The techniques described in this chapter are fundamental to analysis of the complex sounds of ensemble music, where more than one musical instrument or voice is involved. Within the chapter, the repeating pattern extraction technique (REPET) is introduced, which detects periodic functions, e.g., in the form of beat patterns, establishes a model of the repeated patterns, and then segregates these pattern from the acoustic background using time/frequency masks. Another focus of this chapter is multipitch streaming to extract pitch contours of overlaid instruments. The contours are used to construct harmonic masks to segregate the individual instruments. The chapter concludes with the description of techniques to align the sound of a recorded performance to the underlying musical score.

Chapter 16 covers optical recognition methods to automatically extract music scores. Optical music recognition (OMR) is an instrumental process for archiving historic scores based on a symbolic notation. OMR provides a basis for automatic music analysis using the converted scores, where the extracted scores can be easily sonified using a music synthesizer. OMR has its roots in optical text recognition, but is affected by additional challenges that mainly result from the circumstance that music symbols, e.g., notes and staff lines, overlap, while text characters are generally isolated. The chapter provides an overview of different techniques to overcome the resulting technical challenges.

Chapter 17 deals with adaptive digital music systems. While it is often easier and therefore advantageous to describe a system mathematically using linear time-invariant systems, there are clear limitations to this approach. In general, musical instruments are nonlinear, time-variant systems, for example the bore of a wind instrument using keys to produces different pitches. In some cases, time-variant systems can be approximated using a sequence of time-invariant systems, but in many other cases only adaptive systems can simulate the behavior of time-variant systems with sufficient complexity. This chapter focuses on a number of techniques including Kalman filters and autoregressive moving average (ARMA) processes to provide expressive control of digital music systems in the joint time/frequency space.

Chapter 18 covers the fundamentals of wave field synthesis (WFS). WFS is an advanced method that simulates how sound propagates in three-dimensional space. It builds on the Huygens–Fresnel principle, which states that any given wave front can be described through the superposition of elementary spherical sound sources, and the Kirchhoff–Helmholtz integral. The latter demonstrates that by controlling the pressure and velocity along the boundaries of an enclosed space any three-dimensional sound field can be synthesized within it. This assumption works as long as the volume inside the enclosure is source-free. The chapter introduces the theoretical framework for WFS and discusses the practical approach and limitations of rendering sound fields using a two-dimensional array of loudspeakers as elementary sound-pressure sources.

Chapter 19 introduces the finite-difference method (FDM) in the context of musical acoustics. The FDM is a popular tool to describe a set of differential equations by discretizing a space and approximating these equations with difference functions. This method can be used for example by discretizing a geometrical model of a room using a constantly spaced grid (e.g., 10 cm along all three Cartesian coordinates). The difference equations are then solved numerically at the grid positions. The method is a useful tool where the environments are too complex to solve analytically and the dimensions for the desired frequencies are too small to use geometrical methods like ray tracing. This is the case for low frequencies in a small room or for the geometry of many musical instruments that are discussed in this chapter.

Chapter 20 discusses the fundamental problems, solutions, and applications of real-time sound processing. Classical applications where real-time processing is needed are digital music keyboards, live sound effect processors, and virtual reality systems. The chapter covers the main challenges for the design of real-time algorithms to minimize latency and cost of the computational operations. Common real-time algorithms will be explained based on software for field programmable gate array (FPGA) hardware of mobile devices. Mobile devices are becoming increasingly important for musicological research in the form of mobile field recorders, digital tuners and loudness meters, among other tools.

12. Music Studio Technology

Robert Mores

Music studio technology is reviewed with respect to the different tasks involved in recordings, broadcasts, and live concerts. The chapter covers microphones and microphone arrangements, signal preconditioning and sound effects, and matters of digitalization. It also covers equipment technology such as mixing consoles, synthesizers and sequencers. Historical and contemporary audio formats are reviewed including the issues of restoration. Practical matters such as signals, connectors, cables and grounding problems are addressed due to their significance to sound quality. The general trend towards audio networks is shown. Finally, speakers, reference listening and reinforcement systems are outlined, including some of the multidimensional formats.

This book chapter on music studio technology gives an overview of the state of the art in recording and reproduction. Music studios are usually specifically equipped to serve a dedicated task, like the recording of different genres, speech production, film sound production, synchronization, broadcast, sound reinforcement in live concerts, sound design, or art work. Therefore, Fig. 12.1 is only a rough overview of the most common elements of the workflow and equipment typically used for live concerts, broadcasts, or recordings.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_12

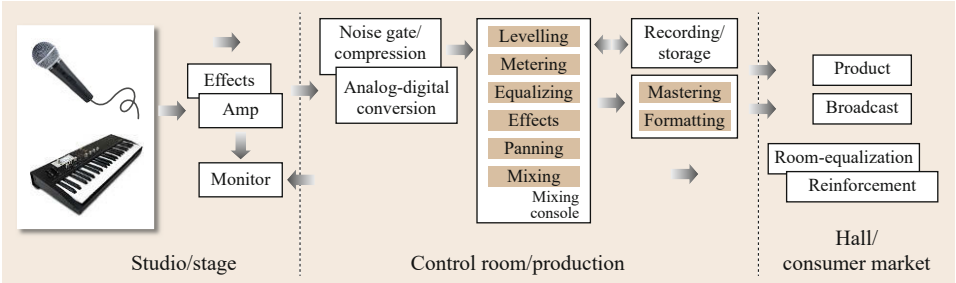

Fig. 12.1 Commonly used equipment and workflow in live concerts, broadcast and studio recording

In the studio or on the stage, there is usually only a limited demand for local amplification or individual effects where the audio signals are taken. Most of the signals are still analog and are converted to digital format in the control room after some noise-gating or dynamic compression. Analog mixing consoles are still popular in live performances and work without an analog–digital converter. First, the mixing console, whether analog or digital, preconditions any incoming signal, such as levelling, dynamic control, or equalization. Second, it facilitates enhancements, such as effects, or reverberation (Sect. 12.2). Third, it allows for the grouping of several sources and for panning to various channels for sound reinforcement or monitoring. For recording tasks, audio signals are stored individually or in groups before being postprocessed in terms of enhancement, mixing, or panning. Mastering is the final step in productions to customize formats or to compensate for limitations of preferred listening situations. Mastering might be done by means of the same mixing console, apart from extensive coding tasks. Today's desktop computing power allows for integration of all mixing console tasks together with the recording, the digital version of the noise gate, dynamic compression, and mastering and coding – all on one computer. This is common practice in small productions and a competitive challenge for professional producers.

This chapter describes the equipment and methods used in the presented workflow and is structured as follows:

1. Microphones and microphone arrangements
2. Signal preconditioning and effects
3. Digitalization
4. Mixing consoles
5. Synthesizer and sequencer
6. Historical and contemporary audio formats and restoration
7. Signals, connectors, cables and audio networks
8. Speakers, reference listening and reinforcement.

Some emphasis is given to microphones, signaling and formats because these issues are likely to be relevant in the projects and studies of musicology students, such as field work recording or retrieval of historical archives.

12.1 Microphones and Microphone Arrangements

There are two defining properties of microphones. Depending on its construction, a microphone can be sensitive to pressure or to pressure difference. Within pressure-sensitive microphones, the membrane, or diaphragm, faces the soundfield on one side and a reference pressure of an enclosed volume on the other side, effectively measuring absolute pressure independent of direction. In pressure-gradient microphones the diaphragm is exposed to the soundfield on both sides, which explains the sensitivity towards gradients normal to the plane of the diaphragm and the insensitivity towards in-plane gradients, see Fig. 12.2. The second property relates to the converter principle. Dynamic microphones follow the inverse principle of loudspeakers. The membrane drives a coil in a magnetic field and the induced signal is strong enough to be transmitted without in-microphone amplification. In condenser microphones the metalized diaphragm, together with a plate form the two sides of a capacitor and excitation of the diaphragm, will change the gap and therefore the capacitor's electrical parameters. The capacitor is usually DC-charged and the weak signal must be amplified within the microphone while the power for this task is facilitated by battery or a remote supply, see Sect. 12.7.2. In piezomicrophones the crystalline structure contains microscopic dipoles where pressure-induced deformation will bring about a weak signal that must be amplified. And, reaching even further in the past, carbon microphones employ the pressure-dependent resistance of anthracite to mod-

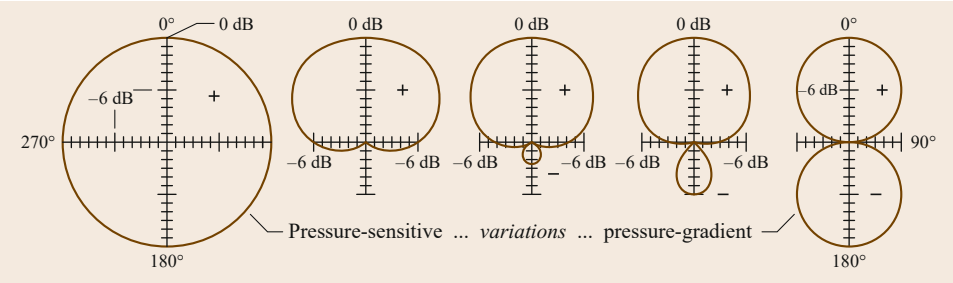

Fig. 12.2 Directivity polar diagrams for pressure-sensitive and pressure-gradient microphones and for constructive variations in between

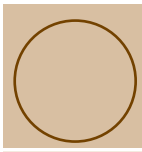
Table 12.1 Main parameters of microphones of specific directivity

Directivity	Omnidirectional	Cardioid	Supercardioid	Hypercardioid	Figure-of-eight
Sensitivity $s(\theta)$	1.0	$0.5 + 0.5\cos(\theta)$	$0.366 + 0.634\cos(\theta)$	$0.25 + 0.75\cos(\theta)$	$\cos(\theta)$
Directivity γ	1.0	3.0	3.732	4.0	3.0
Beam angle −3 dB	–	65.5°	57.5°	52.4°	45°
Beam angle −6 dB	–	90°	77.8°	70.5°	60°
Sensitivity 90°	0 dB	−6 dB	−9 dB	−12 dB	$-\infty$ dB
Sensitivity 180°	0 dB	$-\infty$ dB	−12 dB	−6 dB	0 dB

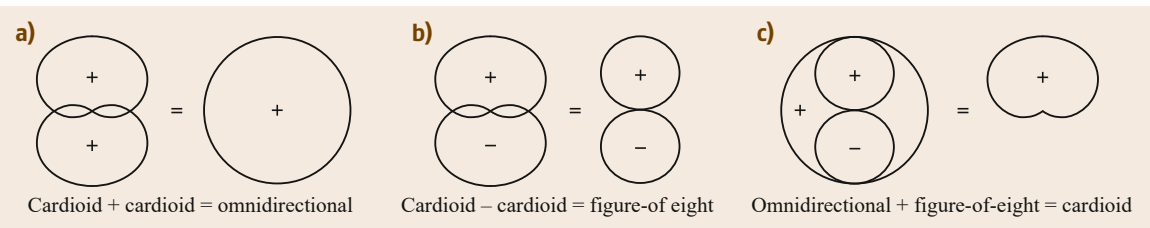


Fig. 12.3a–c Polar diagrams for microphones of varying directivity combined

ulate a DC source at low quality, e.g., high distortion ratio, low signal-to-noise ratio or a strongly limited frequency band. Rare examples of instrumentation use modulation of a laser beam as a principle. Some other instrumentation tasks feature a heated wire for measuring particle velocity at low frequencies. The physical principle behind this instrumentation is that the heated wire will be cooled down by particle movement.

Directivity factors can be further varied by construction (Fig. 12.2; Table 12.1) or by mutual addition or subtraction of signals from several microphones (Fig. 12.3).

Illustrations and directivity parameters presume perfect geometry. However, the outlined directivity patterns come close to reality only for low frequencies. Higher frequencies suffer from shadow, interference and bending effects (Fig. 12.4 for the MK 5 condenser microphone from Schoeps). In principle, the frequencies affected are inversely proportional to the size of the membrane and microphone. The smaller the microphone, the higher the fidelity at high frequencies.

The directivity type conversions illustrated in Fig. 12.3 presume perfect coincidence. However, two microphones cannot be in the same place at the same time. The distance between them will introduce comb filter artefacts. Figure 12.4 also indicates linearity over a wide range of frequencies. Manufacturers usually measure the frequency response on axis, $\theta = 0$. Other directions reveal frequency dependent attenuation. Consequently, the change of color/timbre is well perceivable for microphones when held off-axis. While striving for linearity, there are two major compensation issues. Pressure-gradient microphones respond with a leveraged bass range when held within the near-field of a source, the so-called proximity effect. In soloist microphones, for instance, this is usually com-

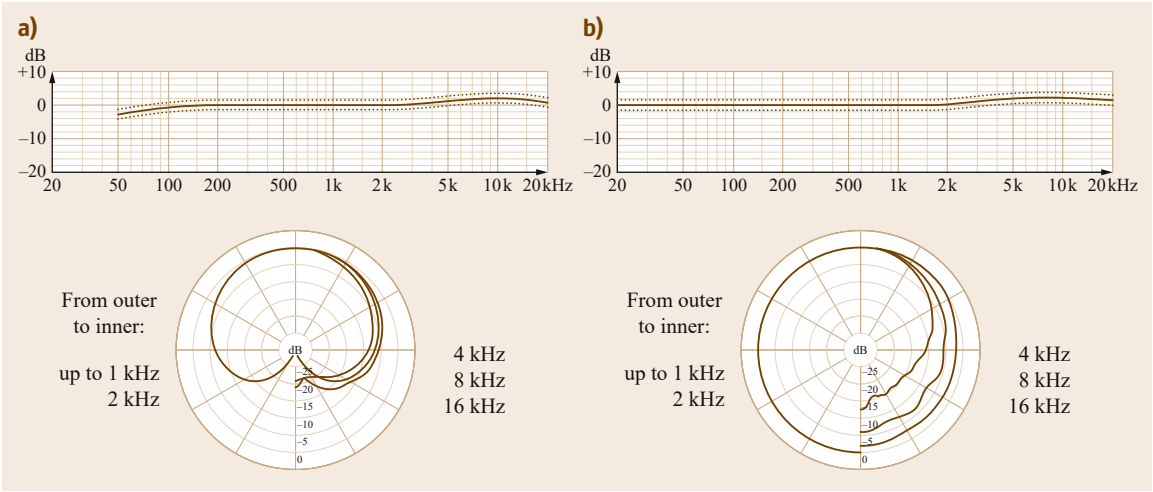

Fig. 12.4a,b Frequency-dependent directivity of a MK 5 microphone in its pressure-sensitive **(a)** and its pressure-gradient **(b)** mode

pensated for. The other major effect is that pressure-sensitive microphones respond with a leveraged treble range in the near-field. This is again compensated for in some microphones.

12.1.1 Coincident versus Spaced Microphone Arrangements

Multichannel recording facilitates spatial hearing while employing three basic principles of binaural listening:

(i) Direction-dependent intensity differences at the ears, or interaural intensity difference (IID)
(ii) Direction-dependent propagation delay, which is particularly dominant while localizing the first wavefront (precedence effect), or interaural time difference (ITD)
(iii) Directional color as determined by the shape of the head and the pinna.

A coincident setup follows principle (i) as microphones are arranged very close to each other to minimize propagation delay while the intensity difference will be achieved only by directionality of the microphones. Space between microphones introduces propagation delay to employ principle (ii) and it is the art of the recording engineer to translate source width and room dimensions into appropriate spacing. A dummy head employs all three principles.

12.1.2 Two-Dimensional Microphone Arrangements

The dimensions of recording and reproduction correspond to each other. Stereo or Dolby surround are two-dimensional and both microphone and loudspeaker arrangements are aligned with the surface plane. The left (L) and right (R) channels of a stereo mix are obtained from mid (M) and side (S) signals or from X and Y signals in coincident setups or from A and B signals in spaced setups (Fig. 12.5). The preferred angle α in XY arrangements is derived from the -3 dB crossover point of the cardioid directivity pattern, but other directivity patterns and other angles are used as well, e.g., $\alpha = 131°$ for cardioid, 115° for supercardioid, and 105° for hypercardioid. Spacing d in AB arrangements

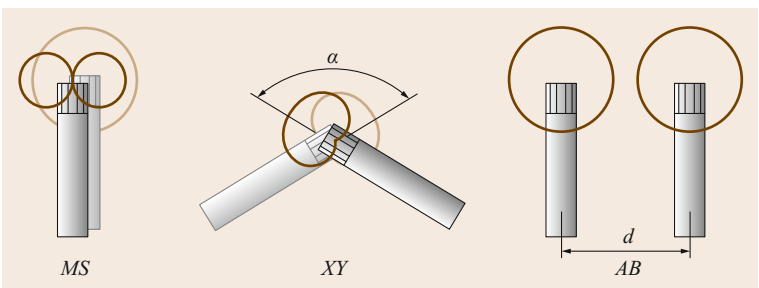

Fig. 12.5 Coincident and spaced microphone setup for stereo

varies from 17 cm to a few meters.

$$L = \frac{M+S}{\sqrt{2}} \quad R = \frac{M-S}{\sqrt{2}} \quad M = \frac{L+R}{\sqrt{2}} \qquad (12.1)$$

L and R result from the addition and subtraction of M and S (12.1). Reverse mixing re-establishes the omnidirectional M signal and is therefore a perfect mono downmix. XY signals directly correspond to L and R, and a mono downmix results in a wide subcardioid. A downmix of AB stereo results in comb filter artefacts and therefore in more or less annoying changes of timbre.

All three arrangements facilitate adaptation to the source width. If the contribution of S in (12.1) is chosen to be larger in relation to M, the captured sound source will appear wider. Likewise, such zooming effects will be obtained by larger α in XY arrangements and by a larger space d in AB arrangements.

A crossed figure-of-eight allows panning. Addition and subtraction will directly result in virtual figures-of-eight that are shifted by 45° (see the Blumlein arrangement in Fig. 12.6). Directions in between can be obtained by respective weighting factors. An additional coincident omnidirectional microphone, when combined with the Blumlein arrangement, will facilitate beam forming and panning. Both can be done even in the aftermath of recordings.

Arrangements for stereo recordings that combine spacing with the directivity of pressure-gradient microphones are shown in Fig. 12.7. The center C in the Decca tree is partially mixed to the left and right channels for stereo, and is routed directly to the center in surround recordings. Office de Radiodiffusion-Télévision France (ORTF) and Nederlandsche Omroep Stichting (NOS) arrangements are national standards but widely used in broadcast.

Arrangements for surround recordings are shown in Fig. 12.8. The most popular approaches are optimized cardioiid triangle (OCT), Ideale Nierenanordnung (INA, english: ideal cardioid arrangement), and the *Williams* [12.1] arrangement. Spacings a, b, c and d range from 8 to 116 cm and are specified for the individual arrangements and for individual angles α and β while following [12.2–4]. The three-microphone arrangement is supplemented by additional microphones for the surround channels. Established arrangements are the Hamasaki square, 4 cardioids spaced 1 to 3 m and far from the front microphones, or the IRT-cross, 4 cardioids spaced up to 1 m.

12.1.3 Three-Dimensional Microphone Arrangements

The principle of coincident arrangements can be extended to the third dimension. Using a double MS arrangement in the horizontal plane and a third figure-of-eight for the vertical direction establishes the three orthogonal directions. Virtually any direction can be achieved, again by multiplexing and by using weighting functions. Such arrangements can also be considered as sensing zeroth-order pressure with the omnidirectional

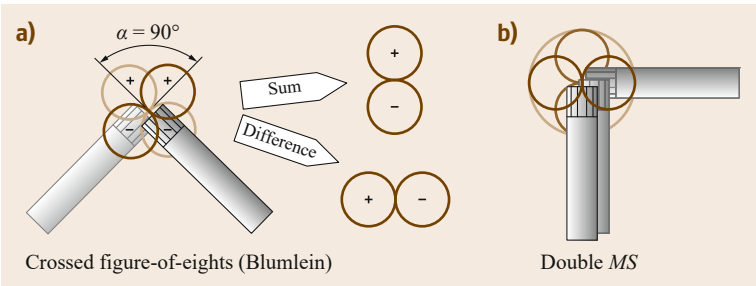

Fig. 12.6 (a) Blumlein and (b) double MS microphone setup

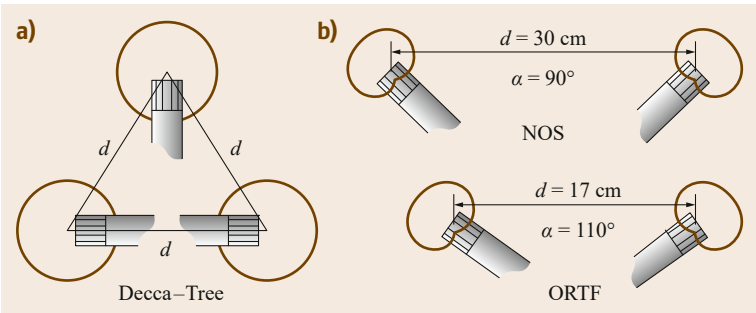

Fig. 12.7 (a) Decca tree, (b) NOS, and (c) ORTF microphone setup for stereo

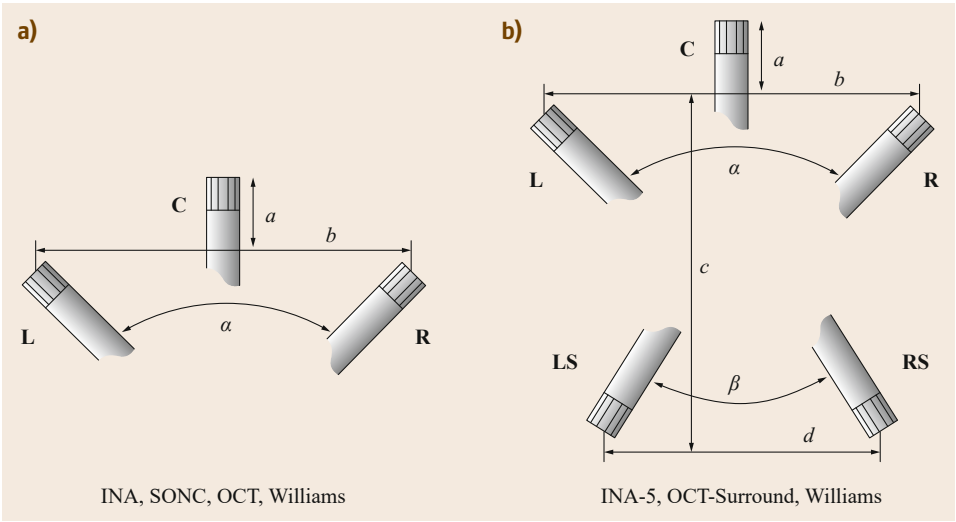

Fig. 12.8a,b INA, OCT and Williams setup for **(a)** stereo and **(b)** surround

microphone and first-order gradient pressure in three directions with the figure-of-eight microphones. Further orders can be developed and a higher spatial resolution obtained by using the Fourier–Bessel series as weighting factors in superimposed spherical harmonics, while also requiring more microphones. Three-dimensional systems of first order require four channels, and systems of second and third order require nine and 16 channels, respectively. Coincidence of the multiple microphones is a challenge. A smart solution was proposed by *Gerzon* in 1975 [12.5], that uses four pressure-gradient microphones arranged in a tetrahedron such that the membranes are in plane with the imaginary surfaces of the tetrahedron (Fig. 12.9). This soundfield microphone outputs the A-format set of signals *LF* (left front), *RF* (right front), *LB* (left back) and *RB* (right back). The B-format is obtained by the matrix (12.2) and can be rotated by angle φ and tilted by angle Φ, (12.3).

$$
\begin{aligned}
W &= \frac{LF + LB + RF + RB}{2} \\
X &= \frac{LF - LB + RF - RB}{2} \\
Y &= \frac{LF + LB - RF - RB}{2} \\
Z &= \frac{LF - LB - RF + RB}{2}
\end{aligned}
\qquad (12.2)
$$

$$
\begin{aligned}
W' &= W\,, \quad Y' = Y\cos\phi + X\sin\phi \\
X' &= X\cos\phi\cos\varphi + Y\sin\phi\cos\varphi + Z\sin\varphi \\
Z' &= Z\cos\varphi - X\cos\phi\sin\varphi - Y\sin\phi\sin\varphi
\end{aligned}
\qquad (12.3)
$$

The B-format can be projected to stereo by (12.4), where the imaginary part of the signal is obtained by the Hilbert transformation and a^* denotes the conjugate complex of a. Microphones with more channels support derivation of higher-order ambisonics (HOA). For instance, the 32-channel Eigenmike (Fig. 12.9d) supports third-order supercardioid.

$$
\begin{aligned}
L &= aX + b^*W + c^*Y \\
R &= a^*X + bW - cY \\
a &= 0.0928 + j0.255\,, \quad b = 0.4699 + j0.171 \\
c &= 0.3225 + j0.00855
\end{aligned}
\qquad (12.4)
$$

Spherical microphone arrays target sound sources and their polar diagrams (Fig. 12.10). Captured data facilitates modelling of the source and playback via a dodecahedron speaker, or other equally-spaced loudspeaker arrangements on spherical grids. Such playback in a real acoustical environment emulates the original sound source in that environment. Spatial resampling on the basis of Fourier transforms is facilitated by the equally spaced grid in the spherical arrangements so that the number of playback speakers may deviate from the number of microphones used in the recording. The captured source can also be listened to within virtually created acoustical rooms. For a tutorial on virtual acoustics, see [12.6].

Plane microphone arrays in rectangular, circular or helical arrangements are often used as acoustical cameras to identify sources of noise. Such cameras can also be used to identify the origin of sound radiation from a shell or a body or from an instrument or a singer. From the sound captured at the microphone array, the surface excitation can be traced back so that the radiation pattern can be fully described, at least for the spatial window covered by the array [12.7].

12.2 Signal Preconditioning and Effects

Signal preconditioning, such as noise gating, compression, or equalization, but also signal enhancement and effects have been implemented with the help of analog components and mostly in dedicated standalone equipment for a long time, while modern digital signal processing emulates such signal conditioning and modification.

12.2.1 Noise Gate, Compressor, and Expander

A noise gate mutes the signal in times of silence so that underlying noise cannot be heard anymore. Noise gating also reduces total noise, because individual contributions in mixes of several channels are likely to be noise-free. The controllable threshold level should be set just above the individual noise level so as to still allow pianissimo passages to be gated. Compression is necessary where the signal's dynamic range is larger than what can be captured or can be adequately processed, or larger than can be appropriately reproduced. For instance, brass instruments or percussions reveal a large dynamic range of 40 dB and up in practice. Microphones are capable of processing such a dynamic range, too. Compression effectively applies a high gain factor for low input levels, and – beginning from an adjustable limiter level – a lower gain factor for high input levels. There is usually a soft transitional crossover between the two linear ranges. Controllable attack and release times define the temporal dynamics and require masterful adjustment, because unfavorable settings cause audible distortion, artefacts, or roughness. Expansion is the supplementary, or reverse, processing step to increase the dynamic range. Here, the gain increases with the input level, and thresholds and temporal dynamics can likewise be controlled.

12.2.2 Levelling

Input levelling is an important preconditioning measure. Source levels and impedances depend on the source type (microphone converter principle, see above, or the type of pickup), and the range of levels additionally depends on the musical performance and the setup. Input levels that are too high will cause clipping and therefore distortion, while input levels that are too low are at risk of suffering from a signal-to-noise ratio that is too low during pianissimo passages. Input levelling therefore adjusts the anticipated input range to the range of the subsequent signal processing. In practice, the setting will be done after observing musicians during their

Table 12.2 Digital word formats and their dynamic range

Format	Minimal amplitude	Maximal amplitude	Max. dynamic range (dB)
16-bit fixed point	$-1 \ldots +1$	$-32\,768 \ldots +32\,767$	90.3
20-bit fixed point	$-1 \ldots +1$	$-524\,288 \ldots +524\,287$	114.4
24-bit fixed point	$-1 \ldots +1$	$-8\,388\,608 \ldots +8\,388\,607$	138.5
32/40-bit floating point	$\pm 1.175 \times 10^{-38}$	$\pm 3.403 \times 10^{38}$	1529
64-bit floating point	$\pm 2.225 \times 10^{-308}$	$\pm 1.798 \times 10^{-308}$	12 318

Table 12.3 Equalizer bands according to DIN 45651 and DIN 45652

Octave band center frequency f_O (Hz)	Third band center frequency f_O (Hz)			Bandwidths B (Hz)
31.5	25	31.5	40	22.4 – 28 – 35.5 – 45
63	50	63	80	45 – 56 – 71 – 90
125	100	125	160	90 – 112 – 140 – 180
250	200	250	315	180 – 224 – 280 – 355
500	400	500	630	355 – 450 – 560 – 710
1000	800	1000	1250	710 – 900 – 1120 – 1400
2000	1600	2000	2500	1400 – 1800 – 2240 – 2800
4000	3150	4000	5000	2800 – 3350 – 4500 – 5600
8000	6300	8000	10 000	5600 – 7100 – 9000 – 11 200
16 000	12 500	16 000	20 000	11 200 – 14 000 – 18 000 – 22 400

fortissimo performance. The observed upper limit will be kept clear by some headroom and will be set comfortably below the technical upper limit of subsequent circuits. The peak program meters (PPM) used for observation usually follow a logarithmic scale and provide a visual overload warning. All of this is true for analog mixing consoles and analog recordings. It is good practice to condition input signals before analog to digital conversion as well. Even though the dynamic range within digital systems might be quite large – depending on the word length and on the arithmetic format (Table 12.2) – the analog-to-digital converter has its own dynamic range due to the inherent noise and quantization error.

12.2.3 Equalization

Equalization is another important preconditioning measure. Individual instruments or voices might suffer from unbalanced timbre. Sometimes microphone positions suffer from local excess due to standing waves or there is some impact or other noise from the surroundings to be diminished. Equalization is also relevant for output signaling, for instance, to ultimately balance mastered sound or to compensate for room acoustical deficiencies when working with public address (PA) systems.

Equalization has its origin in the analog domain where usually first- to fourth-order filters have been used to achieve 6–24 dB attenuation per octave, respectively. Active filters also allow amplification, and the so-called peak filters are defined by their center frequency f_0 and gain. Full-parametric filters also facilitate the control of the Q-factor, $Q = f_0/B$ with bandwidth B. Shelving filters control the low- and high-frequency end of the audio band, rather than specific spots within the audio band. Digital implementations usually follow the analog model. Graphical equalizers are banks of filters of fixed frequency and bandwidth to control gain and attenuation for specific frequency bands in the range of ± 12 dB to ± 15 dB. Filters are arranged in such a way that neutral settings result in a unity frequency response. Typical implementations of graphical equalizers follow the definition of frequency octave bands or of musical thirds, according to DIN 45651 and DIN 45652 (Table 12.3). In practical applications therefore, the 10-band equalizers cover the range 22.4–22 400 Hz, in octaves, and 27-band equalizers cover the range to 35.5–18 000 Hz, in thirds.

12.2.4 Metering and Instrumentation

While the PPM is obligatory in mixing consoles, there are further instruments to assess signal quality. The vector scope superimposes the left and right channel in a vector space, i. e., the amplitude of one channel is plotted versus the amplitude of the other channel. This indicates the correlation or decorrelation of the two channels. For the sake of spaciousness, individual channels in stereo or Dolby surround formats should be strongly decorrelated. Metering allows the control of microphone setup and cabling, since reverse polarity and other failures in a switch matrix are spontaneously

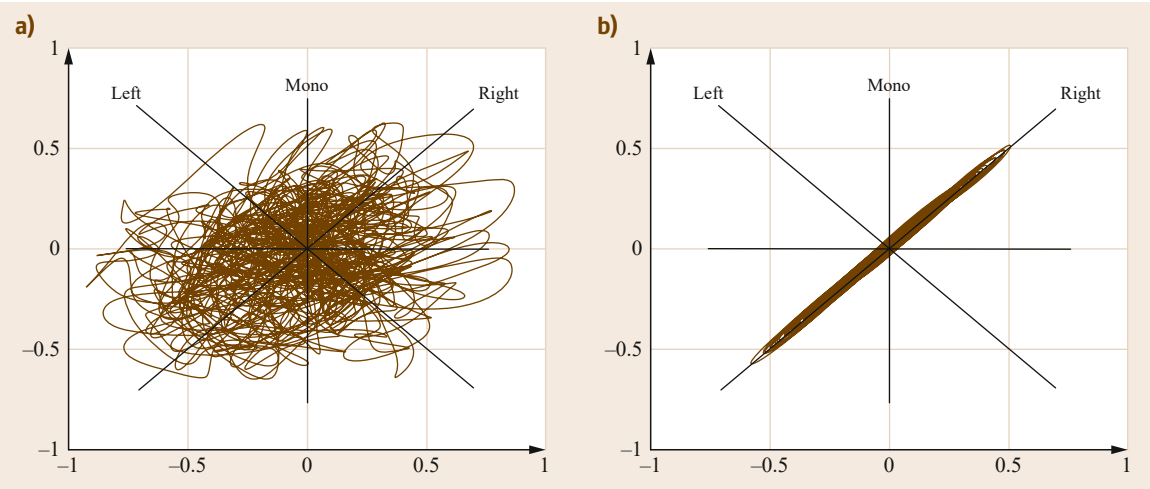

Fig. 12.11a,b Vectorscope plot of a decorrelated stereo signal **(a)** and a signal that is fully panned to the right channel **(b)**

identified. Mixing results can be visually inspected for a desired degree of decorrelation.

In Fig. 12.11, a spacious stereo signal is represented on the left side. Signals panned to either side are represented on either diagonal axis (Fig. 12.11b), mono signals are represented on the vertical axis, and mono signals with a reversed polarity on either channel are represented on the horizontal axis. In a corresponding manner, surround meters prompt the correlation in combination with the signal level for all the five channels in relation to each other.

12.2.5 Distortion, Harmonizer, and Enhancer

Distortion is occasionally a desired enhancement of sound. Strictly speaking, distortion is a widely used term and deserves a structured approach. Linear distortion is achieved by linear operations or processing and is reversible, e.g., by equalization. Nonlinear distortion is the result of nonlinear operations or processing and is irreversible. Nonlinear distortion can be further differentiated into harmonic and nonharmonic distortion. Harmonic distortion may result from operation along a nonlinear amplifier characteristic or from clipping (Fig. 12.12). Nonharmonic distortion adds spectral components that do not follow the series of overtones that are usually found in natural sounds.

The effect of clipping can be calculated analytically using Fourier series. Note that multitudes of the fundamental frequency are developed, which are perceived as harmonics belonging to the fundamental tone. Here, the three-fold, five-fold and further odd-numbered multitudes of the fundamental at 500 Hz are created. The saturation of tubes has a similar effect. However, there is a transitional crossover that effectively weakens the development of higher orders. Saturation at the preamp tube causes what musicians call distortion, while saturation at the output stage is called overdrive. Tubes are likely to create asymmetric clipping, which promotes even-order harmonics. These even-order harmonics match the first, second and third octave of the fundamental (2-fold, 4-fold, and 8-fold), and the fifth in the next but one octave above the fundamental (6-fold). Therefore, the added components fit the musical scale well, which is perceived as a warm and rich enhancement of tone. Harmonizers develop even-order harmonics rather than odd-order harmonics. So-called enhancers and harmonizers use high-pass or band-pass filters to selectively generate higher-order harmonics. The tune parameter facilitates selection while the drive controls the power dosage.

Harmonic distortion can be measured by the distortion factor k,

$$k = 100\% \sqrt{\frac{U_2^2 + U_3^2 + \ldots U_n^2}{U_1^2 + U_2^2 + U_3^2 + \ldots U_n^2}}$$
$$= 100\% \sqrt{\frac{U^2 - U_1^2}{U^2}}\,, \qquad (12.5)$$

where U is the root mean square (RMS), of the signal voltage and U_i is the RMS voltage of the i-th harmonic. The equation suggests that there is nothing else than harmonics in the sound. However, the general form $U^2 - U_1^2$ in (12.5) implies nonharmonic noise, too, in compliance with DIN IEC 60268-2 and AES17. The total harmonic distortion (THD) is the same measure and often denoted in dB. An alternative approach relates the

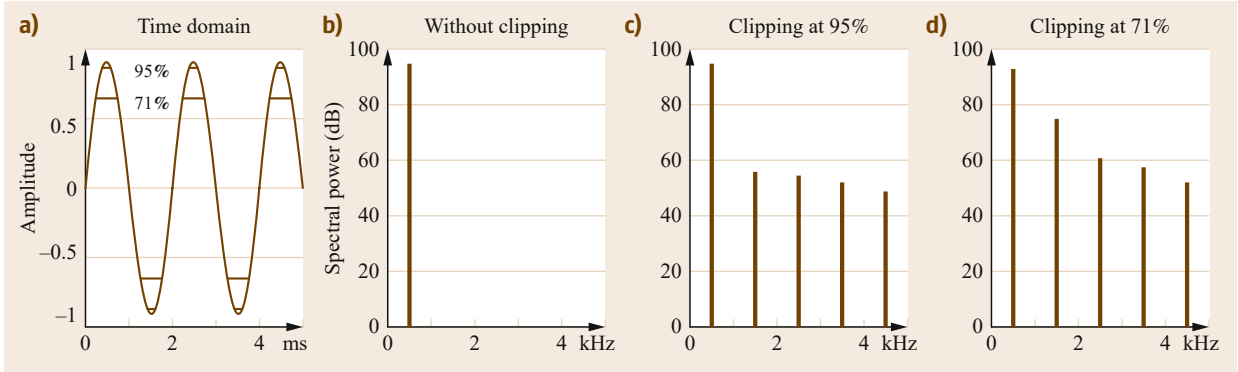

Fig. 12.12a–d 500 Hz sinus **(a)**, and its spectrum without clipping **(b)** and with clipping **(c,d)**

harmonics to the fundamental rather than to the total signal, according to IEEE 1241.

$$\mathrm{THD} = 20\log_{10}\sqrt{\frac{U_2^2+U_3^2+\ldots U_n^2}{U_1^2}}$$
$$= 20\log_{10}\sqrt{\frac{U^2-U_1^2}{U_1^2}} \qquad (12.6)$$

These measures usually qualify the linearity of amplifiers or transformers, and k, or THD, should then be as low as possible. While measuring harmonic distortion, however, k would represent the wanted distortion effect. Finally, nonharmonic distortion can be achieved, for instance, by operating circuits outside their specification, or by adding a chaotic rule set in digital feedback loops, for instance, by operation at supply voltages that are below specification. Nonharmonic components do not comply with the definition of k or THD, but should in general be quantifiable by respective measurement equipment.

12.2.6 Delay Effects, Flanger, and Phaser

Delay and superposition of signals cause manifold perceptual changes of sound in terms of both timbre and localization. The addition of a signal and its delayed representation cause a comb filter effect, or amplification and damping with spectral regularity. Delay by Δt will cause elevation of frequencies $f_{\mathrm{peak}} = n/\Delta t$ and depression at $f_{\mathrm{dip}} = (2n-1)/2\Delta t$ (Fig. 12.13). Such a delay is naturally existent with the well-known echo in any acoustical room and human listening is conditioned to this.

Comb-filter effects are easily audible. Experts can identify the existence of an echo even at levels as low as −18 dB. Figure 12.13b shows a delayed signal at −6 dB.

The parameters to delay effects are: signal delay, level differences, number of delayed signals, time-variance of the delay (modulation), spatial directions of a signal and its *echo*, and the use of feedback. Feedback returns part of the outcome of the delayed signal back to

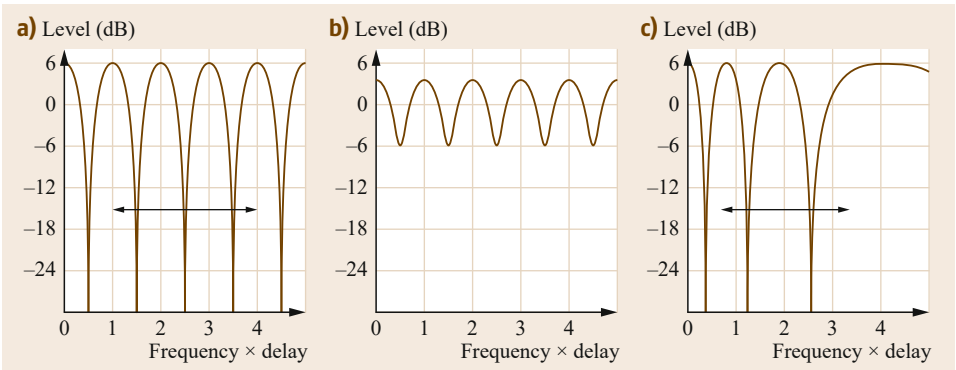

Fig. 12.13a–c Spectral presentation of superimposed signals, **(a)** superposition of a broadband source signal and its delayed version having the same level, the two-sided arrow indicates the variation resulting from a modified delay, **(b)** superposition when the delayed signal is 6dB lower than the source signal, **(c)** for the phaser effect a low delay is periodically varied over time

Table 12.4 Sound effects based on delay and their parameters

Effect	Delay	Modulation	Feedback
Echo	> 100 ms	No	Yes
Double tracking	20 . . . 40 ms	No	No
Multitrap delay	Several individually adjustable delays	Yes/no	Yes/no
Chorus	15 . . . 30 ms	Yes	No
Flanger	1 . . . 10 ms	Yes	Yes

the input. These parameters rule the perception of timbre and space. Echoes can even cause the perception of pitch, especially if signals are broadband signals with little or no tonality. The variation of these parameters results in widely used effects. Echoes use fixed delays above 100 ms with feedback (Table 12.4). Double tracking is used on voice signals and works with delays at the threshold to echo. Multitrap delay uses feedback and modulation to generate nonperiodic patterns and rhythms. For the chorus and the flanger effect, a low delay is periodically varied over time (modulation), which effectively expands and compresses the grid of multiple zeros in the spectral domain. The flanger effect typically works with feedback and with a lower delay than the chorus effect. The flanger effect creates a complex timbre with some tonal character and often sounds like a passing jet, while the chorus effect creates a darker timbre, spaciousness, and fullness of sound.

The phaser effect also has a grid of zeros that is expanded and compressed across the frequency axis, however, the zeros are not equally spaced (Fig. 12.13). The delayed signal passes few or multiple stages of allpass filters, each representing an individually controllable shift of phase.

12.2.7 Reverberation

In natural rooms, early reflections are usually distinct and often separately distinguishable. Reflected sound is fed back into the room and repeated reflections will finally dissolve into a diffuse sound, or reverberation. Reverberation is a desired sound enhancement and human listening is used to it. Recordings might already contain a balanced portion of reverberation or reverberation might be added during sound postproduction after recording in a less reverberant – or dry – studio. In the predigital era, reverberant rooms or tunnels, together with a speaker and several microphones, were used to create reverberation. In the 1950s, a 2 m^2 reverb plate made of steel was used in many studios together with input and output transducers to create mono or stereo reverberation. Today, reverb springs are still commonly used in vintage guitar amps.

An example of an early digital reverb is Schroeder's circuit with four parallel feedback loops with reciprocally allocated peaks and notches, followed by two allpass filters [12.8]. This prototype and its descendent variations, as well as the widely used Lexicon models 224L, 480L, and 960L all have in common that individual parameters of the reverberation are controllable. Examples are room type (church, hall, chamber), reverberation time, structure of early reflections, low frequency reverb (bass multiply), critical frequency for high-frequency attenuation (roll-off), spectral decline of reverberation time (treble decay), and delay between direct signal and reverberation signal (predelay). Time-variant random modification of delay or timbre emulates movement and the liveliness of reverberation.

Another digital technology for reverberation is sampling. The impulse response of a room can be instrumentally sampled and then convoluted with a dry source signal. Such samples contain the true response of a natural room like a fingerprint. Convolution requires substantial calculation power, for instance, $\approx 3 \times 10^{10}$ operations per second for a 5 s impulse response sampled and convoluted at 48 kHz. Fast convolution algorithms [12.9] help to reduce the number of operations but even then convolution-based reverberation only worked on dedicated hardware in the 1990s (Sony DER-777, Yamaha SREV1). Today, sample-based reverberation also works on desktop computers and audio work benches (AWB). The sampling approach, in its simplicity, has only a few parameters to control, e.g., predelay and reverberation time.

In the production workflow, reverberation serves different objectives. Dry sources – sound sources with little or no reverberation – such as a synthesizer sound or a spot microphone need additional reverb. Reverberation technology is also used to enhance or correct the reverberation that comes with the recorded natural reverberation. Sound engineers are cautious not to take too much natural reverberation during the recording, because there is no convincing way of eliminating surplus reverb. Adding reverb, however, is convenient. Reverb is eventually used to emphasize individual instruments, such as a snare drum or guitar. Finally, reverberation is used to fuse the final mix by a common virtual room. In film sound productions, reverberation is used to match voice and sound effects with the ambient noise or with the visual impression of a film scene. For dubbing tasks, reverberation is the key to retrospectively place the dubbing voice into the given scene of the actor in an authentic way.

Reverberation equipment most commonly processes mono, stereo, or surround signals. For stereo signals, a mono signal is derived from the input signals and the reverb is added to both channels.

12.2.8 Vocoder

Vocoders were initially engineered in the telecommunications industry to encode speech signals for efficient transmission. But early in the 1940s, vocoders were already being used to enhance sound. The main idea is to decompose the source and filter parameters of the glottis and the vocal tract to finally transmit parameters. These are used to recompose the voice signal based on a common model. The parameters are: voiced/unvoiced sound, pitch frequency and formant frequencies. On the parametric level, individual components can be substituted. For instance, a guitar can be played to drive a human voice.

12.3 Digitalization

Digitizing signals is a two-step procedure: first, taking samples from a signal at constant time intervals Δt, or at constant rate $f_s = 1/\Delta t$, and second, quantizing the sample amplitude in the value domain with a specific resolution, the quantum q. Therefore, the digital signal is discrete in two domains (Fig. 12.14).

For every sample taken, the digital representation of the signal contains a superposition of the original signal $x(n\Delta t)$ and the quantization error. The digital sound vector $x[n] = x(n\Delta t) + q[n]$ will eventually be converted back to the analog domain for playback. The quantization noise, which is part of the digital signal, will then be converted as well and will be part of the played back audio signal. This quantization error is usually statistically independent from the input signal and therefore the sign of the maximum $q/2$ noise contribution in individual samples is random. As shown in Fig. 12.14 the sign might change rapidly, effectively causing noise of high frequency, or less rapidly, causing noise of relatively low frequency. The spectral density is therefore assumed to be uniform from DC to $f_s/2$. And the energy contained in the noise signal is equivalent to $q^2/12$, while the energy of the signal $x[n]$ is equivalent to the square of the efficient level expressed in multiples of q. Since signals peak at maximum $\pm q^{k-1}$ for bipolar representations of amplitude and for word size k, the ratio of signal to quantization noise is limited by the signal character and the word size. Roughly, each of the k bits contributes 6 dB to the signal-to-noise ratio (SNR). A 16-bit audio format has a potential of 96 dB SNR. However, this maximum value is not achieved since:

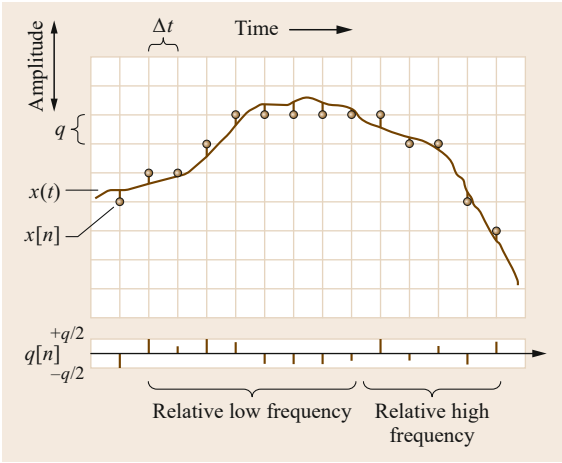

Fig. 12.14 Analog signal $x(t)$, its digital representation $x[n]$ and the quantization noise $q[n]$

1. The careful sound engineer will allow some headroom during recording
2. Signals are transient or they strongly decline and therefore contain little average energy
3. The dynamics of a musical piece already demands a good portion of the total dynamics and silent passages suffer from a lower SNR
4. Each digital processing step and its inherent rounding implies supplemental quantization noise.

In the time-domain, the sampling of a signal can be considered as some kind of gating. An ideal sampling model begins with the multiplication of the input signal with a periodical Dirac impulse. System theory suggests that such multiplication in the time domain is equivalent to a convolution in the frequency domain. The Fourier transform of a periodic Dirac impulse is a spectrally periodic Dirac impulse and, if convolved with a band-limited input signal, forces periodicity of the spectrum of the sampled sound.

This principle is visualized in Fig. 12.15 and formally expressed by

$$\begin{array}{ccccc} x_s(t) & = & x(t) & \cdot & \delta_{\mathrm{PER},\Delta t}\,, \\ \updownarrow \mathrm{FT} & & \updownarrow \mathrm{FT} & & \updownarrow \mathrm{FT} \\ X_s(f) & = & X(f) & \otimes & \Delta_{\mathrm{PER},f_s}\,, \end{array} \qquad (12.7)$$

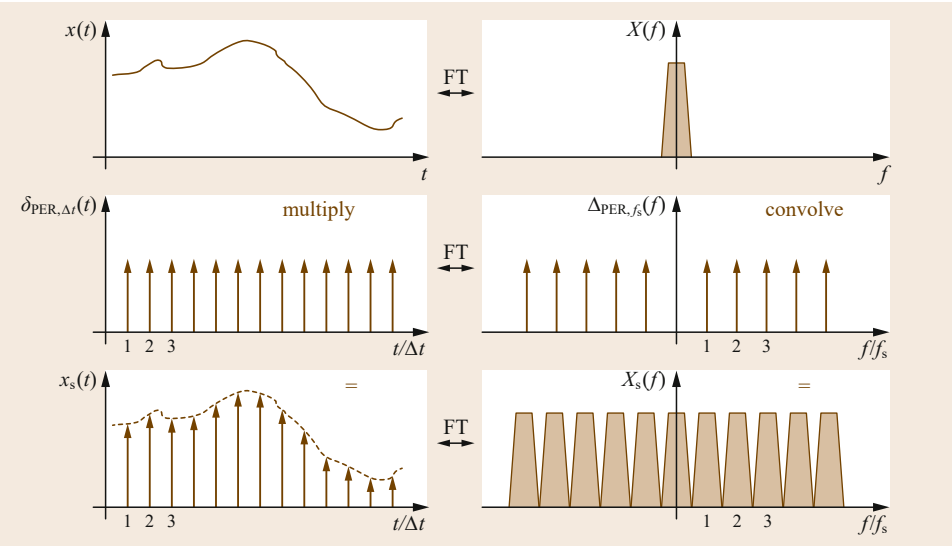

Fig. 12.15 Analog signal $x(t)$, the sampled signal $x_s(t)$ in the time domain and the respective signals $X(f)$ and $X_s(f)$ in the frequency domain

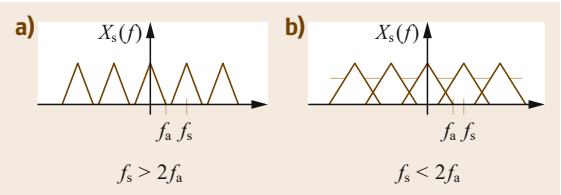

Fig. 12.16a,b Spectrally perpetuated signal without **(a)** and with **(b)** unwanted overlap

with the Fourier transform (FT) mutually relating the time domain and the frequency domain with each other.

The nature of sampling not only implies periodicity of spectral components, but also their superposition. Figure 12.16 shows an example of a signal with properly limited bandwidth that results in no overlap (Fig. 12.16a) and an example of an inadequately limited bandwidth resulting in overlap (Fig. 12.16b). Such overlap is easily audible. Therefore, the basic sampling theorem of Shannon asks that the maximum frequency of the analog input signal, f_a, is limited to half of the sampling frequency f_s.

$$f_s \geq 2f_a \tag{12.8}$$

A priori band limitation of signals is usually achieved with antialiasing filters, with the cut-off frequency set at $f_s/2$. However, the desired attenuation can only be achieved to a certain degree. For instance, the typical fourth-order low pass filter has an attenuation of only 27 dB at f_s, i. e., 3 dB at the cutoff-frequency ($f_s/2$) plus 6 dB per order one octave above f_s. High-end studio equipment not only uses well-defined antialiasing filters but also the shape of the samples to control out-of-band noise. The sampling model above can be extended by convolving each Dirac sample with a certain impulse shape, $i(t)$, which in return implies a multiplication of the periodical spectrum with a weighting function $I(f)$, which is, again, the Fourier transform of the impulse shape $i(t)$.

$$\begin{array}{ccccccc} x[n] & = & x(t) & \cdot & \delta_{\mathrm{PER},\Delta t} & \otimes & i(t)\,, \\ \updownarrow \mathrm{FT} & & \updownarrow \mathrm{FT} & & \updownarrow \mathrm{FT} & & \updownarrow \mathrm{FT} \\ X_A(f) & = & X(f) & \otimes & \Delta_{\mathrm{PER},f_A} & \cdot & I(f)\,. \end{array} \tag{12.9}$$

Figure 12.17 illustrates such an extension using the abstract rectangular shape for $i(t)$, effectively shaping the spectrum with the corresponding Fourier transform, a $\sin(f)/f$ function, while the zero crossings can be defined by the impulse width.

12.3.1 DM and SDM

Besides these so-called Nyquist samplers, oversampling technologies are widely used today, for instance delta modulation (DM) or sigma-delta modulation (SDM). Instead of the two-fold sampling frequency (12.8), DM and SDM use oversampling, i. e., a 32-, 64-, 128-, or 256-fold sampling frequency. The principle of periodicity remains. However, the size of the periodically multiplied spectral slices – as defined by the sampling frequency – is much wider, and therefore, the problems around the antialiasing filter are much more relaxed and noise is effectively reduced.

The principle behind DM is that the absolute value of an input is not quantized but the difference between successive samples. Therefore, the word size does not

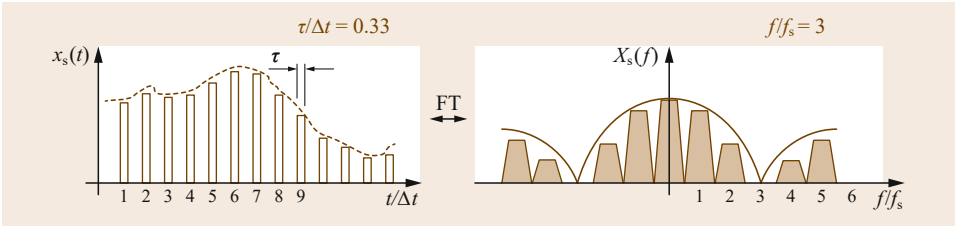

Fig. 12.17 Sampling with impulse shaping and the respective spectral weighting function

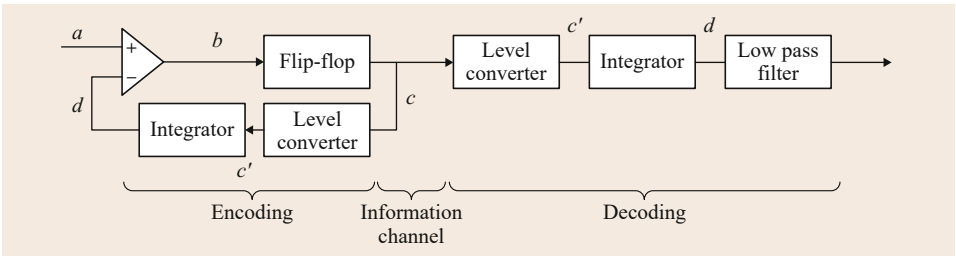

Fig. 12.18 Schematic of a delta modulator

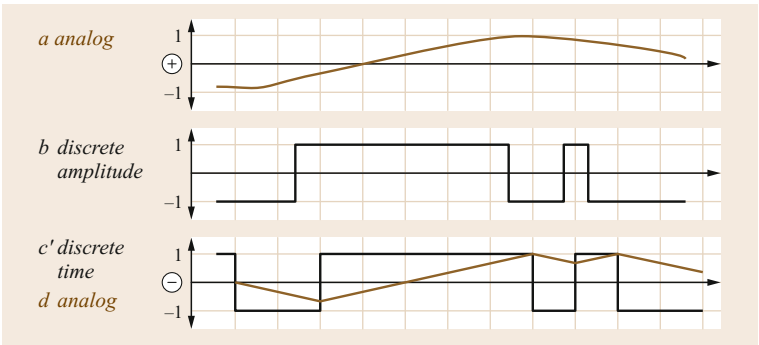

Fig. 12.19 Signal d follows input signal a by up/down integration, as identified by signal b after comparison

need to cover the full input range, but only the expected maximum difference between samples. This is also the basic principle of data compression by prediction. Here, the word size is even reduced to only one bit through oversampling, or in other words, the sampling rate is so high that the difference between successive samples is less than a bit. The analog input signal a in Fig. 12.18 is compared with the signal d, which is constructed stepwise to follow signal a. Signal b directly outputs the result of the comparison between a and d (Fig. 12.19). Signal b is latched by a flip-flop to finally constitute the digital signal c. The level-converted digital signal c' controls the integrator to further follow signal upwards or downwards, as a result of comparison. In the receiver, the corresponding level conversion and integration steps will constitute the same signal d, which will represent signal a after some additional low-pass filtering.

DM has been extensively used in speech transmission. Its signal fidelity is limited by the slope, which is in return predefined by the converter and integrator's time constant. Slope overload is avoided by an extension of the sampling principle, where several predefined slopes can be iteratively adapted to the input. Adaptive delta modulation (ADM) is widely used today.

Another way to prevent slope overload is to use an additional integrator – or sigma – before signal comparison (Fig. 12.20 for SDM). The additional integrator in the signal chain asks for an additional complementary differentiation step, which is obtained by omitting the integration step on the decoder side. While the density of ones and zeros in a DM bit stream represents the positive and negative slopes of the analog signal, in a SDM bit stream it represents the absolute signal level of the analog signal.

In terms of noise, SDM has an additional advantage over DM. While the transfer function of the input signal is unity, the transfer function of the quantization noise is $H(z) = 1 - z^{-1}$, due to the feedback loop. This implies high-pass filtering of the quantization noise. For instance, in systems with a sampling of $128 \cdot 20\,\text{kHz}$, the noise at 20 kHz is additionally reduced by 26 dB and the noise at 5 kHz is reduced by 40 dB. SDM systems are

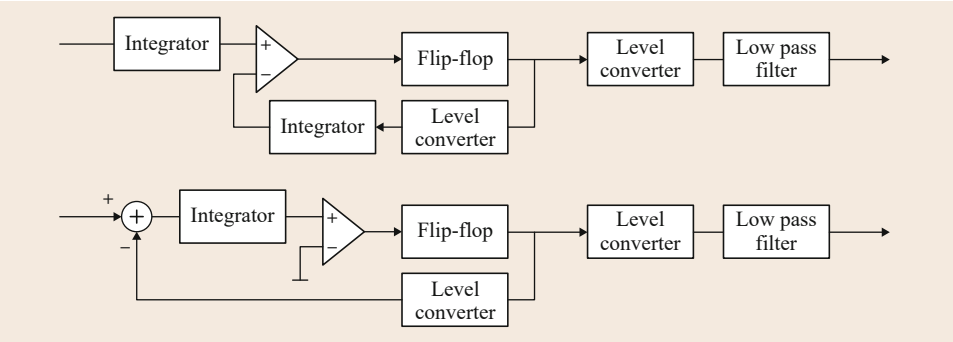

Fig. 12.20 Schematic of the sigma-delta modulator

usually implemented in three cascades and the resulting low-pass filter of the order of three attenuates noise by 78 dB at 20 kHz and by 120 dB at 5 kHz.

The SDM bit stream can be stored directly, e.g., in the superaudio CD format (SACD). However, it must usually be converted to linear formats of, for instance, 16, 20, or 24 bits by decimation in order to allow for standard signal processing and mixing technologies to be applicable. While the aliasing problem is more relaxed with SDM, the art of achieving fidelity lies in the decimation filter, which can vary from simple averaging to sophisticated higher-order approximation of the underlying input signal. Decimation reduces the sampling rate while increasing the word size.

12.4 Mixing Consoles

Mixing consoles are used to mix a larger number of input signals to fewer output signals, such as stereo channels or PA channels. They are typically arranged in a group of input signal channels, one for each input, a set of signal channels to arrange subgroups, and signal channels for mastering the outputs. An *8-4-2* console has 8 input channels, 4 subgroups and 2 master channels. In split consoles, all channels are dedicated to one task and are separately organized, while inline consoles combine input and subgroup tasks within one signal channel and are able to process two signals simultaneously.

An input signal channel typically comprises an input gain control, equalization, a control for effect send, monitor send, and auxiliary send, panning and a fader for the mix. The input gain adjusts the input level. For instance, a microphone signal at −50 to −30 dBu will be amplified to studio reference level at +4 dBu (1.23 V) or +6 dBu (1.55 V). For dBu, see Sect. 12.7.2. The reference is 0 dBu = 0.775 V. Equalization has been adressed in Sect. 12.2.3. In mixing consoles, typically only two or three frequency bands will be controlled. The signal is then amplified and spectrally shaped, if necessary, and is ready for the mix and for further processing. The signal will be used for musicians' monitoring, for effects, for recording or will be assigned to subgroups. Some signals require delay rather than additional effects, for instance spot microphones, or delay lines in a PA setup where PA speakers far from the stage must be delayed according to the Haze effect to avoid irritating the source location. For all of these purposes, auxiliary outputs, but also specific effect-send and monitor-send outputs are provided and controlled by dedicated faders. Signals returned from effect channels can often be inserted inline within the signal channel. So-called inserts deliberately detour the signal over an external device. A panning fader directly maps the signal to the stereo master channels. The sliding fader finally controls the level and therefore the contribution to the mix within a group or the master signal. Consoles differ in the way the auxiliary outputs are arranged in relation to the fader. There are prefader and postfader outputs, sometimes with options. The signal flow within the consoles is arranged by matrices and busses.

Subgroup signal channels are similarly arranged. However, they usually do not have equalization, but rather additional inputs and inserts. Subgroups are directly panned to the stereo master channels and controlled by sliding faders. Stereo panning principally employs both binaural factors for localization, interaural time differences (ITD) and interaural level differences (ILD). However, in mixing consoles, the level difference is commonly the only employed principle due to the desired monocompatibility because stereo signals with time differences between the two channels would cause undesirable comb-filter effects in mono downmixes. There is no standard on how to dose the level for

Table 12.5 Standards for metering signals

	DIN scale	NORDIC scale	British scale	EBU scale	Digital peak meter
Standard	DIN IEC 60268-10 type I		DIN IEC 60268-10 type IIa	DIN IEC 60268-10 type IIb	IEC 60268-18
Scale range	−50 . . . +5 dB	−42 . . . +12 dB	0 . . . 7	−60 . . . +9 dB	
Reference level	*0 dB*	*0 dB*	*6*	*+9 dB*	*0 dB*
Reference voltage	1.55 V	0.775 V	1.94 V	2.18 V	
Integration time	5 ms	5 ms	10 ms	10 ms	1 sample/10 ms
Hold time	1.7 s	1.7 s	2.8 s	2.8 s	1.7 s

the left and right channel in relation to a *linear* panning scale. In the middle position, where −3 dB would seem appropriate, some consoles set the level at −4.5 dB for both channels.

The master channels are organized as stereo channels in most cases. They are equipped with a sliding fader, additional inserts, and level metering. The most common forms of level metering are the volume unit meter (VU) and PPM. A VU meter is usually implemented in the form of a coil instrument and roughly images subjective loudness. It has a range of −20 VU to +3 VU, with the reference of 0 VU = +4 dBu (1.23 V). The VU meter is calibrated to sinusoids and is slowly acting. The integration time is between 35 ms and 300 ms and is therefore not a good choice to control digital clipping. PPM is a better choice for controlling transient overload, since the integration time is between 5 and 10 ms. Some PPMs are equipped with a fast option of only 0.1 ms. There are several different European traditions and standards for metering, which are summarized in the DIN IEC 68268-10 (Table 12.5).

A talkback channel from the control room to the studio or to the stage is a common feature in the master signal channel as well as headset monitoring.

Digital mixing consoles in professional environments are standalone devices, like the analog mixing consoles, and often supplemented by modern hard-disc recording systems. In semiprofessional environments they might be represented by as little as specific software that runs on a standard desktop computer with external microphone preamps and external ADC and DAC devices. The digital console offers flexibility in terms of configuration, complexity and signal processing steps. However, the shared processor and memory resources must be carefully assigned and monitored.

12.5 Synthesizer and Sequencer

A synthesizer is known to be an electronic system to create sound. The history of synthesizers began with hardware-only systems, such as the Theremin, the Trautonium or the Hammond organ in the 1930s and evolved to computer-based software systems, such as Reactor or Max/MSP. Synthesizers are used for both emulation of existing instruments and creation of fancy new sounds or timbres. Often enough, the creativity of technicians and musicians brought along instruments with original sound characteristics, such as the Moog and its little brother, the Minimoog. Early synthesizers were monophone and had to be played manually for every single performance, in the 1970s polyphone systems and systems with program and storage capacities facilitated complexity and reuse.

In correspondence with musical instruments and natural sound creation, the electronic sound creation often follows the source-filter model: a generator process followed by filtering and eventually followed by a resonator or a model of radiation.

For pitched musical sounds, the source is generally an oscillator that generates an impulse train, for instance the jet stream cycle at the reed, the glottis or the labium, or the Helmholtz motion of a bowed string. Even the plucked string generates an impulse train at the bridge. Sharp impulses inherently host a wide spectrum and the repetition of pulses causes the repetition of impulses in the spectrum or the harmonic structure of pitched sound (12.7). These impulses are not necessarily of the same level. The form of the individual impulses rules the general spectral decline (12.8). The plugging or bowing position on a string already introduces formants, irrespective of additional subsequent spectral shaping by resonances or damping. The resulting envelope represents the outcome of the filter part. For voice, the related formants host the vowel quality, for musical instruments the envelope hosts the timbre.

Synthesizers use similar construction principles; the basic elements are oscillation, filters, and modulation.

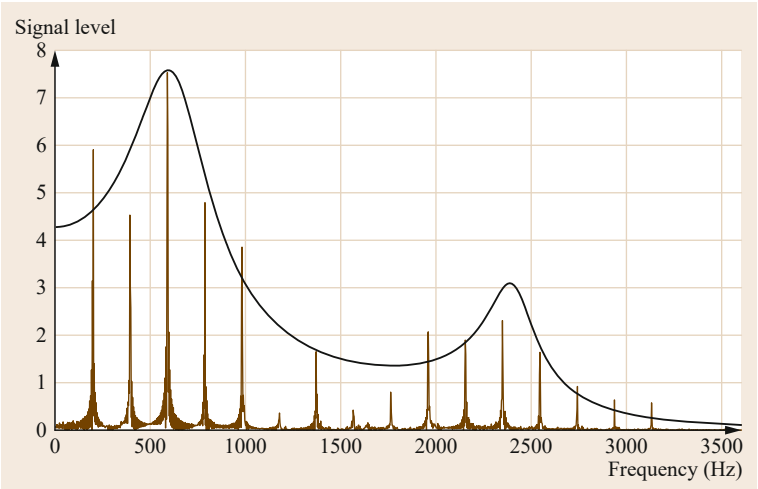

Fig. 12.21 Harmonic spectrum of a 200 ms long section of sound for the note g played on a cello, radiated sound recorded by microphone and the approximation of the spectral envelope by linear prediction (LP) of order 8

Oscillators might generate harmonic wave shapes or impulse trains. As already outlined, impulse trains inherently host a harmonic structure. Periodical functions, such as a saw tooth or a rectangular function host a harmonic structure, too, as the commonly known Fourier correspondences suggest. A voltage-controlled oscillator (VCO) usually generates a harmonic wave shape while the frequency is controlled by an input voltage. Therefore the pitch can be controlled or the sound can be modulated, e.g., by vibrato. Oscillators can be built by analog circuits or by digital loops.

Filters allow equalization, spectral shaping, phase modulation, or the construction of specific formants. For instance, the spectrum of the cello in Fig. 12.21 can be interpreted as having two formants. Time-invariant filters can be used to create the flanger or the phaser effects, see Sect. 12.2.6. Again, filters can be implemented in analog and digital fashion.

In a modulator, the multiplication of signals results in spectrally wide or less distinct signals, or in a frequency shift. The effect depends on the frequency of the modulating signal $s_m(t)$ and of the modulated audio signal $s_a(t)$.

$$s(t) = s_a(t)\, s_m(t) = s_a(t)\, \hat{s}_m cos(\omega t + \phi) \quad (12.10)$$

FM synthesis has its origin in broadcasting and has been used for sound synthesis since the 1980s. With FM synthesis the argument of the trigonometric function is modulated rather than the amplitude.

$$s(t) = \hat{s} \sin(\omega_c t + I \sin(\omega_a t)) \quad (12.11)$$

This standard notation is quoted to understand the nature of frequency modulation. In practical application, the trigonometric function in the argument of the other trigonometric function is directly replaced by an audio signal, which in return might represent superimposed harmonic functions. The nature of the nested function is such that modulation creates a series of sidebands at multiples of ω_a around the carrier with frequency ω_c. The amplitudes of the sidebands are determined by $J_k(I)$, the k-th Bessel function of first kind, while I is the modulation index and a parameter to the synthesis. A main sound effect of FM synthesis is vibrato. Another effect is the creation of a harmonic structure to sounds that only come along with a fundamental frequency.

Additive synthesis is the principle of piecewise construction from elementary periodical functions and allows for the creation of a harmonic structure. For example the Hammond organ uses tone wheels for the fundamental tone and each of its harmonic overtones. The player controls the timbre by activating respective registers. The Hammond organ by construction hosts a summation point for many signals. Today's digital versions of a Hammond organ reuse the additive method.

In subtractive synthesis, a spectrally wide signal is disposed to achieve the desired sound. Referring to the cello example, repetitive sharp impulses initially host all harmonic overtones without spectral shaping and the following filter, the one that approximates the envelope in the above example, introduces the formants and effectively subtracts all harmonic overtones above 3500 Hz, which finally brings the synthesized sound close to its natural paragon. The Moog synthesizer uses the subtraction method.

In granular synthesis, sound elements of smallest possible size in the time and the frequency domain are used to construct sound. The grains consist of a harmonic signal windowed by a Gaussian envelope, for instance. The widely-used short-time Fourier transform (STFT) also uses windowing for the sliced input vector,

and the output coefficients reveal how well the windowed input relates to a harmonic signal. In contrast, the inverse transform or synthesis rebuilds the original signal by adding all tiny elements together. In (12.12) the window can be thought of as being applied to the sliced input familiar in STFT. It can also be thought of as being applied to the harmonic function, representing a grain. The same is true for synthesis. The windowed complex harmonic function serves as a grain for synthesis, while the coefficients $F(\omega)$ select the type of grain and control the weight.

$$\text{FT} \quad F(\omega) = \int \overbrace{f(t)\, w(t-\tau)}^{\text{windowed input}} \mathrm{e}^{\mathrm{j}\omega t}\mathrm{d}t \quad \text{analysis}$$

$$\text{IFT} \quad f(t) = \int F(\omega) \underbrace{w(t-\tau)\, \mathrm{e}^{\mathrm{j}\omega t}}_{\text{windowed weighting function}} \mathrm{d}\omega \quad \text{synthesis} \tag{12.12}$$

Such composition allows for the synthesis of tones with harmonic overtones, since grains can be concatenated in an overlapping fashion to establish continuous pure tones. But transients can also be created in the same manner since transients can be transformed into the frequency domain as well. Strictly speaking, the granular synthesis is a special form of the additive method. The analysis/resynthesis method can also be applied with other transforms, such as the wavelet transform, or with analysis methods that decompose into a representation of noise plus transients plus sinusoids.

For the sampling method, samples of desirable sounds are taken by recording and are used as elementary functions in an additive and/or parameterized approach. Resampling is one of the methods used to adjust the pitch for a given sample. Pitch and envelope are typically controlled separately.

In physical modelling synthesis, physical representations of a musical instrument are used to create sound numerically. This might be a discrete geometrical model with physical properties using numerical methods such as the finite element method (FEM), finite difference method (FDM) or boundary element method (BEM). Alternatives are the above-mentioned source-filter method and the wave-propagation model.

The reader is referred to *Poli* [12.10] for an overview of musical signal representations.

The objective of synthesizing sounds with fidelity or creating sounds of sensation deserves a brief discussion. First, Fig. 12.21 shows – on purpose – the envelope of the nonregular harmonic spectrum of a real instrument. The approximated envelope does not represent the irregularities in the structure. Fluctuations in the tone cause an ever-changing sound texture and the analyzed spectrum changes for every section of sound. Irregularities and fluctuations are well perceivable to listeners and significantly add to the desired senstion of tone.

These, however, ask for additional rule sets or modelling under the synthesis paradigm. Second, the noise floor, or in general the nontonal components in a sound are not yet covered by the sinusoids. Such components must again be modelled separately.

Third, the harmonic spectrum is not as regular as it first appears. The stiffness of strings, for example, causes a frequency shift upwards for higher overtones. This is significant. For example, in the middle register of a piano, the frequency of the 17th harmonic is already a factor of 18 above the fundamental rather than a factor of 17. Such effects again ask for extended modeling.

Fourth, the above-mentioned components and methods are likely to produce sounds where the partials are in a coherent relation to each other. Coherence implies stationary phase conditions between signals. For instance $\cos(\omega t)$ and $\cos(2\omega t)$ are coherent, as are $\cos(\omega t)$ and $\sin(3\omega t)$. Loops or mutually synchronized loops typically produce statically arranged sounds, which are likely to cause only little sensation. Breaking up the coherence again requires additional rule sets.

Finally, digital modelling ignores the impact of impedance. Digital signals can be copied without losing power. This is not possible for analog signals. The source impedance is a major factor for signals under load. For instance, the tone wheel of the Hammond organ carries a sinusoid wave shape and the digital model of it therefore only loops a digitized sinusoid. On the real instrument, however, pressing a key implies that a short-circuit coil will be opened and the induced voltage faces the high impedance of the open-circuit coil at a particular instance, which causes the well-known *dirty* sound attack of the Hammond organ. Modelling a signal by levels, i. e., voltages or currents, is not enough to emulate such effects.

12.5.1 MIDI

In studios, a variety of control signals are used to remotely control devices or to switch signals. Among these control-signal-only formats is the Musical Instrument Digital Interface (MIDI). It does not carry audio signals, but key parameters of sound, such as pitch, onset and dynamics. It was designed to interface musical instruments, in particular synthesizers, but mi-

Table 12.6 MIDI control signals for $n = 0$ to 15 individual channels. Data bytes cover the range 0 to 127 (always headed by 0)

Status + MIDI channel	Data byte 1	Data byte 2	Action	Description
8*n*	*kk*	*vv*	Key off	Stop playing note *kk* apply release velocity *vv*
9*n*	*kk*	*vv*	Key on	Start playing note *kk* apply dynamic level *vv*
A*n*	*kk*	*vv*	Polyphonic aftertouch	Apply dynamic level *vv* to the already played note *kk*
B*n*	*cc*	*vv*	Control change	Change operational Status *cc* of a controller to the value *vv*
C*n*	*pp*		Program change	Assign musical instrument *pp* to channel *n*
D*n*	*vv*		Monophonic aftertouch	Apply dynamic level *vv* to all notes in channel *n*
E*n*	*vv*	*ww*	Pitch bending	Pitchwheel Status set to the value *wwvv* (14 bit)
F0...7	*xx*		System message	Specific control data *xx* for up to eight devices

grated into other applications, such as effects, sampling, fading, panning and even the control of lightshows. Composing, arranging and music writing have taken advantage of the direct back-path from keyboard to music.

MIDI is a serial interface operating at 31 250 bps and using DIN5 connectors. A control command consists of three bytes that need a total of 960 µs for transmission. For example, the three bytes are (i) on- or off-keying, (ii) key/note and (iii) dynamic level (Table 12.6).

Apart from the essential control data for the music to be played, there is a wide range of sound controls specific to the employed devices (B*n* in Table 12.6). Among the 127 mostly predefined commands are the control of the modulation wheel, pedal, portamento, sostenuto, legato, harmonic content, attack time, release time, brightness, stereo balance and effect control, i. e., depth of tremolo, chorus or phaser. MIDI also facilitates synchronization of devices so that several playback devices, synthesizers, keyboards and recording devices can act together. The MIDI clock subdivides each beat of a predefined beats per minute (BPM) into 96 ticks. The limits of MIDI are the control of scales when not tempered and the speed of control. Standard MIDI files (SMF) are indicated by the *.mid or *.kar extension. MIDI may also be captured in RIFF-RMD files with the extension *.rfi or within the Extensible Music Format (XMF). The sample dump standard (SDS) combines MIDI together with linear PCM audio for coordinated playback and synthesis.

Sequencers are, in principle, recording and playback devices for sequences of MIDI control signals, e.g., the complete arrangement of a song. Hardware sequencers are standalone devices with control through front-panel functions and a keyboard. Sometimes a sequencer is already hosted within a keyboard. Software sequencers work on the basis of computers and go beyond programming, recording and playback, since they also employ graphical interfaces for editing and audio sample processing. Such a combination of editing audio and MIDI together is referred to as a digital audio workstation (DAW).

12.6 Historical and Contemporary Audio Formats and Restoration

This section reviews historical audio formats and restoration methods for the study and research of audio archives. Basically, historical formats are analog, while contemporary data formats are digital, as further discussed below. There are, of course a few exceptions to this rule. For instance, at the beginning of the 20th century, piano music by Mahler, Strauss and other composers was recorded using punch cards and these *digital* recordings can still be reproduced on the so-called pianola.

12.6.1 Historical Audio Formats

Wax cylinder, shellac and vinyl records share the same idea of grooving the analog signal into material, a mechanical representation of the signal. Formats and technologies have changed over the course of 100 years (Table 12.7). Admittedly, these formats are not widely used today but they retain their importance due to the heritage of historical recordings.

Recording on steel wires began in 1889 with wires 1 mm thick at a recording speed of $v = 20\,\mathrm{m/s}$. From

Table 12.7 Important historical storage formats

Substrate	Year	Size	Speed	Channel/groove
Wax cylinder	1902–1929	10.5× Ø 5.1 cm	160 rpm	1 Vertical
Shellac	1904–1960	Ø 10″/12″	78 rpm	Vert. or horiz.
Vinyl	Since 1930	Ø 12″	33 1/3 rpm	1 Horizontal
Vinyl	Since 1949	Ø 7″	45 rpm	1 Horizontal
Vinyl	Since 1958	Ø 7″/12″	45/33 1/3 rpm	2 Diagonal 'x'

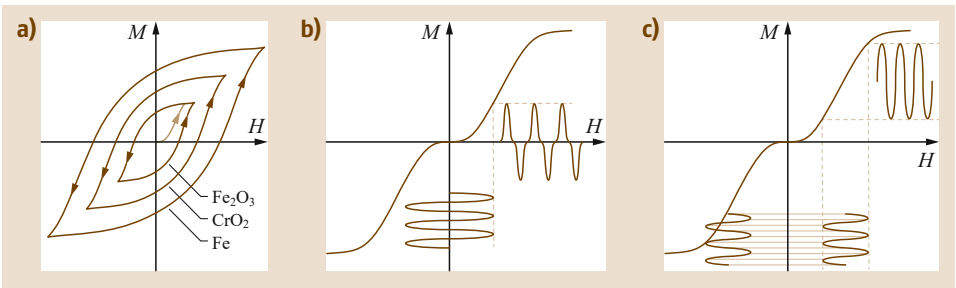

Fig. 12.22 (a) Magnetization M versus magnetic field intensity H for different tape coatings, (b) remanent magnetization M versus magnetic field intensity H and signal modulation, (c) id., but with a biased modulating signal to shift the modulation into the linear region

1930 to 1954 the BBC worked with Poulsen's steel band machine. The 3000 m long steel band was 3 mm wide and 0.08 mm thick. The speed was 1.5 m/s, delivering 4 kHz bandwidth and a dynamic range of 25–30 dB.

Storage of analog signals on magnetic tape promised improved sound quality. However, magnetization implies the problem of nonlinearity. The magnetization of a tape in relation to the magnetic field is nonlinear. The magnetization follows a hysteresis function when excited by a bipolar magnetic field (Fig. 12.22).

Important for the nonlinear effects of recording in combination with playback is the remanence of the magnetic tape. The remanence is the magnetic strength that remains in the tape after releasing the magnetic field (values at $H = 0$ in Fig. 12.22a). An input signal that drives the magnetic field will result in a recorded signal that is distorted due to nonlinearity (Fig. 12.22b). Typically, a third harmonic will develop. To avoid such nonlinearity, a bias signal with a frequency well above the audio frequency band is added to the input signal during recording. The operating range is effectively shifted towards the linear region of the remanence curve (Fig. 12.22c). Nonlinearity cannot be fully avoided but a properly adjusted bias can reduce the distortion factor significantly. Adjusting the bias for minimum distortion, however, reduces the output signal during playback and so the achievable dynamic range, especially for higher frequencies of the audio signal. Therefore, a sound engineer in those days had to compromise between a high dynamic range and low distortion. For this purpose, professional recording systems facilitated manual control of the bias amplitude.

The high-frequency content of an audio signal already has a similar effect to the bias signal and the two work together in terms of an effective bias. On the other hand, high-frequency components of an audio signal suffer from too much bias. The HX Pro System was one of the approaches to adjust the necessary bias in relation to the recorded input signal. Another important impact factor to bias adjustment is the type and the quality of the tape used. Professional recording machines can measure the necessary bias. In summary, analog tape recordings reveal individual quality in terms of dynamic range and distortion.

Magnetic tape playback suffers from several losses. First, the air gap between the tape and playback head is approximately 1 µm. The physical size of one wave of a 15 kHz signal recorded on a tape at $v = 4.75$ cm/s is only 3.17 µm. An air gap of 3 µm would dampen the signal by roughly 50 dB. Second, the size of the gap in the playback head will define losses. The damping follows a $\sin(x)/x$ curve with the zeros at multiples of b_{eff}/λ, where b_{eff} = effective head gap, λ = geometric size of the wavelength on the tape, typically 2.5–12 µm in the recording head and 1.5–6 µm in the playback head for professional systems. Third, a mismatched position or angle of the head gap will introduce further losses. Therefore, working with old recordings may require adjustments on the playback head. Fourth, tapes are rolled on a reel and the tape sections that are layered upon each other will mutually magnetize each other. The resulting pre- and postecho can be heard. This copy effect depends on the frequency and is strongest for frequencies at about 400–1000 Hz. Mag-

netic density grows with frequency therefore the copy effect also grows with frequency. However, the distance between the layers in relation to the physical size of a recorded wavelength raises with frequency and therefore the copy effect again declines with higher frequencies.

Playback of tapes of unknown origin implies further uncertainties. Usually, high-frequency components are amplified for recording up to +20 dB. Such pre-emphasis and the complementary de-emphasis during playback should match each other. However, the pre-emphasis selection is subject to the tape quality and the tape speed v, according to different standards, and it will be aligned to an assumed amplitude statistics of the input signal (Table 12.9). As there are different filter time constants defined for de-emphasis, there should be clarity about the tape type used and the standard followed during recording to match the de-emphasis. The often used dynamic compressor Dolby B is yet another recording feature that adds uncertainty since it asks for complementary expansion during playback. In summary, without knowledge of the specific recording parameters, the playback may differ from the intended recording in terms of spectral balance and dynamic.

There are tapes from 1/4 to 2 in width for tape speeds v from 1.875 to 30 in/s (Tables 12.8 and 12.9).

Table 12.8 Magnetic tape widths and track numbers

Tape	Tracks
Compact cassette 3.81 mm	Consumer: 2 plus 2 (reverse) Philips: 1 plus 1 for timecode Tascam: 2 plus 1 for timecode /4/8
1/4″	1 track NAB: 2/2 plus 1 for timecode DIN: 2 4
1/2″	2/4/8
1″	4/8
2″	16/24

Table 12.9 Tape speeds and time constants for bias modulation

Tape speed v	Standard	τ (µs) treble	τ (µs) bass
15 in/s	NAB	50	3180
38.1 cm/s	DIN	35	–
7.5 in/s	NAB	50	3180
19.05 cm/s	DIN	70	–
3.75 in/s	NAB	90	3180
9.53 cm/s	DIN	90	3180
1.875 in/s	DIN (Fe_2O_3)	120	3180
4.75 cm/s	DIN (CrO_2)	70	3180

In the 1980s digital audio tape (DAT) formats were also used. R-DAT is based on video recorders with rotating heads, with the following operating modes:

1. 2 channels 16-bit linear at 48 kHz sampling rate
2. 2 channels 16-bit linear at 32 kHz
3. 12-bit nonlinear at 32 kHz
4. 4 channels 12-bit nonlinear at 32 kHz
5. 2 channels 16-bit linear at 44.1 kHz playback only.

The format extensions DA-88 and ADAT facilitate 8-channel recording. The parity protected 30 ms frames host supplementary data such as search IDs. S-DAT stands for digital audio recording with stationary heads. The digital compact casette (DCC) is the consumer format and is based on the compact cassette at $v = 1.875$ in/s. It uses MPEG 1 coding to reduce the linear 16-bit/48 kHz format down to 384 kbps for two channels. The tape hosts 8 channels plus 1 supplementary data channel, and another 8 plus 1 channels in the reverse direction. The professional extensions digital audio stationary head (DASH) and ProDigi work at high tape speeds to record 2 to 64 linear channels on 1/4, 1/2 and 1 in tapes. The data format works with interleaving and channel coding, so that the digital tapes can be manually edited in the same way as analog tapes.

12.6.2 Restoration

Restoration may be necessary when working with historical recordings. The reasons for derogated sound quality are damaged media, unprofessional storage or limitations or problems with the recording or playback equipment. This section gives a brief overview of typical problems and methods, although practical work in this field is usually assigned to professionals. Workbenches or software packages for restoration are often based on audio workbenches and comprise manual or automatic detection of distorted signals and tools for repair. A monitoring function allows control of the restored signals but also of discarded components to ensure that not too much of the desired sound gets lost.

The analysis identifies the type and duration of impairments, e.g., noise, tonal components, transients or typical background noise. Noise originating from the signal chain or the medium can be spectrally analyzed and a predicted spectrum will be subtracted from the signal. Passages of silence allow extraction of a fingerprint of the noise, which is more precise than a prediction. Subtraction always affects the sound, and there are specific denoisers for speech and for music. The typical downside of denoising is a loss of brilliance. Artefacts such as ringing or tonal components can be avoided by carefully selecting thresholds and parameters.

Scratches, clicks and cracks are classified by level and duration. Scratches have a large impulse level and are several milliseconds long in duration. They result, for instance, from mechanical damage on cylinders, shellac or vinyl. Noise from dust in the grooves of these media can be reduced by wet playback. Clicks are of lower level and shorter in duration. Crackles have low levels but come at a high rate. Impulse shapes are already characterized for common problems and can be automatically identified. Descratchers, declickers and decrackers cut out the disturbing impulse and restore the resulting gap by interpolation, polynomial fit or using the B-spline method.

Pop noise resulting from close-up speech or singing is often simply reduced by high-pass filtering. Clipping artefacts may result from poor input adjustment and a declipper will restore the waveform by lowering the level and interpolating the impacted section. Overemphasized voiced dental fricatives or sibilant noise are reduced by a de-esser which consists of an amplifier in parallel with a limiter, where the threshold and frequency can be adjusted.

The power supply often causes noise in amplifiers and recording equipment. Poor ground loops cause humming and power dimmers cause buzzing. A debuzzer will employ comb filters to reduce the tonal components of 50 or 60 Hz supply systems and respective multiples of these frequency components.

Tape-recording azimuth errors are caused when the recording head and the playback head are not well aligned to each other. Such differences on the order of tens to hundreds of microseconds between tracks adversely affect the stereo image and the treble range. These differences can be analyzed by correlation. Modern deazimuth tools can even detect differences as low as a small fraction of one sample and can compensate for the difference by internal oversampling. Preferably, the mismatched alignment is compensated for during playback by individually adapted adjustment of playback heads, even if the setting is abnormal.

Temporary dropouts may result from erosion of the magnetic coat on a tape, from kinks or from poor splicing. Such impairment will be compensated for by manual levelling.

12.6.3 Contemporary Digital Formats

Contemporary digital formats for storage on hard disc, optical disc or flash memory are strongly related to specific coding technologies. The overwiev of these is organized along three issues: audio quality, data type and data embedding. In terms of quality, coding reduces the necessary storage volume and is likely to reduce the sound quality as well. Second, there are different types of formats, such as raw sound data, sound data with fully embedded description for archives and formats for streaming or broadcast. Third, there are container formats that link between several audio components or between audio, video, presentations and project data. Other context formats are, for instance, proprietary formats to capture sessions in specific production environments.

To begin with the first issue, sound quality in digital formats, the prominent parameters to mention are the word size and sampling rate. As outlined above, each bit contributes to potentially 6 dB dynamic range. Linear data formats, or linear pulse code modulation (PCM), hold such data sample by sample. These formats can be edited sample-wise. Linear PCM is often hosted in WAV files and it is also the format of the compact disc. Lossless coding reduces the data rate with virtually no loss of audio quality. Only some procedures use calculations that ask for rounding, which is equal to introducing an additional quantization step, including quantization noise. An example of lossless coding is the predictive coding that uses signal differentiation, complemented by signal integration in the decoder. The format is called differential PCM (DPCM). A derivative of this method additionally adapts differentiaton increments to the type of input signal and is called adaptive DPCM (ADPCM) (ITU-T G.726) [12.11]. Another example is redundancy reduction by entropy, or variable-length coding, e.g., Huffman coding. The word size is not fixed, but varies with the probability of occurrence. Frequently appearing values are coded by short words, effectively reducing the data volume. Examples of respective formats are Free Lossless Audio Codec (FLAC), Apple lossless, Windows Media Audio Lossless and MPEG4-ALS.

Lossy coding discards components that seem irrelevant to human listening. Decoded data will therefore reveal technically observable differences to the original audio sample, but hopefully no perceptual differences. While the linear format captures the dynamic range according to the word size across the entire band from 0 Hz to half of the sampling rate, human listening is limited and the dynamic range depends on frequency. Figure 12.23 indicates the threshold of human listening according to ISO R226 [12.12]. The word size can be reduced for a wide range of frequency bands because the quantization noise cannot be heard. Furthermore, pure tones in a signal mask spectrally adjacent bands (Fig. 12.23, lines). In these adjacent bands, the word size can be even further reduced. Additionally, there are dynamical masking effects in the range of 10 to 20 ms that encourage segment-wise scaling of segments. Scaling is equivalent to achieving full-scale levelling for each segment, effectively reducing quantization noise.

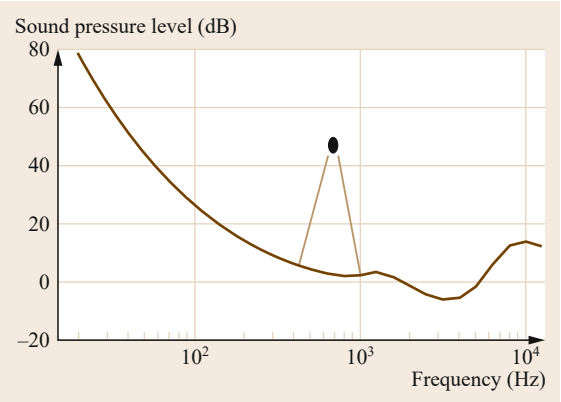

Fig. 12.23 Hearing threshold according to ISO R226:2003 (*brown*) and masking effect (*yellow*) of a pure tone (*black dot*)

Of course, such scaling will be reversed in the decoder. To facilitate word size reduction in spectral bands, the input signal is segmented into 32 (MPEG-1 layer 1) or 576 (MPEG-1 layer 3) bands by filter banks. These processing steps are supplemented by nonlinear quantization (dynamic compression), reducing the redundancy between stereo channels and final Huffman coding.

AAC and AC-3 coding follow the same method of tolerating psychoacoustically irrelevant quantization noise to minimize data volume. Instead of a filter bank, the discrete cosine transformation (DCT) is used, the spectral resolution of which will be dynamically matched to the input audio characteristics. Additional features of AC-3 coding are: dithering, spectral band expansion, karaoke mode and more. HE-ACC (or ACC+) and HE-ACC v2 (or ACC+ v2) use spectral band replication (SBR) to achieve very low data rates, namely 32 to 80 kbps and 16 to 40 kbps, respectively. Instead of encoding all tonal components of a sound, only tonal components of low frequency are encoded plus a rule set on how the tonal components of high frequency can be replicated from the encoded components.

The digital theatre system (DTS) format is defined for use in cinemas and home theatres. The code comes along with a timecode to allow for synchronization with the film, even when played from a separate CD or DVD player. The advanced DTS-HD can host linear lossless formats of 5.1 channels at 192 kHz or 7.1 at 96 kHz, with data rates up to 24 Mbps.

The second issue is the type of format. Basically, there are formats that are composed in a way to facilitate the sharing or archiving of audio data, and formats that facilitate broadcasting or streaming. Formats for data sharing and archiving typically embed associated metadata and only limited means of error protection. The amount of embedded metadata and the size of the data file are limited in some formats. Streaming formats follow the idea of an endless stream. They are equipped with powerful error correction, or channel coding, to facilitate forward-error correction (FEC) upon reception over long-distances and transport over channels of vague transmission quality. Often, the streaming formats are able to host more than just one stereo stream or just one 5.1 audio stream. They might contain an entire program of a broadcaster. Finally, metadata is usually not part of the stream but rather linked to the stream and hosted in separate files, or separate streams. The audio data stream, however, will embed enough supplementary information on a regular basis to allow a decoder to jump in at any time and start its decoding process after a negligible initialization period. Examples of audio streaming formats are briefly summarized in Table 12.10, audio file formats are listed in Table 12.11.

In terms of sharing or archiving audio data, many audio file formats emerged from the 1985 Interchange File Format (IFF) and the later Resource Interchange

Table 12.10 Digital audio streaming formats

Format	File extension	Coding	Audio channel	Sample rates (kHz)	Bit rates (kbps)	Channel coding
MPEG-1	.mpeg .mpg	MPEG-1 layer 1	1–2	32/44.1/48	Fixed 32 . . . 448

Table 12.11 Digital audio file formats

Format	File extension	Coding	Application
WAVE	.wav	Linear PCM, DPCM	Studio, consumer
BWF	.wav	Linear PCM, MPEG plus metadata	Studio, broadcast
RF64	.wav	Linear PCM plus metadata	Studio, broadcast
AVI	.avi	Diverse audio and video codecs	Consumer, studio
AIFF	.aiff .aifc .afc	Linear PCM	Studio

File Format (RIFF). The common idea is that a preceding header provides information about the type of data (audio, video, pictures or text), then about the format, and then details of the data, which follows in a larger data field. The widely-used WAVE format is a specific RIFF format. It holds linear PCM but sometimes also DPCM and is limited to 4 GB of data.

The Broadcast Wave Format (BWF) was developed for exchange between broadcasters. The format identifies the production and informs about the digital rights of use. Extensions and supplements of this format now facilitate the recording of a coding history together with the data, but also the linking of formats for concatenating files of limited size. RF64 is a standardized format to overcome the limitation of 4 GB [12.13]. RF64 is not limited to just one audio mix and just PCM coding. It may host up to 18 channels and non-PCM coded data. Audio Video Interleaved (AVI) is also a specific RIFF format, but seldom used for just audio alone. The Audio Interchange File Format (AIFF) Is based on IFF and only admits linear PCM, while the extension AIFF-C also admits lossy coding. It also features the support of markers, loop-identifiers, MIDI-data and commentary for handy editing tasks.

The third issue is the scope of the data format and how data is embeded. The formats described above all have in common that they describe one single presentation, independent of the type – file or stream – even if they are already composed of audio and video and other content. So-called container formats not only host media of different type but also independent presentations, supplementary timecodes, structural data, text and markers. Container formats more easily link to existing technology platforms, such as players or audio production environments, and facilitate compatibility, see Table 12.12.

Quicktime, introduced by Apple in 1991, was one of the earliest formats. The package includes the data format and the encoder, but also the player, authoring and streaming technology. It is hierarchically organized to facilitate any desired link between granular data entities. The encoding of Quicktime 7 supports linear PCM, MP3, AAC, ADPCM and Apple lossless.

MPEG-4 is based on Quicktime but follows an object-oriented approach to govern independent or synchronized streams of media, or to conduct media syntheses or content analyses. The associated Delivery Multimedia Integration Framework (DMIF) covers the channel coding and other transport issues for broadcast or streaming, so there is a modular approach for the tasks of data organization and of transport. MPEG-4 audio supports ACC coding with options for low delay and spectral band replication as well as for parametric stereo to further compress data (HE-AACv2). With parametric stereo, the redundancy between channels is analyzed and modelled. Determined model parameters will conduct the resynthesis of the stereo image for the incoming audio data. Synthesis is supported by the codefined Structured Audio Orchestra Language (SAOL), the Structured Audio Sample Bank Format (ASBF) and a text-to-speech algorithm. Data streams and synthesized entities together compose a complex scene, for instance for films, in a compact way while still keeping the individual entities apart and controllable during play.

Open Media Framework Interchange (OMF or OMFI) is a proprietary format and widely used in post-

Table 12.12 Digital audio container formats

Format	File extension	Objects	Application
Quicktime	.mov .qt	Multimedia	Consumer
MPEG-4	.mp4	Multimedia	Consumer
MPEG-4 Audio	.m4a .m4b .m4p	ACC audio	Consumer

OpenMg	.oma .omg	ATRAC audio, DRM	Consumer

production environments by AVID and Digidesign. The further evolved Advanced Authoring Format (AAF) and Material Exchange Format (MXF) target the interchange of data for video production. The AES31 format extends the features towards production issues even further. Examples are track numbers, cuts and overlays, or control information for automation.

Windows Media Audio (WMA) covers a family of audio encoders and describes file and stream properties, content description and marker objects. Real Media came as a platform covering format, encoding, streaming server and media-client technology; it was widely used between 1995 and 2000. OGG is an open-source format specified in RFC3533, capsuling audio, video and text. Likewise, Matroska is an open-source format. OpenMG is proprietary and supports digital rights management (DRM) and encryption. SDIF was defined for composition, production and research. There are descriptors for pitch, energy, spectral coefficients, envelopes, synthesis. It supports matrices and the choice between fixed and floating-point numbers. Entities are IFF-like organized together with time-tags to guarantee synchronicity.

12.7 Signals, Connectors, Cables and Audio Networks

The transport of audio signals between devices in a production chain has its own history and complexity. First of all, there are usually control signals and also supply signals next to or superimposed to the audio signals for remote operation. The benefits, but also the problems, of using as few cables as possible created a variety of technical solutions. Additionally, the analog audio signal is more and more replaced by digital signals on a variety of alternative copper or fiber links, with a strong trend towards Internet Protocol (IP) technology.

12.7.1 Cables, Fibers, and Wireless Local Connections

The physical link has an impact on the forwarded signal. A cable is, physically speaking, a circuit of a spatially expanded capacity and a likewise expanded inductance. Therefore, cables have intrinsic impedance that depends on frequency. The spectral deficiencies of cables usually do not emerge due to the low frequency of audio.

However, cables are susceptible to external noise and distortion. Any electromagnetic field in close proximity will induce currents that will be superimposed on the wanted audio signal. Sources of distortion are radio broadcast, mobile devices, power transformers, switched electrical loads or local thunderbolts. Twisted cables are more robust against such unwanted electromagnetic interference (EMI) than parallel cables, since the twist flips the orientation of the wire pair within a given electromagnetic field and therefore flips the polarity of induced levels every few inches along the cable. A homogenous twist will therefore compensate locally.

Shielding is another protective measure. The braids usually applied around the signal wires protect against the electrical component, but not against the magnetic component of a field. Protection against the electrical field is only in effect if the braid is properly terminated by grounding. Grounding, in almost all examples of studio technology, is a simple low-impedance connection between the cable shielding and local ground. Broadband shielding requires a termination resistance that matches the impedance of the shielding, otherwise most of the signal energy will be reflected at the point of termination and will remain on the shielding, where it feeds back to the wires.

Symmetric signals are another means of protection. For any audio signal to be transmitted, its polarity-reversed representation will be generated, either by high-quality transformers or by differential amplifiers. The symmetric pair of signals will be transmitted and in the receiver the difference of these signals will bring about the audio signal and at the same time suppress the common-mode signals resulting from external distortion. Efficient common-mode suppression requires low-impedance drivers and high-impedance receivers to reach 30–40 dB in standard technology and it additionally requires adaptive circuits to reach 100 dB in professional equipment.

Digitalization aggravates distortion artefacts, because time-discrete sampling potentially shifts high-frequency distortion into the audible band. The principle of spectrally periodic perpetuation not only applies to the wanted audio component in a signal but also to all components irrespective of their spectral origin (Figs. 12.15 and 12.16). So even if the monitoring of an arriving analog audio signal seems to be fine, originally nonaudible components will be contained in the digital representation after sampling. The antialiasing filter will only attenuate such distortion for high frequencies. Digitalization therefore asks for awareness of potential sources of distortion, especially in the frequency range of 20–150 kHz, which is well within the operating range of professional audio preamps, and in which the antialiasing filter does not have a strong attenuation.

Digital signal transmission on cables is less susceptive to distortion. However, noise always causes some

residual bit errors. In local installations the bit error rate (BER) is typically between 10^{-12} and 10^{-8}. This seems small, but on a gigabit Ethernet connection with BER $= 10^{-9}$ this is equivalent to one bit error every second. Channel coding technologies allow for compensation to achieve quasi-error-free (QEF) transmission. However, coding implies significant delay and contradicts requirements of real-time applications.

Optical fibers are not susceptible to electromagnetic interference, but to damping. Glass fibers only have about 1 dB attenuation per km and 1 dB loss per connector, but they are not practical in nonstationary environments. For instance, the popular 50/125 micron multimode fibers (50 µm core with 125 µm cladding) are used in MAD optical, but also in LAN computer networks (Sect. 12.7.9). Polymer optical fibers (POF) are more practical in nonstationary and in rugged environments and are used in semiprofessional applications, but they have a considerable attenuation of about 0.2 dB/m. They are typically not used across a building or between buildings. For an overview on copper and optical links see [12.14].

FM-modulated radio links in the ultra high frequency (UHF) band (300–3000 MHz) have been popular for a long time to connect microphones with a mixing console. The typically used frequency range of 790–814 MHz is now dedicated to LTE networks and cannot be used anymore. Frequency reallocations within the broadcast market and rededication of bandwidth from broadcast to mobile communications are heterogeneous across Europe. This reorganization will last beyond 2017. Wireless applications will eventually relocate into diverse gaps. A license-less band across Europe is defined at 863–865 MHz, while the wider bands in the former TV channels 61–63 and 67–69 for professional users ask for licenses. At the same time, the wireless link for microphones has become digital. For instance, some microphones now use modern digital modulation techniques, such as frequency-hopping spread spectrum, and these operate in the unlicensed 2.4 and 6 GHz bands.

12.7.2 Signals and Grounding

Analog audio signals are referenced to a specific level to be compatible between components. Power adjustments refer to 0 dBm, which is 1 mW power or 0.775 V at an impedance of 600 Ω. The commonly used voltage reference reuses the 0.775 V level to define 0 dBu. The so-called line level of inputs and outputs is usually defined at 0 dB = +4 dBu = 1.23 V, or at +6 dBu = 1.55 V.

The phantom supply for microphones and external equipment is symmetrically fed into the signal wire pair and is defined at 48 V (Fig. 12.24).

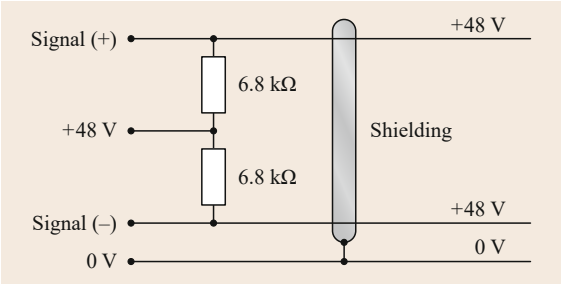

Fig. 12.24 Phantom supply to remote microphones and devices

Digital signal levels are defined by the respective standards of the corresponding digital links, such as Ethernet and others.

An example of such external equipment is the direct injection box (DI-box). These are widely used to convert asymmetric signals, such as those from a guitar pickup, into symmetrical signals (Fig. 12.25). If this conversion is done by differential amplifiers, an extra power supply is required and is conveniently cotransmitted on the symmetrical line that links with the mixing console. DI boxes also address the problem of grounding. The quality of grounding depends on matching impedances and the thoughtful selection of a sparse set of grounding points to avoid ground loops. Loops of grounded shielding should be prevented since the area enclosed in such loops relates to the level of immission. Star configurations have no such enclosed area, but a central grounding point. Therefore, the option of omitting the grounding in DI boxes is helpful in practice.

12.7.3 Digital Connections

In terms of digital connections, there is a wide variety of technical solutions. Some systems target studio-only applications, basically replacing signal lines by digital lines. Some systems target digital workflows and transmissions beyond a studio. Some systems are open and flexible to allow for optional replacements of modules; some proprietary systems are not.

12.7.4 The OSI Model

The open standard interconnection (OSI) structure for communications is useful to understand the scope and potential of solutions. The reader is briefly introduced to its seven layers. The physical layer represents the physics of transmission, which covers cables, antennas, fibers, modulation, connectors and clock regeneration. It works on a bit level, without any comprehension of meaning. The data link layer works with frames or

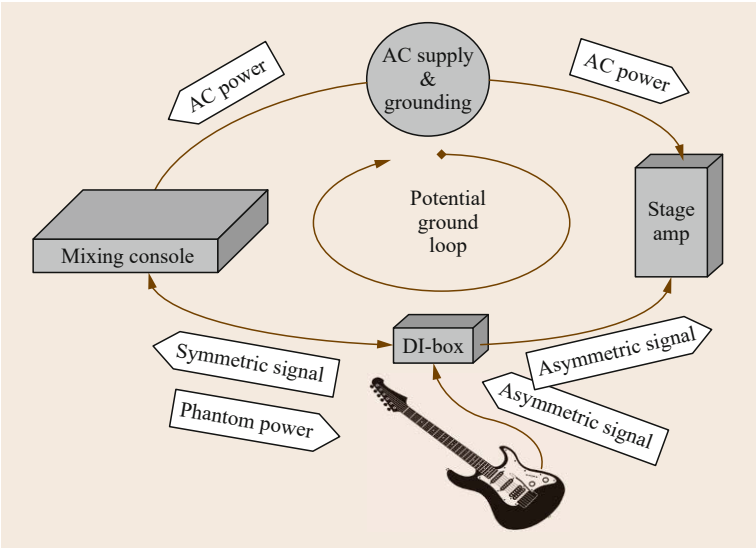

Fig. 12.25 DI-box application and potential ground loop

blocks of data ensuring the proper delivery between two connected points. This implies the error-detection or error-correction, flow control, monitoring of sequences of frames and losses. On this layer, a lost or erroneous frame might be automatically repeated by request (ARQ) which raises the matters of memory in the transmission device, and of delay introduced by the retransmission and its protocol.

The network layer is responsible for establishing the route across the multitude of point-to-point connections within smaller networks but also across the world. In the world of connected computers, or productivity, this is called routing, while in telecommunications it is called circuit switching. In broadcast, data sinks and sources are rather stationary and the routes are still kind of hard wired by installation. The transport layer covers issues of quality of service (QoS) while restoring sequences, managing alternative routes and fees. The session layer might link more than two parties together. It organizes transmission jobs over time and quarantine services in case of absence. Data sharing is organized in larger segments and associated protocols silently ensure reasonable connectivity in times of temporary disconnections.

The presentation layer covers everything concerning the meaning or presentation of data, such as the form factor, data compression, encryption and keyboard mapping. In terms of audio, the form factor answers the question of audio channels involved and the type of data and stream (Tables 12.10 and 12.11). The application layer is not the application software but the entity that manages resources in a system, such as memory and I/O entities. It handles rights of access, data constancy, and operational tasks, such as remote jobs or data bank services.

Table 12.13 shows the layers and the well-established protocols associated with these layers. Clearly, digital workflows in modern audio productions demand professional and seamless systems at all levels.

12.7.5 Stereo Digital Audio Links

In 1985 the AES3 standard evolved on the basis of Sony's SDIF link. The family of two-channel standards

Table 12.13 OSI layered communication model and well-established protocols

based on AES3 is ANSI S4,40, EBU Tech. 325-E, ITU-R BS.64, BS 7239, DIN 60958 and IAJ CP-120 [12.15]. They have differential, symmetrical signal transmission at 2–7 V level on 110 Ω shielded cables with XLR connectors in common. One of the differences is that the EBU standard asks for galvanic isolation with the help of transformers. The physical layer therefore specifically defines levels for digital transmission while reusing existing cables and connectors. The data link layer is also specific. Blocks of 192 frames are transmitted in a specifically defined structure (Fig. 12.26). The data frame structure and data rate directly correspond to transmitting uncompressed native audio in linear PCM format. Data rate R and sampling rate f_s are therefore strictly related: $R = f_s\, C\, 32$, for the number of channels C. The use of auxiliary bits and interpretation of amended check bits vary from standard to standard.

Extensions and variations to this standard relate to the evolution of supplementary control signals and to migration into other applications. For instance, AES18 facilitates the user bit to carry radio data system (RDS) data or MIDI signals organized in frames of 192 bits under control of the widely applied HDLC protocol. AES3-id promoted 75 Ω coax cables and video-compatible signal levels to migrate into video applications. While IEC 60958 Type I (professional) is fully compatible with AES3, IEC 60958 Type II is the consumer version known as S/PDIF which differs in terms of electrical specifications and the use of amended check bits. This widely applied digital interface uses 0.5 V on 75 Ω cables and cinch connectors. TOSLink or S/PDIF optical work on plastic optical fibers (POF) at maximum distances of 10 m, while using the same data frame. AES3 family links are also used to transmit multichannel compressed audio instead of uncompressed stereo, following IEC 61937. SDIF-2 and SDIF-3 use separate links for two channels and for the system clock. These are not derivatives of AES3.

12.7.6 Multichannel Digital Audio Links

The multichannel audio digital interface (MADI) is specified in AES10 [12.16]. It reuses the AES3 subframe structure for individual channels but organizes 56 or 64 of these within each MADI frame to transport 64 audio channels at $f_s = 48$ kHz, or 32 audio channels at $f_s = 96$ kHz, with 16, 20, or 24 bit word size. The resulting data rate of $R = 125$ Mbps restricts the MADI coax to quite narrow electrical specifications to facilitate links of up to 50 m. MADI optical works on 50 µm glass fibers to bridge up to 2000 m.

There is a variety of proprietary digital serial and parallel links to carry multichannel audio. The ADAT lightpipe (ODI), Mitsubishi digital interface (PD, ProDigi), Roland R-bus, and Tascam digital interface TDIF-2 are merely specified to link multichannel recording equipment over short links.

Multichannel audio can also be embedded within video signals. The serial digital interface (SDI) and HD-SDI take up to 16 channels that are organized in the vertical blanking interval of the video signal while using the same AES3 subframe format.

12.7.7 High-Speed Digital General Purpose Links

Another class of links is distinguished by a high data rate, by support of various formats of video and audio, by connecting many systems and by synchronous transmission capability.

The IEEE Firewire interface connects up to 63 devices at data rates of 400, 800, 1600 or 3200 Mbps [12.17]. Links are physically limited to a few meters, suggesting usage within racks. Only low data rates would allow usage across a studio. With its synchronous transmission mode, Firewire can serve as a digital signal line for audio or video. While i.Link is

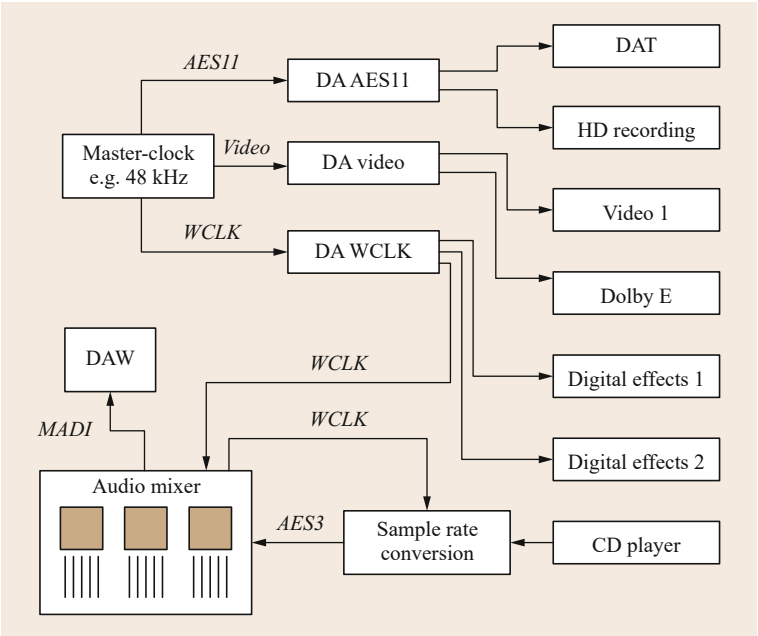

Fig. 12.27 Word clock distribution in a professional production environment with video components. Only clock signals are shown (no video or audio signals). Two concepts are combined: distribution by DA, and daisy chaining from device to device

Firewire plus Sony's video transport layer, mLAN is Firewire plus Yamaha's audio transport layer. The related audio and music transmission protocol supports 16 channels of 96 kHz audio at 24 bit word size, as well as compressed formats and metadata. Devices with mLAN connectivity require Firewire ports with an open host controller interface (OHCI).

The high-definition multimedia interface (HDMI) is a general purpose video and audio link that allows synchronous transmission between devices. It transports a wide range of compressed and uncompressed video and audio formats. In terms of audio links, it can host 8 channels at 192 kHz at 24-bit word size, or 8 channels SACD. HDMI can carry streams such as MPEG or other digital video broadcast (DVB) streams. It is preferably employed in presentation context rather than in production environments.

In summary, the AES3 family and the other families of audio links have similar data link layers that are combined with a variety of physical layers. From the OSI perspective, the data link layer and the presentation layer are unfavorably related with each other, since the data rate is directly derived from the sampling rate. Such strict relation between link and presentation is unusual in data networks. Furthermore, transport, routing and session layers are not specified for any of the mentioned AES3 family members. The transport layer is only marginally defined in an application-specific way for HDMI and Firewire. The OSI perspective makes it clear that these digital links are much more signal line replacements than general purpose data connections.

12.7.8 Synchronization

Mixing consoles, recording equipment, analog-to-digital (ADU) converters and digital effects must be synchronized to the same sampling frequency not only nominally, but also physically. With only the nominal accuracy of a quartz crystal in the range of ± 300 ppm, the systems would gradually drift apart and sampled words would get lost. Such coherent operation is mandatory in live performance, live broadcast and recording. In order to synchronize studio equipment, there are several types of clock sources and concepts. A professional clock source is a device that also generates a timecode and that may even be linked with a global time domain, such as DCF77 or GPS. In video productions, video black & burst is a preferred clock source that is derived from the video line frequency and image frequency.

Conceptually, if only a few components are to be synchronized, the ADU might be used for direct control of the mixing console and the recording device if the three components are not already integrated within one audio workbench (AWB). Professional productions have a wider scope in terms of functionality and workflow and require a synchronization strategy for each production. Figure 12.27 illustrates an example using both the concepts of word clock distribution amplifiers (DA) and word clock daisy chaining, while employing different formats at the same time, AES11, video format and an explicit word clock format.

12.7.9 Ethernet and IP-Based Links

Postproduction and playback do not require the coherent operation of systems, since the recording/production and the consumption are not committed to the same progression of time. Audio can be played back, listened to and processed without any problem if the presentation rate slightly deviates from the original sample rate of the recoding session. Second, parallel workflows encourage file sharing, rather than sharing of signals. Third, multisite productions and broadcast encourage the use of established data networks. These three reasons drive the use of IP-based links in audio production.

Employing general data network technology in audio implies both inheriting the mass market advantage but also the QoS limitations. Data packet networks work on the basis of probabilistic access, where the availability might be high but the latency times and loss rates are typically high as well. Capacity is not guaranteed in data networks. This is one of the reasons why some systems reuse parts of the general data network technology but still define a specific data link or transport layer to follow the concept of signal distribution with defined QoS. These systems take advantage of economies of scale while reusing Ethernet technology.

AudioRail reuses the physical layer of Ethernet and a specific link protocol to host 32 channels at 48 kHz or 16 channels at 92 kHz sampling rate, with 24-bit word size. It only carries native audio data but not any supplementary control data or MIDI.

Rocknet is another proprietary system that uses the Ethernet physical layer, however with XLR connectors. It supports up to 160 channels at 48 kHz and at 24 bits word size over a single CAT-5 cable. Additionally, the devices support redundant cabling and redundant power supply.

Cobranet reuses both, Ethernet's physical and data link layer. The proprietary protocol specified on top of this facilitates unicast and broadcast transmissions of up to 64 channels. Cobranet facilitates sample clock extraction from data. MIDI and control data can be transmitted together with the audio data, for instance for remote control tasks.

Ethersound also reuses an Ethernet physical layer and data frame. It is organized as a strict synchronous network with fixed capacities for 64 channels at 48 kHz or 16 channels at 192 kHz. Likewise, Ethersound has no potential of carrying general purpose data together with the audio data.

Dante differs from the three Ethernet-based systems in that it works on top of the network layer. It works on any IP based system and can be switched across wider networks. Audio traffic can be mixed with other traffic, but this must be operationally managed in terms of performance. Latency is in the sub-ms range and deterministic, because Dante uses voice over IP (VoIP) QoS, which is already provided in modern switches. WLAN is not recommended, and typically, IP will locally operate on top of Ethernet.

Ravenna, like Dante, works on top of the IP protocol. So while in most cases of local area networks Ethernet will be the option of choice, Ravenna is not so restricted. It can be established together with already existing IP networks in a building, and it even works across wide-area networks (WAN). Quality of service must be cared for by statistics in operation and maintenance. This is possible since today's routing IP devices support traffic shaping and traffic-specific control of QoS.

Ravenna directly supports AES3 subframes, but also any other format, such as a 32-bit floating point. It also provides synchronization across devices through the [12.18]. Precision Time Protocol (PTPv2) is a separate protocol devoted for real-time IP traffic. PTPv2 provides means for synchronizing local clocks to a precision in the lower nanoseconds range provided that all participating switches natively support PTPv2.

The European Broadcasting Union promotes a general approach of audio over IP (AoIP). The framework is defined by EBU Tech 3326 [12.19] and recommends

jitter buffering, FEC and error concealment to compensate for the unpredictable QoS in unmanaged IP networks. For a tutorial see EBU Tech 3329 [12.20].

The OSI perspective finally allows one to distinguish between classes of systems. Table 12.14 gives an overview of the structured layers. Without specifications for layers 5 to 7, all of these systems come without session management, coding for presentation or format, access rights management, digital rights management (DRM) or data consistency management. Future systems will incorporate these aspects to facilitate seamless workflows between live performance/recording, postproduction and distribution/broadcast.

12.7.10 Connectors

Connectors form part of the physical layer, since they codetermine the mounted type and amount does of wires or fibers. The identified connector not always directly determine the type of link associated with it, because widely spread connectors have been reused for other links. For instance XLR, the classical microphone connector, is also used for the digital AES/EBU link (Fig. 12.28 for an overview).

Figure 12.29 sketches the popular 3-pin XLR (XLR-3) connector and its pinning. The XLR-5 connectors carry stereo signals (Canon's X-series latched connectors (XL), with resilient connector filling (XLR)).

12.8 Loudspeakers, Reference Listening and Reinforcement

The fidelity of sound reproduction is defined by the quality of speakers, while the quality of the spaciousness and envelopment is defined by the speaker arrangement within a given room and the match of this arrangement with the underlying principle of the microphone arrangement used.

12.8.1 Loudspeakers

Similar to microphones, there are various principles of conversion. First, classical electrodynamics is used in speakers to convert electrical signals into mechanical displacement, or to sound. A current-carrying coil within a magnetic field $\boldsymbol{B}$ will experience the Lorentz force

$$\boldsymbol{F} = I\,(\boldsymbol{l} \times \boldsymbol{B}) \qquad (12.13)$$

given the length $\boldsymbol{l}$ of the coil-wire. In speakers, the coil is conducted in a gap of a strong magnetic field such that the effect is maximized and that the coil experiences a degree of freedom in the direction of force. This force will cause displacement of the coil, which in return drives a membrane. Large displacements are possible, which is of particular importance for low frequencies. However, large displacements also constitute

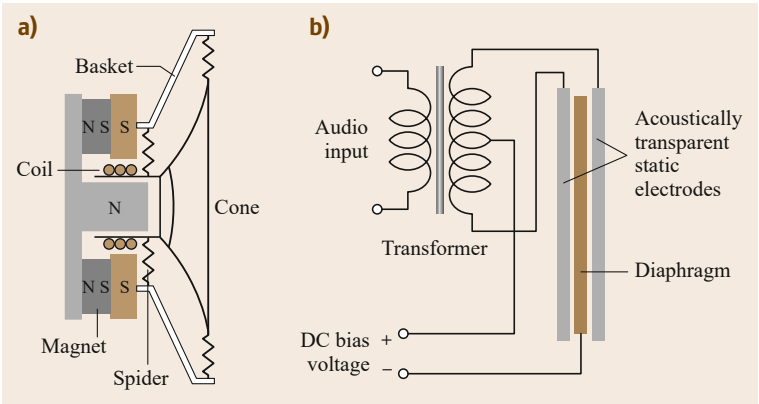

Fig. 12.30a,b Operational principle of **(a)** electrodynamic and **(b)** electrostatic speakers

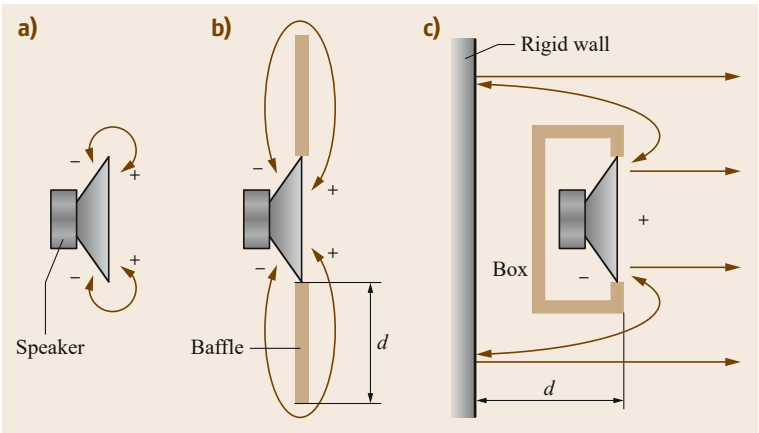

Fig. 12.31 **(a)** Acoustically short-circuited loudspeaker, **(b)** loudspeaker in a baffle, **(c)** loudspeaker in a closed box in front of a rigid wall

inhomogeneous conversion since the coil might leave the magnetic field, at least partially. This is one of the reasons for nonlinearity in speakers. Second, ribbon speakers use the same electrodynamic principle but the current directly flows through a plane membrane. Third, electrostatic speakers employ the force that is in effect on an electrical charge Q

$$|\boldsymbol{F}| = \frac{QU}{d} \qquad (12.14)$$

with the voltage U and the physical distance d between electrodes. Flipping the polarity of the charge will not flip the force direction (see the magnitude for force in (12.14)). Therefore, for bipolar audio signals, a high DC voltage is used to bias the system (Fig. 12.30). The electrostatic principle will typically facilitate only small displacements of the membrane or diaphragm.

Another conversion principle uses the piezoelectric effect, however reversely operated when compared with the piezomicrophone (Sect. 12.1). The voltage across the crystalline structure will cause deformation and therefore displacement. The displacement is very small and therefore these converters are used for high-frequency applications or for buzzing in low-end applications. Other principles use ionized air and again others use structure-borne sound across large plane panels, so-called distributed-mode loudspeakers (DML).

All the conversion principles have in common that the typical arrangement implies only one degree of freedom and therefore the speakers typically radiate a figure of eight, potentially short-circuiting acoustically (Fig. 12.31a). The air that is pushed away at the front side of the speaker is simply pulled in at the back side and reversed. The effect of short-circuiting is frequency-dependent and can be prevented by using an extended baffle (Fig. 12.31b). Now the pressure wave has to travel around the baffle to be compensated by a matching sink. Travel time is twice the distance d at the speed of sound $c \approx 340\,\mathrm{m/s}$. The critical frequency below which the radiation suffers by 6 dB/octave is

$$f_0 = \frac{c}{4d}\,. \qquad (12.15)$$

A closed box has the effect of an infinitely extended baffle, since the direct acoustical short-circuit is prevented (Fig. 12.31c). However, loudspeakers are

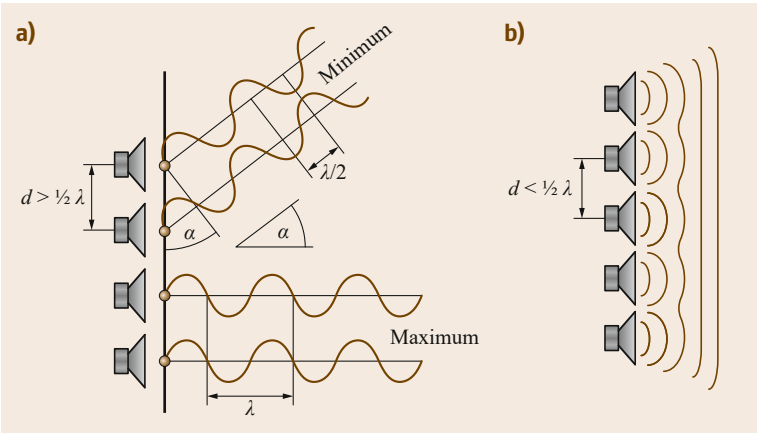

Fig. 12.32a,b Soundfields from lines of loudspeakers separated by distance d with **(a)** interference ($d > \lambda/2$) and **(b)** plane wavefronts ($d < \lambda/2$)

usually placed within buildings and in many cases in front of walls. The travel time of a pressure wave to the wall behind and back to the plane of the speaker cone is twice the distance d at speed c and defines frequencies of compensation.

$$f_n = \frac{c\,(1+2n)}{4d}\,, \quad n = 1, 2, 3, \ldots \tag{12.16}$$

At these frequencies, the radiated power is much lower, at least for listeners on axis. When listening off-axis, the geometry constitutes derivatives of the simple form in (12.16).

In most electrodynamic speakers, the membrane is a cone, further defining nonlinearity but also the radiation beam. The membrane is not completely stiff and the cone geometry will increase stiffness only to a certain degree. An impulse generated at the center will need time to travel across the membrane. The vibrational modes of the membrane therefore codetermine the general frequency response of a speaker. The radiation pattern of speakers constitutes narrow beams for high frequencies and wide beams for low frequencies. Sound pressure measurements are usually only done on axis and are no reference to the spaciously integrated total radiation power.

The electrodynamic principle is also used in horns, which are usually designed to radiate sound of higher frequencies. The horn geometry is typically designed such that the cross sectional area grows exponentially along the horn in order to gradually adapt the driver impedance to air impedance.

If several speakers are driven by the same signal, the geometrical arrangement again constitutes cases of attenuation and amplification, of interference and plain wavefronts. In cases where the distance d between speakers is more than half of the wavelength λ the superposition of pressure waves gets a destructive component. The relation of d to λ defines the direction α with respect to the normal axis in which individual waves have a phase shift of $\lambda/2$, or π, effectively compensating for each other (see the minimum in Fig. 12.32a). This is true also for phase shifts of $3/2\lambda$, $5/2\lambda$ and so on. The general relation for the off-normal-axis angle reads,

$$\alpha_n = \arcsin\left(\frac{(1+2n)\,\lambda}{2d}\right) d > \frac{\lambda}{2}\,; \quad n = 1, 2, 3, \ldots \tag{12.17}$$

In cases of d smaller than half of the wavelength λ, (12.16) cannot be solved and circular wavefronts of the elementary sound sources jointly establish a plane wavefront according to Huygens' principle (Fig. 12.32b). For a given loudspeaker arrangement with a distance d between loudspeakers, sound components below a critical frequency will be radiated in the form of a plane wave.

$$f_{\text{crit}} = \frac{c}{\lambda_{\text{crit}}} = \frac{c}{2d}\,, \quad d = \frac{\lambda_{\text{crit}}}{2} \tag{12.18}$$

At the same time, sound components above the critical frequency will suffer from interference. The principle of establishing plane wavefronts is followed in line arrays (LA) and in wave field synthesis (WFS). But the principle also applies to two-way or three-way speakers, where speakers are distant to each other but the spectral range they serve is not separated without a crossover. Certainly, any listening room raises further and even more complex scenarios of interference due to multiple reflections.

12.8.2 Reference Listening

Reference listening addresses several issues beyond the sound quality of the speakers. How well does the

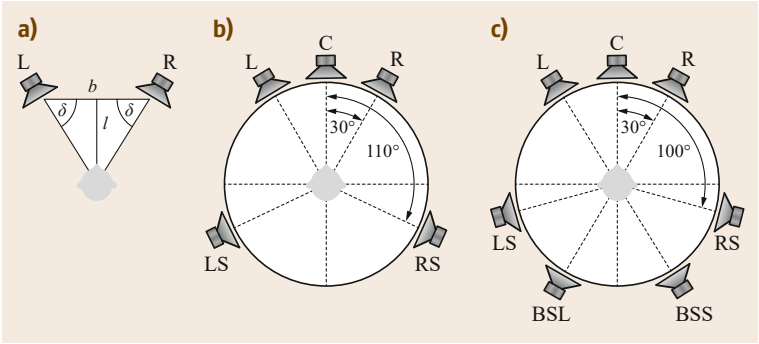

Fig. 12.33a–c Recommended loudspeaker arrangements according to (a) DIN 15996 and (b,c) ITU-R BS.775-1

speaker arrangement match the underlying principle of microphone arrangement? How well does the generated soundfield represent the fictional soundfield that was intended by an audio designer? While for stereo and DTS there are reference listening arrangements and standards, for many of the three-dimensional and application-specific formats standards currently evolve.

12.8.3 Two-Dimensional Loudspeaker Arrangements

According to DIN 15996, stereo playback is recommended with the two speakers separated by $b = 3{-}4.5\,\mathrm{m}$ and the listener position at a distance of $l = (0.9{\pm}0.3)b$. The ideal arrangement is equilateral, however there is some tolerance defined, $\delta = 60° \pm 15°$ (Fig. 12.33a). Reference arrangements for 5.1 and 7.1 according to ITU-R BS.775-1 incorporate the original stereo triangle and all speakers are on a circle (Fig. 12.33b and 12.33c). Dolby Digital is the consumer market format to capture stereo and multichannel audio with and without the low-frequency effects channel (LFE), respectively 5.0 and 5.1 (Table 12.10).

Another reference for stereo is ITU-R BS.1116-1. This standard also specifies listening conditions beyond the loudspeaker geometrical setup, such as operational ranges for loudspeakers and for room-acoustical parameters. In terms of sound quality assessments there are specific recommendations, such as ITU-R BS.1284-1 [12.21] and handbooks on general methodology for sound quality evaluation [12.22]. More specifically, the EBU Tech. 3286 [12.23] specifies parameters for the quality assessment of stereo sound. Among these are spatial impression (subparameters: homogeneity of spatial sound, reverberance, acoustical balance, apparent room size, depth perspective), stereo impression (subparameters: directional balance, stability, sound image width, location accuracy), transparency, sound balance, timbre and more. So there is nuanced expert knowledge shared by audio engineers and equipment OEMs if it comes to stereo.

Wave field synthesis (WFS) employs the outlined planar wave propagation principle to control a two-dimensional soundfield. Loudspeakers are densely spaced, for instance at $d = 17\,\mathrm{cm}$ to achieve plane waves for frequencies below $f_{\mathrm{crit}} = 1000\,\mathrm{Hz}$. A listening arrangement can easily ask for several hundred speakers. With WFS, a pressure wave front can be formed to simulate source positions that lay behind the row of loudspeakers (see source 1 in Fig. 12.34). This is achieved by appropriately delayed loudspeaker signals. The operational technology even allows to model sound sources that are in front of the line (see source 2 in Fig. 12.34). Likewise, the acoustical room and its real reflections can be modelled as well by treating reflections as additional sound sources.

WFS modelling is a complex task even for stationary sources and listener positions, since the directivity of the speakers codefine the synthesis operators [12.24] and directional room-impulse responses must be generated for each pair of listening position and sound source, which can be done by parameterized recordings from circular microphone arrays [12.25].

The two-dimensional sound representation in WFS and the modelled source distance are convincingly perceived when high-fidelity impulse responses are used. Even more complex is the model for sources in motion.

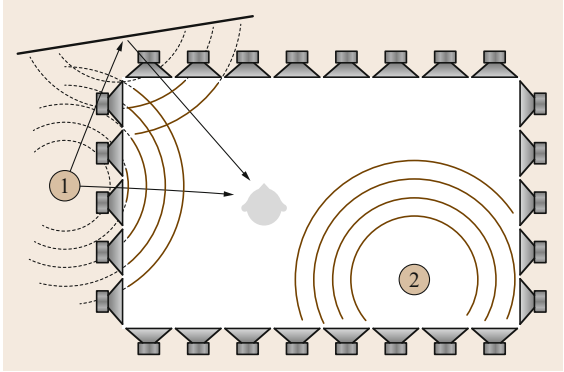

Fig. 12.34 Wave field synthesis

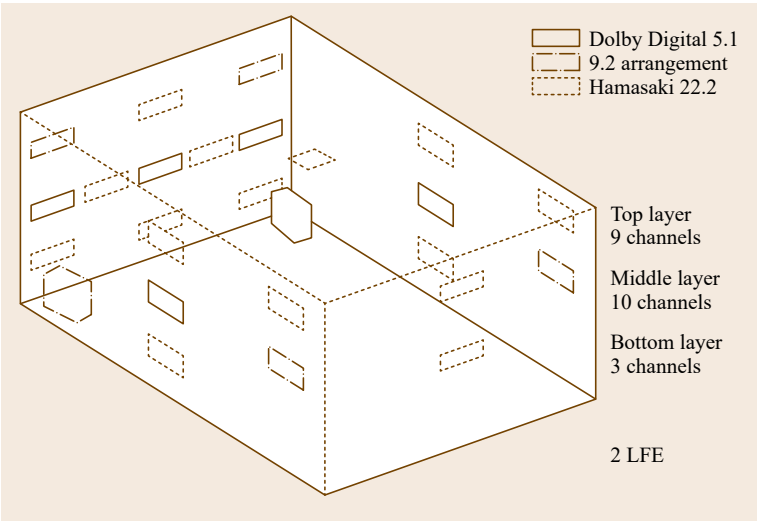

Fig. 12.35 22.2 Loudspeaker arrangement according to Hamasaki

Moving sound sources are so impressive nowadays that only little effort has been made to achieve high-fidelity input parameters. WFS today is often used for fictional sound and audio drama, while relatively large PA speakers are spaced at $d = 1$ m. The resulting $f_{crit} = 170$ Hz does not really facilitate plane waves for speech and music. WFS therefore is more commonly operated as a multichannel surround system for applications without preferred listening direction.

12.8.4 Three-Dimensional Loudspeaker Arrangements

There are various loudspeaker arrangements that consider elevation in sound reproduction. The intentions differ from application to application. In music recording, the envelopment is strongly enhanced by reproducing ceiling reflections, while in cinema, discrete sound sources fictionally move above, but also possibly below the audience.

Auro 3D addresses elevation in two versions. The Auro 3D 9.1 proposal targets the home theatre and is identical with the 5.1 arrangement (Fig. 12.33b) for the base level and it uses four more speakers for the upper level, one above each of the side channels. When standard formats such as 4.0, 5.1, 6.1, or 22.2 are used in cinemas, the arrangement of speakers is adapted to the much larger listening area. In particular, the side channels LS and RS are distributed over multiple loudspeakers along the side, and even from the rear. In the Auro 3D 11.1 for cinema applications, this is also the case, and the side is even extended towards the back side. The upper level has the same format as the lower level. In addition, there are speakers in the ceiling (voice of God). Auro 3D is a complete system with its own theory to support direct upmixing of stereo or 5.1 to the 9 or 11 spatial channels. The conversion engine creates multiple decorrelated channels from the few inputs. It can also convert to three-dimensional (3-D) headphone representations.

The Hamasaki 22.2 arrangement [12.26] was developed in the context of high-definition television (HD-TV) and is standardized [12.27]. It facilitates elevation, both above and below the audience, but also an improved resolution in the front (Fig. 12.35).

The 5.1 multichannel file and streaming format has also been used to accommodate elevation in the form of 2+2+2 channels. *Dabringhaus* promoted this format of 2 front, 2 rear, and 2 elevated front channels, working for a maximum of room ambience and auditor envelopment with a minimum number of channels [12.28]. This format reuses the 5.1 technology both in production and in consumer electronics. It is not widely used but the concept is convincing, because the multichannel recording can directly be projected to the loudspeaker arrangement at a nuanced expert level. Sound engineers familiar with stereo recording can directly project the outcome of their microphone arrangement. Listening to 2+2+2 is a convincing experience and there is a selection of fine recordings of classical music.

Ambisonics is the keyword of 3-D spatial representation. The loudspeaker arrangement complements the 3-D coincident microphone arrangement, or A-format and B-format, as outlined in Sect. 12.1.3. Coincident loudspeakers are not possible and near-coincident speakers are typically approximated by dodecahedrons. Ambisonics arrangements are typically equally spaced on a spherical grid. The soundfield must be encoded for the specific number of channels on the grid. Technologies in this field facilitate conversion of standard

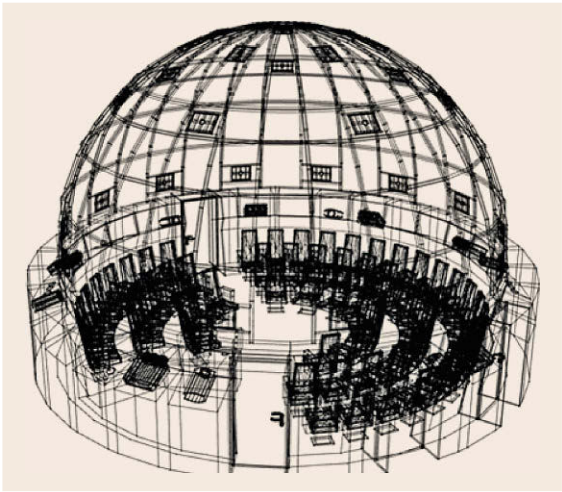

Fig. 12.36 Planetarium in Kiel, Germany – an example of individual 3-D auralization

formats to ambisonics, but also the creation of virtual acoustical spaces.

There is also a wide range of application-specific solutions for exhibitions, fairs, museums and shows. For instance, in the Kiel planetarium, the position of speakers is codetermined by building construction. There are three levels, with 14 speakers on the ground level and 7 speakers on each of the upper layers (Fig. 12.36). Input to the system is a matrix of sound sources and time-dependent vectors. Standard 5.1 and stereo panning technologies have been combined to seamlessly move individual sound sources across the sky.

Headphones are also widely used for reference listening. The advantage is that the soundfield is free of disturbing reflections from walls, or more generally speaking, there is no acoustical interference from the listening room that would degrade the room acoustics contained in the presented sound. However, there are also problems and disadvantages. First, for stereo, the geometry strongly differs from the intended 60° arrangement. While in reference stereo both channels reach both ears, under headphone conditions the channels and ears are strictly separated. The stereo image is much wider and strongly deviates from the intended scene. This does not mean that such wide stereo is disliked. Second, the headphone is in many cases equivalent to a pressure chamber, introducing additional rules for equalization. Third, for many samples and for many people, the so-called in-head localization is very annoying. The sound source might well be spatially discriminated, but it is inside rather than outside the head. Interaural time difference (ITD) and interaural intensity difference (IID) which are usually the main factors for spatial discrimination do not necessarily translate in a standardized form for every shape of the head. Microphone arrangements that imply an equivalent ITD have an advantage for headphone listening (e.g., ORTF in Fig. 12.7), even though they are problematic in mono downmixes. Reflections from the torso are likewise important to translate the soundfield into a real-world experience, but these reflections are missing in headphone listening, too.

Dummy head recordings simulate the real-world listening scenario since ITD and IID apply, but also the shadow of the head and the form of the pinna and concha. But even with the dummy head, in-head localization remains a problem for many people, because dummy head parameters only approximate the average listener. Based on anechoic dummy head recordings, there also exist direction-specific head-related transfer functions (HRTF). *Algazi* et al. provided an extended reference library of spatial high-resolution HRTFs [12.29]. There is also a general model derived from this data [12.30]. However, again it is only by chance that the perceived direction of a sound source will match the true direction of the dummy head in the original recording setup. Given these restrictions, there are technologies that translate 5.1 formats to the two-channel format for headphone listening. Some of these even allow the head to be moved, while the virtually created reference 5.1 monitoring remains statically fixed with respect to the room.

Perceived elevation in binaural listening is strongly determined by the pinna and cochna shape. Reference

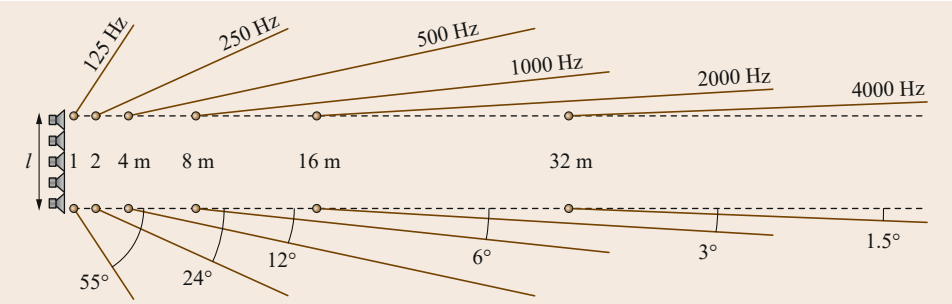

Fig. 12.38 Frequency-dependent transition between near-field and far-field for a $l = 2.3$ m long line array

HRTF recordings inherently incorporate this and this know-how is used to encode 3-D audio in such a way that it can be represented on the two channels for headphone listening. The pinna and cochna shape can also be used to directly model elevation in individual HRTFs [12.31].

12.8.5 Reinforcement

Line arrays of speakers are another example of establishing plane wavefronts and are widely applied in reinforcement systems or PA systems. Solitary speakers radiate spherically, with a loss of −6 dB sound pressure level (SPL) for each doubling of distance R, beginning with the frequency-dependent far-field. Line arrays, as they approximate ideal line sources, radiate cylindrically with a loss of only −3 dB SPL (Fig. 12.37 for a comparison of geometry).

The transition from cylindrical to spherical radiation, or from near-field to far-field, is given at the distance

$$r_{\text{transition}} = \frac{3fl^2}{2}\sqrt{1-\frac{1}{(3fl)^2}} \qquad (12.19)$$

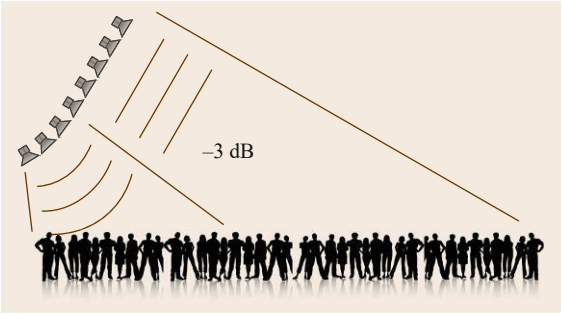

Fig. 12.39 J-curved line array with the straight section creating cylindrical waves to reach far listeners

for line arrays of limited length l and frequency f in kHz [12.32]. Figure 12.38 illustrates this frequency dependency for a 2.3 m long line array.

The reduced loss of SLP for line sources can also be expressed by a focused beam. This advantage is used in PA systems where a wide auditory space has to be covered at possibly comparable SPL for listeners in the front and in the rear. Figure 12.39 illustrates a J-curved line array where far listeners are reached by cylindrical waves, while nearby listeners are not.

13. Delay-Lines and Digital Waveguides

Gary Scavone

A digital delay line is a particular type of finite impulse response (FIR) filter that has many useful applications in audio signal processing. Simply put, signals that are input to a delay line reappear at the output after a specified time period (in samples). Delay lines are often implemented to support delay times that can vary dynamically. As well, delay times corresponding to noninteger sample lengths can be approximated.

Time delay of signals is fundamental to signal processing systems. In this chapter, we focus on applications in digital audio signal processing and in particular, the modeling of wave propagation in air and in strings. The fundamentals of delay lines will be introduced and their implementation detailed, including common fractional-delay filtering techniques. Feedforward and feedback comb filters are simple signal processing structures built with delay lines and they exhibit characteristics that not only make them interesting for delay-based audio effects algorithms, but also as simple models of acoustic wave propagation. Finally, the use of delay lines to simulate wave propagation in one-dimensional waveguides will be introduced with a focus on the synthesis of plucked string instrument sounds.

13.1 Digital Delay Lines

For an input signal given by the time series $x[n]$ with sample indices $n = 0, 1, 2, \ldots$ and a delay-line length of M samples, the delay-line output is defined by the difference equation

$$y[n] = x[n - M], \quad n = 0, 1, 2, \ldots ,$$

where $x[n]$ is equal to zero for sampled time step indices of $n < 0$.

The functioning of a delay line can be visualized as in Fig. 13.1, assuming $M = 4$ and a discrete-time unit impulse input signal defined as

$$\delta[n] = \begin{cases} 1, & n = 0 \\ 0, & n \neq 0 \, . \end{cases}$$

For every time step n, the signal value in the last (rightmost) memory location is output from the delay line, the remaining stored values are propagated to adjacent memory locations (to the right), and a new input sample

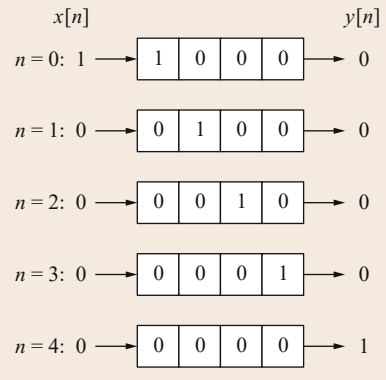

Fig. 13.1 Signal flow in a digital delay line of length $M = 4$ samples

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_13

is written to the first (left-most) memory location. Thus, the sample value of 1 that is input at time $n = 0$ will appear at the delay-line output at time step $n = 4$. For this particular example, all subsequent inputs and outputs to the delay line are zeroes. In this way, the finite length impulse response of the length $M = 4$ digital delay line is given by $h = \{0, 0, 0, 0, 1\}$.

It is straightforward to apply standard filter analysis methods to investigate the behavior of digital delay lines in the frequency domain. For example, application of the z-transform to the difference equation above results in a transfer function for this system of

$$H(z) = Y(z)/X(z) = z^{-M} .$$

The frequency magnitude response, determined by replacing z with $e^{j\omega}$ and evaluating the magnitude for $0 \le \omega \le \pi$ (corresponding to frequencies from 0 to $f_s/2$ Hz at the sample rate f_s, where $\omega = 2\pi f/f_s$ is the normalized discrete-time radian frequency), is equal to one across all frequencies. This should not be surprising considering that the delay line does not change the input values in any way aside from delaying them in time. The phase response for the example $M = 4$ delay-line system is shown in Fig. 13.2, plotted both in radians (a) and as *phase delay* in samples (b), from which its linear phase response is clear.

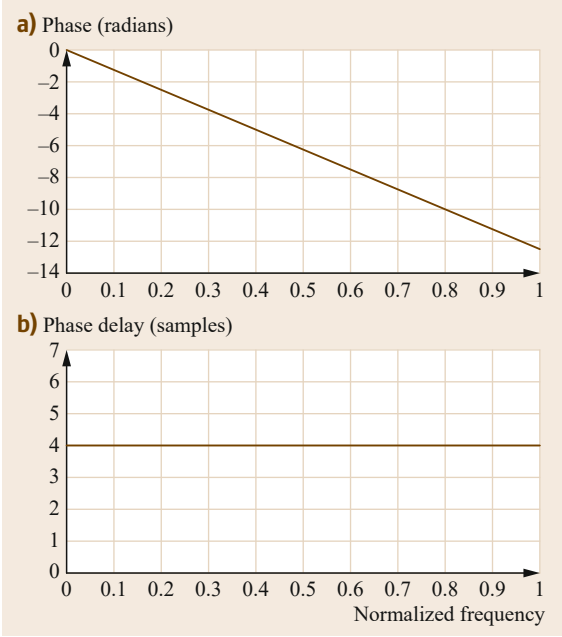

Fig. 13.2a,b Phase response of a digital delay line of length $M = 4$ samples: **(a)** phase in radians; **(b)** phase delay in samples

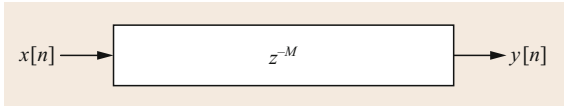

Fig. 13.3 The block diagram representation of a digital delay line of length M samples

In digital filter block diagrams, the digital delay line is typically represented as shown in Fig. 13.3, where the length of the delay is given by the exponent of z.

13.1.1 Delay Line Implementation

The delay-line visualization of Fig. 13.1 implies a significant computation burden associated with its implementation. That is, from the description above it might seem that every signal value stored in the delay line must be copied over to an adjacent memory location for every new input/output value. However, digital delay lines can be very efficiently implemented in computer programming environments, requiring only sufficient memory and one or two memory pointers. For example, the fixed-length $M = 4$ digital delay line can be implemented with just four samples of memory storage and a single pointer as demonstrated in the following Matlab example:

```
N = 60; % time steps to compute
x = [1, zeros(1, N-1)]; % unit impulse
M = 4; % delay line length
delayline = zeros(1, 4);
ptr = 1;
y = zeros(1, N); % output signal

for n = 1:N,
  y(n) = delayline(ptr); % read output
  delayline(ptr) = x(n); % write input
  ptr = ptr + 1;  % increment pointer
  if ptr > M,     % check pointer limit
    ptr = 1;
  end
end
```

The approach demonstrated above also supports dynamically variable delay-line lengths. The example will work for any value of M in the range $1 \le M \le 4$. It is only necessary to allocate enough memory to support the maximum desired delay-line length. The example above does not support a delay-line length $M = 0$. For that to work, it is necessary to use and increment two pointers, one each for the input and output memory locations. Memory allocation can be a relatively time consuming operation in a real-time synthesis environment. Thus, in situations where the delay length may change over time, a large buffer of some maximum size

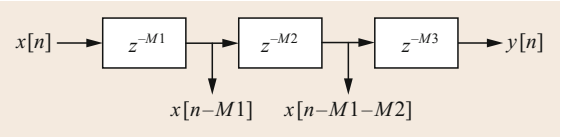

Fig. 13.4 The block diagram representation of a tapped digital delay line with two internal output taps

is usually created during program initialization (for example, the fourth line of the Matlab example could be changed to `delayline = zeros(1, 50)` to support values of M in the range $1 \leq M \leq 50$).

13.1.2 Tapped Delay Lines

There are often contexts where it is desirable to access the contents of a delay line at one or more intermediate delay length values. Such a system is referred to as a tapped delay line. The block diagram of Fig. 13.4 illustrates a tapped delay line of total length $M1 + M2 + M3$ samples and two taps located at delay lengths of $M1$ and $M1 + M2$ samples. In general, a tap delay line is implemented as a single buffer in memory but with as many *read* pointers as taps. Such functionality could be added to the Matlab example above using a new pointer for each intermediate tap length.

13.1.3 Delay-Line Interpolation

The delay lines discussed thus far have had lengths given by an integer number of samples. In many contexts, especially when the delay length can change dynamically, it is necessary to compute the output of a delay line for lengths that correspond to some fraction of a sample. For example, if a delay-line length was to be slowly increased from 30 to 32 samples over a time of one second, it would be necessary to perform this increase at small increments (perhaps 0.1 sample increments or less) in order that the change be smooth and free of audible artifacts.

While signal values in a delay line are stored at integer multiples of the sample period $T_s = 1/f_s$, it is possible to apply interpolation techniques to approximate values between those in memory. A large body of literature exists on such interpolation techniques [13.1]. The most common interpolation techniques used in conjunction with delay lines are first-order linear interpolation and allpass interpolation.

Linear Interpolation

Linear interpolation is an efficient technique for determining sample values at fractional delay-line lengths. Intermediate values between two neighboring samples are found by effectively *drawing* a straight line connecting those two samples and returning values at desired positions along that line.

Let Δ be a number between 0 and 1 that indicates how far to interpolate a signal y between time steps n and $n-1$. The linearly interpolated value $y[n-\Delta]$ between known values $y[n]$ and $y[n-1]$ is given by

$$\begin{aligned} y[n-\Delta] &= (1-\Delta)\cdot y[n] + \Delta \cdot y[n-1] \\ &= y[n] + \Delta \cdot (y[n-1] - y[n]) \,. \end{aligned}$$

This operation is equivalent to a first-order FIR filter. The use of linear interpolation at the output of a delay line is diagrammed in Fig. 13.5. The frequency magnitude response and phase delay for a linear interpolation filter is shown in Fig. 13.6 for fractional delays between 0 and 1. The *ideal* interpolation filter would have a constant magnitude of one and a constant phase delay exactly equal to Δ across all frequencies. In other words, the filter would time-shift its input by the desired amount without modifying the gain, irrespective of the signal frequency content. From Fig. 13.6, it is apparent that linear interpolation becomes less accurate at higher frequencies, though this nonideal behavior varies with Δ. As an example, when $\Delta = 0.5$ the phase delay is exact across all frequencies but higher frequency components are attenuated (their magnitude response falls well below 0 dB).

Linear interpolation is also known as first-order Lagrange interpolation. Higher order Lagrange interpolators can be more accurate but are less efficient to implement.

Allpass Interpolation

Allpass filters have a unity magnitude response but variable phase delay properties. This makes them potentially useful for fractional-delay filtering, as they are guaranteed to pass signals without attenuating their

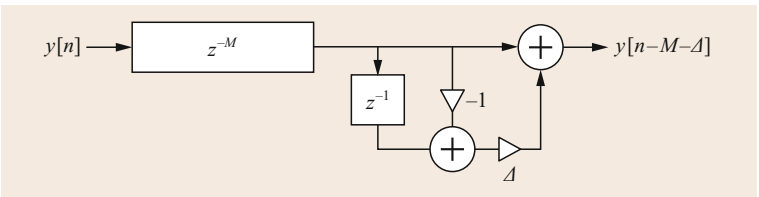

Fig. 13.5 A linearly interpolated delay line

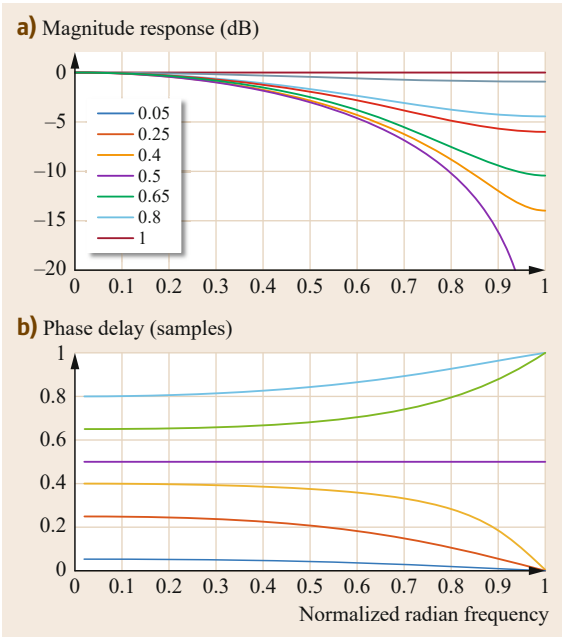

Fig. 13.6 **(a)** Frequency magnitude and **(b)** phase delay for linear interpolation with fractional delays between 0 and 1

magnitude. The problem then becomes one of finding an allpass filter with the desired phase delay property.

The difference equation for a general first-order allpass filter is given by

$$\begin{aligned} y[n] &= a \cdot x[n] + x[n-1] - a \cdot y[n-1] \\ &= a \cdot (x[n] - y[n-1]) + x[n-1] \,. \end{aligned}$$

Its transfer function is

$$H(z) = \frac{a + z^{-1}}{1 + az^{-1}} \,,$$

from which the phase delay can be estimated for low frequencies as [13.2]

$$-\frac{\angle H(\mathrm{e}^{-\mathrm{j}\omega})}{\omega} \approx \frac{1-a}{1+a} \quad \text{as} \quad \omega \to 0 \,,$$

where $\angle H(\mathrm{e}^{-\mathrm{j}\omega})$ is the phase response of $H(z)$ at normalized discrete-time radian frequencies $\omega = 2\pi f / f_\mathrm{s}$, with sample rate f_s. Thus, the allpass coefficient a can be determined for a given desired fractional delay Δ as

$$a = \frac{1-\Delta}{1+\Delta} \,.$$

The phase delay of the first-order allpass filter for fractional delay values between 0.1 and 2 is plotted in Fig. 13.7. From the plot, it is clear that the phase delay of the filter is not constant across all frequencies (other than for $\Delta = 1$), with the phase delay converging to one at $f_\mathrm{s}/2$ for all fractional delay values. A general rule of thumb is to choose values in the range $0.3 \le \Delta \le 1.3$ to obtain more constant phase delay response at lower frequencies, together with the fastest decaying impulse response, which is desirable to minimize transient effects when dynamically changing the fractional delay length. The transient responses of first-order allpass filters used to implement several different fractional delay values are shown in Fig. 13.8. Note how values of Δ closer to 0.0 have significantly longer transient *tails*.

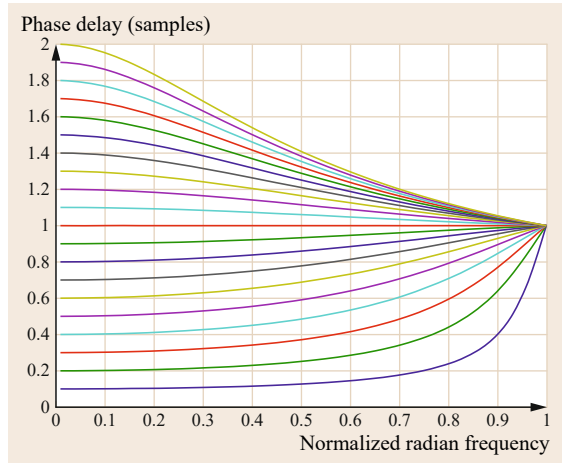

Fig. 13.7 Phase delay for first-order allpass filters with fractional delay settings between 0.1 and 2

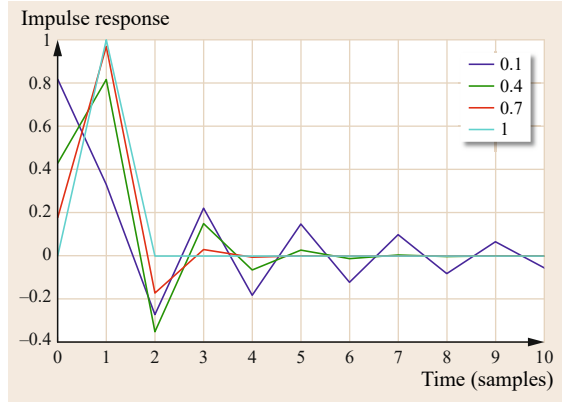

Fig. 13.8 Impulse response of first-order allpass filters with fractional delay settings of $\Delta = 0.1$, 0.4, 0.7, and 1.0

A block diagram for a first-order allpass interpolation filter at the output of a delay line is shown in Fig. 13.9. For values of $\Delta > 1$, a unit of delay can be subtracted from the adjoining delay line.

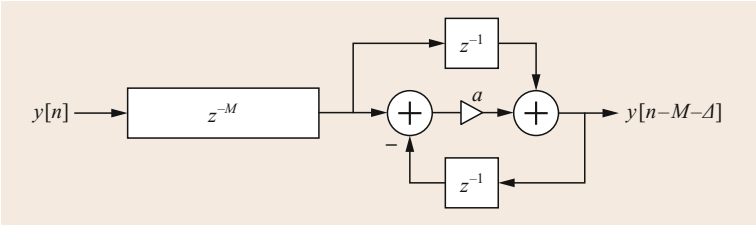

Fig. 13.9 A first-order allpass interpolated delay line

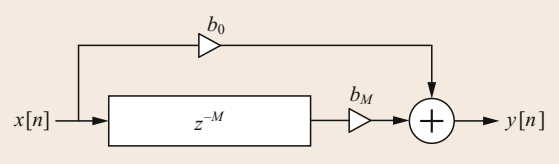

Fig. 13.10 A feedforward comb filter block diagram

First-order allpass and linear interpolation both involve the same level of computational complexity, though allpass interpolation does not introduce higher frequency attenuation. That said, linear interpolation provides the shortest transient response when changing Δ values and its phase delay is generally flatter out to higher frequencies. As well, linear interpolation can be used to arbitrarily interpolate between sample values in a delay line at any instant in time, which is not possible with allpass interpolation filters because of their transient response behavior (they must be *warmed up* before reaching their steady-state response). Thus, there are trade-offs and the best choice will depend on particular algorithm constraints.

13.1.4 Comb Filters

Comb filters are simple signal processing structures, made with delay lines, that have applications in many digital audio effects algorithms, including flanging and artificial reverberation. They get their name from the shape of their frequency magnitude responses, as will be shown below.

The signal processing block diagram for a feedforward comb filter is shown in Fig. 13.10. The difference equation for the filter is

$$y[n] = b_0 x[n] + b_M x[n-M] \,,$$

from which its transfer function is determined as

$$H(z) = b_0 + b_M z^{-M} \,.$$

The frequency magnitude response of the feedforward comb filter is thus given by

$$\left|H(\mathrm{e}^{\mathrm{j}\omega})\right| = \left|b_0 + b_M \mathrm{e}^{-\mathrm{j}\omega M}\right| \,, \quad -\pi \le \omega \le \pi \,,$$

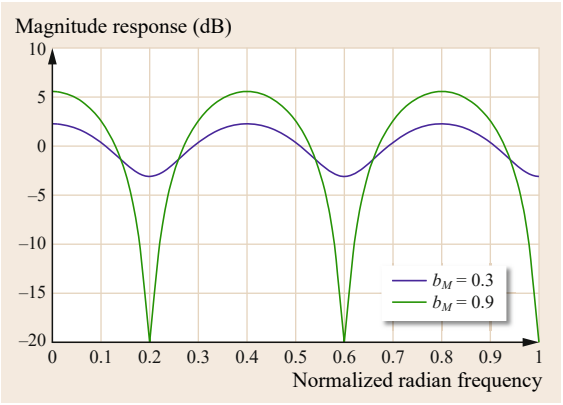

Fig. 13.11 Magnitude response of a feedforward comb filter with $M = 5$, $b_0 = 1$, and $b_M = 0.3$ and 0.9

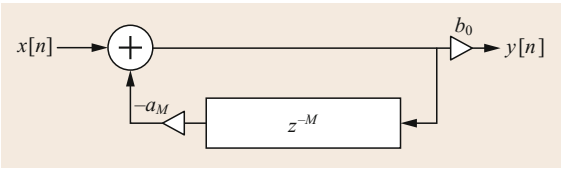

Fig. 13.12 A feedback comb filter block diagram

which is plotted in Fig. 13.11 for $M = 5$, $b_0 = 1$, and $b_M = 0.3$ and 0.9. The maximum gain is 6 dB (or a linear gain of 2), which occurs at frequencies for which the output from the delay line is in phase with the direct path. In between these frequency values, the two signals are out of phase and thus destructively interfere with each other, to an extent controlled by the coefficient b_M.

The frequencies of the notches in Fig. 13.11 occur at the roots of the transfer function $H(z)$. For b_0 and b_M positive, there are M notches evenly spaced in frequency from $f_s/(2M)$ to f_s Hz at increments of f_s/M Hz. If either b_0 or b_M is negative, the notches are shifted in frequency to start at 0 Hz and increment by f_s/M Hz. Note that the frequency axis of Fig. 13.11 is normalized from 0 to $f_s/2$ Hz.

The block diagram of a feedback comb filter is illustrated in Fig. 13.12. The difference equation for this filter is given by

$$y[n] = b_0 x[n] - a_M y[n-M] \,.$$

For stability, the coefficient a_M must have a magnitude < 1. The transfer function of the feedback comb filter is

$$H(z) = \frac{b_0}{1 + a_M z^{-M}} ,$$

from which the amplitude response is found as

$$G(\omega) = \left|H(e^{j\omega})\right| = \left|\frac{b_0}{1 + a_M e^{-j\omega M}}\right| ,$$
$$-\pi \le \omega \le \pi .$$

The magnitude response of a feedback comb filter is shown in Fig. 13.13 for $M = 5$, $b_0 = 1$, and $a_M = -0.3$ and -0.9. The frequencies of constructive feedback can be found from the roots of the denominator of the transfer function. The maximum gain is $b_0/(1 + a_M)$, which involves constructive feedback at the same frequencies where the notches were found in the feedforward comb filter.

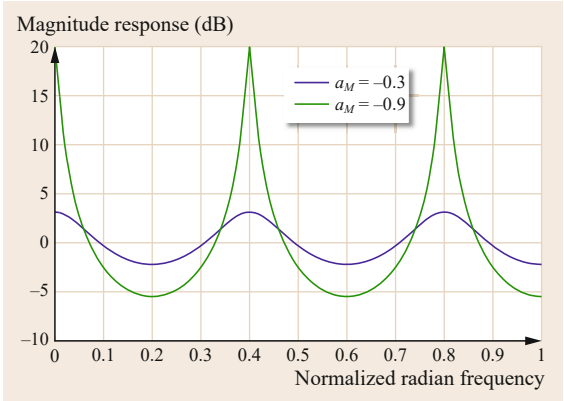

Fig. 13.13 Magnitude response of a feedback comb filter with $M = 5$, $b_0 = 1$, and $a_M = -0.3$ and -0.9

13.2 Simulating Sound Wave Propagation

Sound is transported through air via waves that travel at an approximate speed of 341 meters per second (at room temperature). As a result, there is a time (or propagation) delay for sound to travel from an emitting source to a listener some distance away. This is most obvious when the distance between a sound source and listener is large, for example when observing fireworks from a few kilometers away. But these inherent time delays are equally important for various acoustic phenomena over shorter distances as well. For example, the propagation delay for sound waves traveling inside a clarinet controls the resulting frequency of reed oscillations, or the sounding frequency of the instrument. When the effective length of the clarinet is shortened by opening holes along its length, the distance traveled by the waves inside the air column decreases and the sounding frequency increases.

Given what has previously been said about delay lines, it should come as no surprise to learn that delay lines are commonly applied in audio signal processing contexts to simulate sound wave propagation. A given distance d between source and listener will result in a time delay of d/c seconds (where c is the speed of sound propagation). In a discrete-time signal processing context, this time delay must be related to the sample period $T_s = 1/f_s$, where f_s is the sample rate in samples per second. Thus, the length of a delay line in samples M needed to simulate sound propagation over a distance d is given by $M = d/(cT_s)$. Note that the quantity cT_s represents the distance traveled by sound in a single sample period, which is about 7 mm at a sample rate of 48 000 Hz.

Sound waves emitted by a source will generally decrease in pressure level (and thus perceived loudness) as the distance from the source increases. For waves traveling in an open space or a large room, this decay or attenuation is due in part to the spreading of wavefront energy over a larger and larger spherical surface area as it propagates away from the source, as well as losses due to molecular interactions in air. For waves traveling in a confined space, such as a uniform pipe, there will be losses due to interactions with the surrounding walls, though not necessarily any attenuation due to wavefront spreading (if the wavefronts are assumed to be planar, which is typically the case in uniform pipes). Thus, an accurate simulation of sound travel must incorporate some distance-dependent gain control.

A distributed simulation approach would make use of gain factors g to represent the loss experienced over the distance traveled per unit delay, as diagrammed at the top of Fig. 13.14. For efficiency, these factors can be *commuted* (assuming linearity) and implemented at a single (or just a few) discrete locations in the system (as shown in the bottom of Fig. 13.14). In reality, these losses will be frequency dependent (typically more losses at higher frequencies) and thus more accurately represented with appropriately designed digital filters.

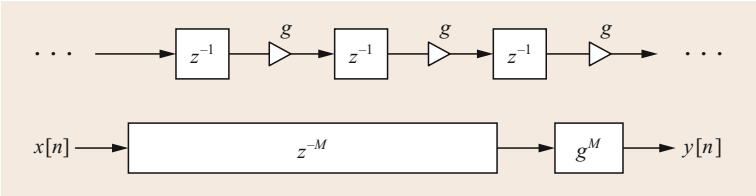

Fig. 13.14 Damped traveling-wave simulators with losses per unit sample (*top*) and with commuted losses (*bottom*)

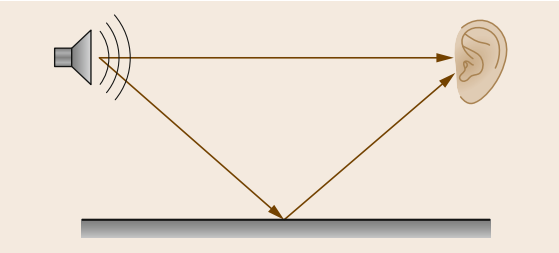

Fig. 13.15 Floor reflection illustration

13.2.1 Wave Reflections

If a traveling wave encounters a change in the physical properties of the medium through which it propagates, the wave will be perturbed where the change occurs. This perturbation generally involves some level of reflection, absorption, and transmission at the boundary. For example, if a wavefront impinges on a perfectly rigid surface, all of the wave energy will be reflected from the surface. However, if the surface is instead covered with a layer of absorbing material, only a portion of the wave energy will be reflected, with the remainder being trapped and damped within the material. The extent of such reflection can be characterized by a reflection coefficient (R), which specifies the ratio of reflected to incident wave energy. Materials that are very reflective will have a value of R close to 1, while R will be close to zero for materials that are very absorptive. In general, the reflection coefficient will be frequency dependent. In other words, materials will normally reflect or absorb waves of differing frequencies by different amounts.

Wave reflection from surfaces will also depend on the shape of the surface. If an acoustic wave encounters a rigid wall that is flat over at least several wavelengths in all directions, the wavefront will be reflected from that surface at an angle equal to its angle of incidence (referred to as *specular* reflection). Conversely, a wall that is very uneven will reflect a wavefront in many directions (referred to as *diffuse* scattering).

Waves can be *guided* within structures of uniform geometry, a common musical example being the roughly cylindrical air column of a clarinet. Wave reflection will occur in such *waveguides* at any geometrical discontinuity, such as the location of an open hole. Wave components will be partly reflected at such a discontinuity and partly transmitted through it into the surrounding air, with lower frequency components generally being more strongly reflected than higher frequency components. The size of the hole will control the frequency-dependence of this behavior.

Figure 13.15 illustrates a source–listener arrangement with sound wave reflection from an assumed rigid floor of infinite extent. In this case, two propagation paths exist for sound wave travel between the source and listener. The system of Fig. 13.16 (*top*) provides a signal processing block diagram to simulate the sound wave propagation using digital delay lines. The scale factors g_d and g_r account for losses over the respective direct and reflected paths due to air absorption and spherical spreading. If the floor had a reflection coefficient less than one, this could also be included in the g_r factor. The height of the source and listener will control the time delay between the arrival of the direct and reflected waves. The delay common to the two

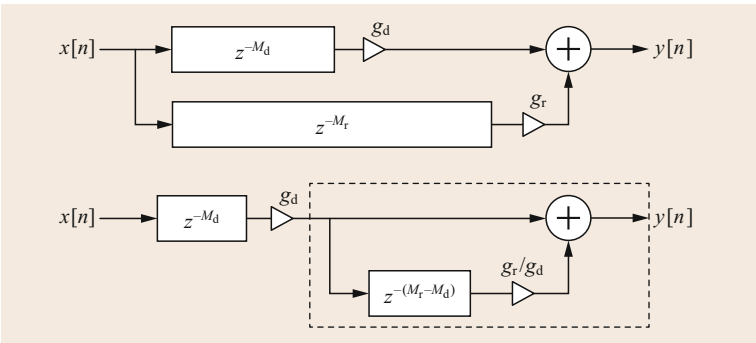

Fig. 13.16 Floor reflection block diagrams

paths can be pulled out and implemented separately, as illustrated in the lower part of Fig. 13.16. In this case, the length of the delay line for the reflected path must be adjusted by subtracting from it the common delay length and its attenuation factor appropriately scaled.

The portion of the signal processing block diagram within the dashed lines at the bottom of Fig. 13.16 is a feedforward comb filter. This simulated system results in a feedforward filter structure because none of the propagated sounds return to the listener. Thus, depending on the distance between the direct and reflected paths, certain frequency components in the sound will be destructively canceled at the listener position, which would correspond to the notches in the frequency response of the feedforward comb filter. In this way, the feedforward comb filter is a computational physical model of a source–listener arrangement involving a direct and single reflected path.

Another simulated source–listener arrangement is shown in Fig. 13.17, where the emitted sound is assumed to propagate back-and-forth between two parallel rigid walls of infinite extent. The corresponding signal processing block diagram is shown in Fig. 13.18. In this case, the sound is reflected back to the listener in a repeated fashion, thus the resulting filter structure has a feedback path. The portion of the signal processing structure within the dashed lines in Fig. 13.18 is a feedback comb filter. If the distance between the two walls is d and the listener is located at the wall opposite the source, the length of the initial delay line is $M1 = d/(cT)$, while the delay line in the feedback loop will be of length $M2 = 2d/(cT)$ (because the sound will return to the listener after propagating to the opposite wall and back). The gain factors would have to be determined

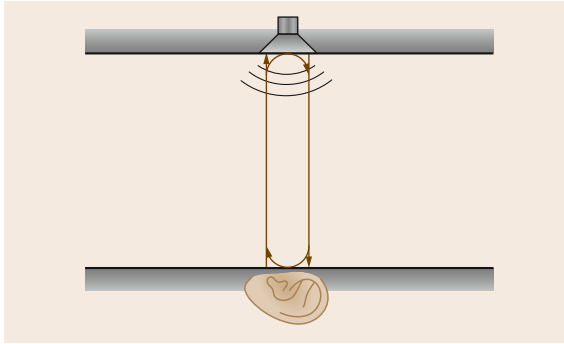

Fig. 13.17 Illustration of reflections between parallel walls

based on losses corresponding to air attenuation. If the walls were not assumed rigid, their reflection coefficient would also need to be included. As seen with the feedback comb filter, certain frequency components will feedback in phase with the emitted sound, producing *room* resonances at frequencies that are evenly spaced across the spectrum based on the distance between the walls. Such a phenomena is referred to as *flutter echo*. Thus, the feedback comb filter can be regarded as a computational physical model of a series of echoes, exponentially decaying and uniformly spaced in time.

Signal processing structures using delay lines have been widely explored to simulate much more complex room acoustics scenarios and artificial reverberation algorithms [13.3–7]. The fields of room acoustics modeling and artificial reverberation are well beyond the scope of this chapter but the underlying concepts are the same. In general, most artificial reverberation work has focused more on achieving flexible, efficient, and good sounding results without concern for accurately modeling particular room geometries.

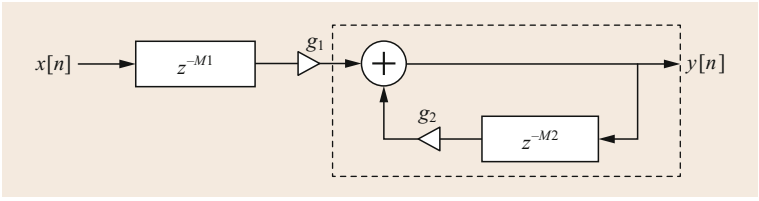

Fig. 13.18 Block diagram for simulation of reflections between parallel walls

13.3 Digital Waveguides

It is clear that delay lines provide an efficient way to simulate traveling-wave propagation. The concept of a *digital waveguide* derives more specifically from the discrete-time solution to the general one-dimensional (1-D) wave equation. Digital waveguides have been explored with great success over the past 30 years to achieve high-quality sound synthesis of musical instruments [13.8–17]. This brief treatment will focus on applications to plucked string instruments, though much research has been conducted on the use of digital waveguides in wind instrument modeling and synthesis as well [13.18–24].

13.3.1 1-D Traveling Waves

To first approximation, wave motion on a stretched string can be reasonably well approximated as 1-D, such that the string is considered to move only within an x–y plane. Lossless one-dimensional wave propagation along a stretched string is described by the 1-D wave equation as

$$\frac{\partial^2 y}{\partial t^2} = c^2 \frac{\partial^2 y}{\partial x^2} ,$$

where $c = \sqrt{\tau/\epsilon}$ is the speed of wave motion on the string, τ is the string tension, and ϵ is the mass density of the string. A particular solution to this equation was published by d'Alembert in 1747 having the general form

$$y(t,x) = y_\mathrm{r}\left(t - \frac{x}{c}\right) + y_\mathrm{l}\left(t + \frac{x}{c}\right) ,$$

for arbitrary functions $y_\mathrm{r}(\cdot)$ and $y_\mathrm{l}(\cdot)$. The subscripts r and l refer to right and left, respectively, because a function of $(t - x/c)$ can be interpreted as a fixed waveshape traveling to the right (in the positive x direction) over time and a function $(t + x/c)$ can be interpreted as a fixed waveshape traveling to the left (in the negative x direction) over time, both with speed c. As such, this solution describes *traveling waves* moving in opposite directions along a one-dimensional string, the superposition of which results in the observed physical displacement of the string. Note that it is theoretically possible to have only a single traveling-wave component present on the string, though a real string must be of finite length and thus fixed at one or both ends. A wave component that propagates into a fixed or free end will be reflected back in the opposite direction (as further described below).

To develop a discrete-time model or simulation of traveling-wave motion, it is necessary to sample the traveling-wave amplitudes in both time and space. The temporal sampling interval is T_s seconds, which corresponds to a sample rate $f_\mathrm{s} = 1/T_\mathrm{s}$ samples per second. The spatial sampling interval is given most naturally by $X = cT_\mathrm{s}$, or the distance traveled by a wave in one temporal sampling interval. In this way, each traveling-wave component moves left or right one spatial sample for each time sample.

The time and spatial sampling is accomplished with the following change of variables

$$\begin{aligned} x &\to x_m = mX \\ t &\to t_n = nT_\mathrm{s} , \end{aligned}$$

where n and m are integer indices of time and space, respectively. The traveling-wave solution then becomes

$$\begin{aligned} y(t_n, x_m) &= y_\mathrm{r}\left(t_n - \frac{x_m}{c}\right) + y_\mathrm{l}\left(t_n + \frac{x_m}{c}\right) \\ &= y_\mathrm{r}\left(nT_\mathrm{s} - \frac{mX}{c}\right) + y_\mathrm{l}\left(nT_\mathrm{s} + \frac{mX}{c}\right) \\ &= y_\mathrm{r}[(n-m)T_\mathrm{s}] + y_\mathrm{l}[(n+m)T_\mathrm{s}] . \end{aligned}$$

This representation can be further simplified by suppressing explicit reference to T_s and defining

$$\begin{aligned} y^+(n,m) &= y_\mathrm{r}(nT_\mathrm{s}, mT_\mathrm{s}) , \\ y^-(n,m) &= y_\mathrm{l}(nT_\mathrm{s}, mT_\mathrm{s}) , \end{aligned}$$

where the superscripts '+' and '−' denote wave travel to the right and left (or $+x$ and $-x$ directions), respectively. The resulting expression for physical displacement at time index n and location index m is given as the sum of the two traveling-wave components

$$y(t_n, x_m) = y^+(n-m) + y^-(n+m) . \qquad (13.1)$$

The term $y_\mathrm{r}[(n-m)T_\mathrm{s}] = y^+(n-m)$ can be interpreted as the output of an m-sample delay line of input $y^+(n)$. Similarly, the term $y_\mathrm{l}[(n+m)T_\mathrm{s}] = y^-(n+m)$ can be interpreted as the input to an m-sample delay line with output $y^-(n)$. The physical wave variable (string displacement in this case) is given by the superposition of the two traveling-wave components. Thus, we can accurately model one-dimensional motion on a string using two systems of unit delays, to model left- and right-going traveling waves, with delay-line values summed at corresponding *spatial* locations to obtain physical outputs, as depicted in Fig. 13.19.

In most modeling contexts, the calculation of physical output values can be limited to just one or two

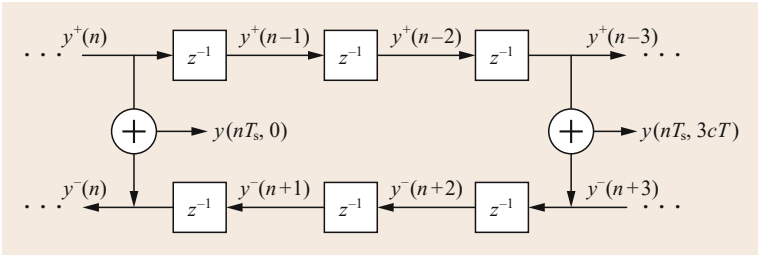

Fig. 13.19 Discrete-time simulation of ideal, lossless wave propagation with observation points at $x = 0$ and $x = 3X = 3cT_s$

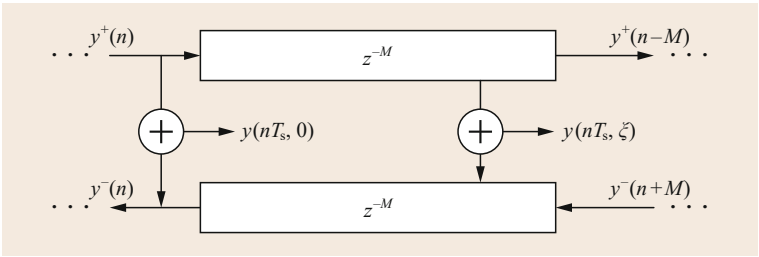

Fig. 13.20 Digital waveguide simulation of ideal, lossless wave propagation using delay lines

discrete spatial locations. Individual unit delays are more typically combined and represented by digital delay lines, as shown in Fig. 13.20.

Any ideal, lossless, one-dimensional waveguide can be simulated in this way. The model is exact at the sampling instants to within the numerical precision of the processing system. The delay lines can be initialized with displacement data corresponding to an initial pluck waveshape, though the waveshapes must be bandlimited to less than half the sampling frequency to avoid aliasing (as in all discrete-time systems).

13.3.2 Lossy Wave Propagation

Real wave propagation is never lossless. Sound waves in air lose energy via molecular frictional forces. Mechanical vibrations in strings are dissipated through yielding terminations, the viscosity of the surrounding air, and via internal frictional forces. In general, these losses vary with frequency.

Losses are often well approximated by the addition of one or more terms to the wave equation. In the simplest case, we can add a frequency-independent force term that is proportional to the transverse string velocity ($\partial y/\partial t$),

$$\tau \frac{\partial^2 y}{\partial x^2} = \epsilon \frac{\partial^2 y}{\partial t^2} + \mu \frac{\partial y}{\partial t} ,$$

where μ is a resistive proportionality constant. That is, the force lost to internal damping in the string is assumed to scale linearly with velocity. Assuming the resistive coefficient is relatively small, the following general class of solutions to this equation can be found

$$y(t,x) = \mathrm{e}^{-(\mu/2\epsilon)x/c} y_\mathrm{r}(t - x/c) + \mathrm{e}^{(\mu/2\epsilon)x/c} y_\mathrm{l}(t + x/c) .$$

The sampled solution is then

$$y(t_n, x_m) = g^m y^+(n-m) + g^{-m} y^-(n+m) ,$$

where

$$g = \mathrm{e}^{-\mu T_s/2\epsilon} .$$

Thus, a small decay factor should be inserted between each unit delay, as illustrated in Fig. 13.21.

Because the system is linear and time-invariant, the loss terms can be commuted and implemented at discrete points for efficiency as previously discussed in Sect. 13.2. In the more realistic situation where losses are frequency dependent (and typically of *lowpass* characteristic), the g factors are replaced with frequency responses of the form $G(\omega)$. These responses can likewise be commuted and implemented at discrete spatial locations within the system.

13.3.3 Reflections

Thus far, we have only considered wave propagation along a uniform, one-dimensional string of undefined length. In an anechoic or nonreflecting waveguide, waves traveling in only one direction may exist and can thus be simulated with just a single delay line. But in real situations, the media in which waves travel are of finite length and reflections occur at the boundaries that

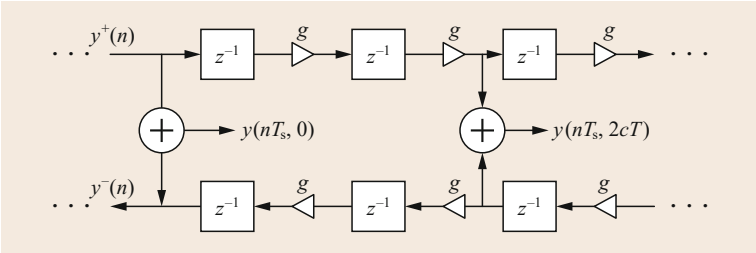

Fig. 13.21 Discrete-time simulation of lossy wave propagation

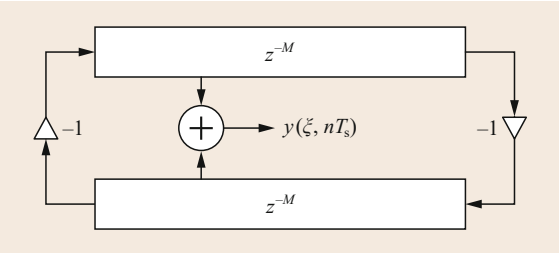

Fig. 13.22 Digital waveguide simulation of 1-D wave propagation on a string fixed at both ends

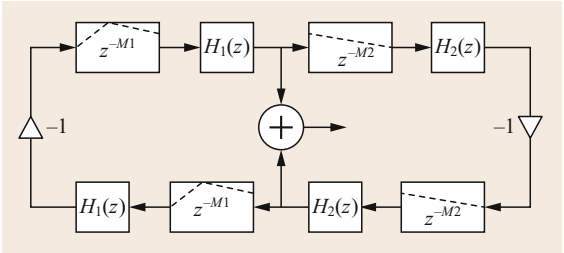

Fig. 13.23 Digital waveguide simulation of lossy wave propagation on a string fixed at both ends (with initial displacement)

give rise to waves traveling in two directions per dimension.

If we consider a string to be rigidly fixed at a position L, the boundary condition at that point is $y(t, L) = 0$ for all time. From the traveling-wave solution to the wave equation, we then have $y_r(t-L/c) = -y_l(t+L/c)$, which implies that displacement traveling waves reflect from a fixed end with a change of sign (or a reflection coefficient $R = -1$). Thus, a displacement wave component traveling into a rigidly fixed boundary at $x = L$ will be completely reflected back from that boundary, though it must be inverted when reflected back so that the boundary condition $y(t, L) = 0$ is satisfied. The simulation of displacement wave motion in a string rigidly terminated at both its ends (and without losses) is illustrated in Fig. 13.22.

In general, any change in the physical properties of the string (such as a diameter change) will cause wave scattering, which involves partial reflection and partial transmission at the boundary in such a way that energy is conserved.

13.3.4 The Plucked String Model

Finally, a full plucked string model is obtained by adding loss filters to the rigidly terminated string model from above and providing an initial displacement condition before the model is computed, as illustrated in Fig. 13.23. For example, if we assume the string is initially plucked by pulling it upward at a position $x = L/4$ and then releasing it, this condition would be simulated by initializing the internal elements of the upper and lower delay lines with values corresponding to that shape (1/2 of the displacement for each delay line, since the physical displacement of the string is given by the sum of the two traveling-wave components at any given position). For the moment, we will not be concerned with the details of the loss filters, though they would have a lowpass characteristic with a cutoff frequency that depends on the number of samples in each delay line (thus, the length of the simulated string).

The plucked string digital waveguide model above is typically modified in several ways to better correspond to the physical reality of plucked string instruments. In general, the majority of the sound produced by string instruments does not come directly from the string itself because strings do not transfer their vibrations well into the surrounding air (one might simply say that they cannot *push* the air in an efficient way). Rather, some of the string energy is transferred through one of the string terminations (the bridge) into a soundboard that can better transform the mechanical vibrations of the string into sound pressure fluctuations in air. Thus, the bridge termination of the string is not perfectly rigid as originally assumed but in fact can vibrate in a way that allows some of the string energy to *leak* into the body and then be radiated into the air. Rather than be represented by a reflection coefficient of -1, the bridge termination should be modeled by a frequency-dependent filter, $H_b(z)$, that simulates this behavior.

The output of the model is taken from both sides of the bridge filter as shown in Fig. 13.24a, which corre-

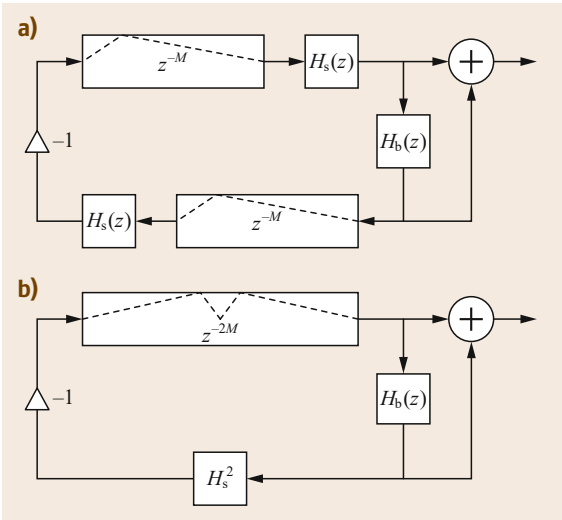

Fig. 13.24a,b Digital waveguide simulation of lossy wave propagation on a string with output through a nonrigid bridge. **(a)** Two delay line implementation. **(b)** Simplified (commuted) and more efficient implementation

sponds to the physical motion of the bridge. Because the system is linear, this structure can subsequently be simplified by rearranging and combining the two delay lines and the two string loss filters as illustrated in Fig. 13.24b.

The model output as calculated in Fig. 13.24 represents the motion of the bridge in response to vibrations of a plucked string. To accurately represent the sound from a string instrument, this output should then be input to a filter representing the vibrational response of the instrument body and its subsequent radiation of sound into the air. The body response is typically given by its time-domain impulse response, which can be measured or simulated. For example, one can tap lightly on the bridge of an instrument and record the resulting sound at some position away from the instrument in an anechoic room. The time samples of this recording, normally several tens of thousands of samples long, become the coefficients of an FIR bridge-to-air filter. Every output sample from the digital waveguide string model is then filtered by this body filter. As all parts of the model are assumed to be linear, however, it is possible to rearrange the body and string responses using an approach referred to as *commuted synthesis* [13.10]. In linear systems, the order of operations can be changed without affecting the overall output. For the plucked string model, commutivity thus allows the body impulse response to be used as the input to the delay line representing the string, with some prefiltering to account for pluck position. This results in significant computational savings because implementation of the long FIR body filter is avoided.

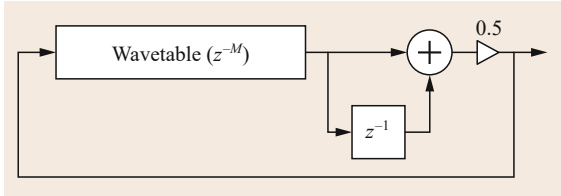

Fig. 13.25 The Karplus–Strong algorithm (reproduced from [13.25])

A variety of further simplifications are often exploited for computational efficiency. For example, the bridge, loss filters, and *nut* multiplier (the −1 scalar) are typically commuted together and the output taken from only one *side* of this filter. The resulting single loss filter can be designed based on a desired string decay rate [13.2]. Also, the resulting output of the system continues to sound like a plucked string for almost any sort of initialization of the delay line values. That is, any sort of wide-bandwidth input (including a single impulse in only one memory location of the delay line) will produce the sensation of a plucked string sound. These simplifications do not necessarily have physical justifications but are made for efficiency and because the resulting auditory result remains convincing.

At this point, it is interesting to consider the signal processing block diagram of Fig. 13.25 proposed by *Karplus* and *Strong* [13.25] to produce *surprisingly rich and natural* plucked string sounds. Karplus and Strong had been experimenting in the late 1970s with variations on wavetable synthesis in an effort to find efficient ways to achieve more interesting sounds. Wavetable synthesis generally involves the storage and subsequent playback, at varying rates (or frequencies), of a single period of a periodic sound. Perfectly periodic sounds do not sound natural and thus, Karplus and Strong added an operation at the output of the wavetable (Fig. 13.25) involving a simple averaging of the current and previous outputs, to change the content of the table over time. This operation is defined by the difference equation $y[n] = 0.5(x[n] + x[n-1])$, a first-order FIR filter that is equivalent to a linear interpolation filter with $\Delta = 0.5$ (with a frequency response as shown in Fig. 13.6). Karplus and Strong suggested initializing the wavetable with noise. By comparing Figs. 13.24 and 13.25, we see that the Karplus–Strong model can be interpreted as a simplified computational physical model of a plucked string, a result that was noted by *Jaffe* and *Smith* [13.2].

The Matlab code below, a minimally altered version of the delay line implementation provided in Sect. 13.1.1, implements the Karplus–Strong plucked string algorithm.

```
fs = 44100;
N = fs * 4; % compute 4 seconds
M = 60; % fixed delay line length
delayline = 2 * rand(1, M) - 1;
ptr = 1;
y = zeros(1, N); % output signal
xm1 = 0; % previous delay output

for n = 1:N,
  x = delayline(ptr); % delay output
  y(n) = 0.5 * (x + xm1); % do average
  xm1 = x; % save last output
  delayline(ptr) = y(n); % feedback
  ptr = ptr + 1; % increment pointer
  if ptr > M, % check pointer limit
    ptr = 1;
  end
end
soundsc( y, fs );
```

This section only touched upon the basics of musical instrument modeling and digital waveguide synthesis. Many more extensions have been proposed to account for numerous physical phenomena. For example, bending stiffness in strings results in dispersion, or a frequency-dependent speed of wave propagation, and this effect can be modeling using allpass filters [13.26]. The analysis and synthesis of transverse, longitudinal, and torsional string vibrations in multiple dimensions coupling at the bridge is reported in [13.27, 28]. The bowed string interaction has been studied in depth and efficient models developed in [13.29, 30]. Finally, digital waveguide modeling of wave propagation in two-dimensional (2-D) and three-dimensional (3-D) systems, such as in drum membranes, was first proposed by [13.31, 32]. The interested reader should consult the references provided in this chapter, as well as the comprehensive overview of [13.17].

14. Convolution, Fourier Analysis, Cross-Correlation and Their Interrelationship

Jonas Braasch

The scope of this chapter is to derive and explain three fundamental concepts of acoustical signal analysis and synthesis: convolution, Fourier transformation, and cross-correlation. Convolution is an important process in acoustics to determine how a signal is transformed by an acoustical system that can be described through an impulse response, a room, for example. Fourier analysis enables us to analyze a signal's properties at different frequencies. This method is then extended to Fourier transformation to convert signals from the time domain to the frequency domain and vice versa. Further, the method of cross-correlation is introduced by extending the orthogonality relations for trigonometric functions that were used to derive Fourier analysis. The cross-correlation method is a fundamental concept to compare two signals. We will use this method to extract the impulse response of a room by comparing a signal measured with a microphone after being transformed by a room with the original, measurement signal emitted into the room using a loudspeaker. Based on this and other examples, the mathematical relationships between convolution, Fourier transformation, and correlation are explained to facilitate deeper understanding of these fundamental concepts.

In this chapter, we introduce and discuss three related methods to analyze and process time-based functions and systems: convolution, Fourier analysis, and cross-correlation. All three methods are of fundamental importance when examining acoustical systems such as musical instruments, concert venues, and electroacoustic systems, among many other acoustical applications. These techniques are also essential to understand how the auditory system processes sound.

14.1 Convolution

D'Alembert [14.1] was the first to publish an equation representing the convolution integral. A few years later, *Laplace* [14.2] used convolution to calculate the mean of a distribution – see [14.3] and [14.4]. *Doetsch* [14.5] and others laid the mathematical foundation to use the convolution operation to process signals. In the 1980s, computers were available to convolve audio signals with longer impulse responses in the frequency domain [14.6].

Convolution is a mathematical process in the time domain that describes a system with a defined impulse response as shown in Fig. 14.1. A signal passing through the system is transformed by convolution with the system's impulse response. A good example for such a system is an acoustical enclosure, such as the music performance space shown on the left in Fig. 14.2. A room has a characteristic impulse response, as shown on the right in Fig. 14.2, which determines much of what we hear when we speak or play an instrument in the aforementioned space. To hear this impulse response, we can excite the room with a very short impulsive signal such as a handclap, a balloon pop or a starter pistol.

An important property of the type of system we are investigating is that the duration of the impulse response

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_14

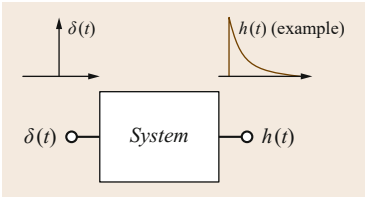

Fig. 14.1 Impulse response $h(t)$ of a system as the system's output to an impulsive input signal $s(t)$

is usually longer than the brief impulse. The duration of the impulse response of a typical church, for example, is in the order of several seconds. The central point that will allow us to grasp the concept of convolution is to understand how the system will respond to input signals of longer duration and how we can describe this mathematically.

To illustrate the general problem, let us next assume that we have two consecutive handclaps that generate an impulse response in a room (Fig. 14.3a) where the two resulting impulse responses overlap in time (Fig. 14.3b). Now we need to find a method describing how to overlap the impulse response of the first signal with that of the second. For this purpose, we mathematically define the handclap as an impulse. We will then see that we can describe any complex signal as a series of such impulses over time. The Dirac delta is strictly mathematically speaking not a function, but to intuitively understand the Dirac delta it is often represented as

$$\delta(t) = \begin{cases} \infty & \text{for } t = 0 \\ 0 & \text{for } t \neq 0 \end{cases} . \tag{14.1}$$

It is an impulse of infinite amplitude. Mathematically, only the distribution of the Dirac delta is defined, setting the area over the Dirac delta to be one

$$A = \int_{-\infty}^{\infty} \delta(t)\mathrm{d}t = 1 . \tag{14.2}$$

(The other commonly used delta function is the Kronecker delta, defined as

$$\delta(t) = \begin{cases} 1 & \text{for } t = 0 \\ 0 & \text{for } t \neq 0 \end{cases} , \tag{14.3}$$

with amplitude of 1.)

According to Fig. 14.1, the response of the room to the impulse signal $\delta(t)$ is

$$h(t) = \psi\left\{\delta(t)\right\} , \tag{14.4}$$

where ψ is the system response.

If we assume that the response of a room can be treated as time invariant, we will get the same impulse response $h(t)$ for a time-shifted impulse $\delta(t-\tau)$; the impulse response is simply shifted by the same time interval τ

$$h(t-\tau) = \psi\left\{\delta(t-\tau)\right\} . \tag{14.5}$$

Since the room is a sufficiently linear system, a change of the amplitude a of the input impulse $\delta(t-\tau)$ will change the amplitude of the impulse response in the same way

$$ah(t-\tau) = \psi\left\{a\delta(t-\tau)\right\} . \tag{14.6}$$

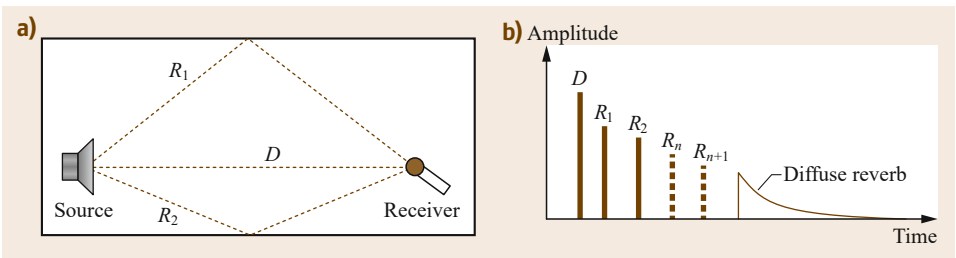

Fig. 14.2 **(a)** Example sound pathways, including one direct D and two wall reflections R_1 and R_2, between source and receiver in a room, forming the room impulse response shown in **(b)**

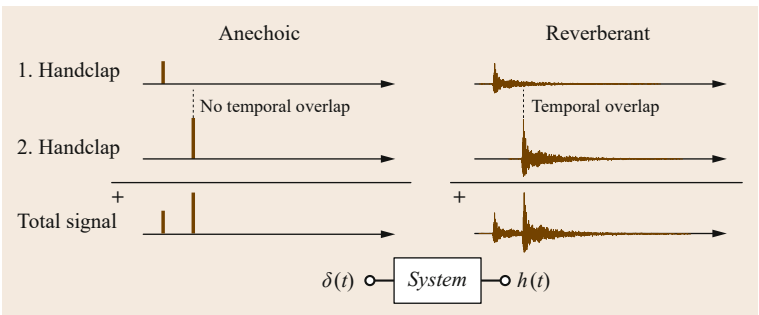

Fig. 14.3 Example of acoustically exciting a room with two successive handclaps. The *left graphs* show the time courses of the two handclap source signals individually (*two top graphs*) and as a total signal (*bottom graph*). The *right graphs* show the same signals but measured at a distance where the signals are affected by the room impulse. In this case, the two handclaps overlap in sound (*bottom-right graph*)

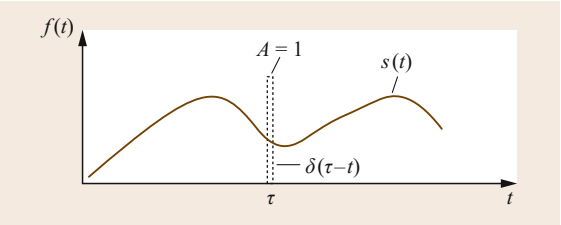

Fig. 14.4 Determining the value of a signal $s(t)$ using a Dirac delta function $\delta(t)$ with area A of 1

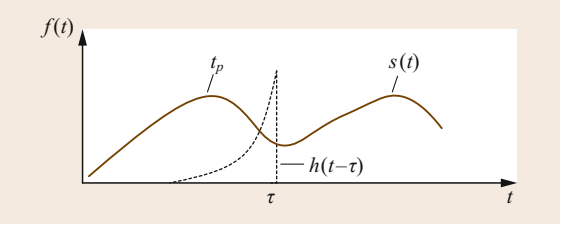

Fig. 14.5 Relationship between the signal $s(t)$ and the flipped impulse response $h(t)$ in the convolution process

The example of two consecutive impulses from Fig. 14.3 can now be written as

$$\begin{aligned} a_1 h(t-\tau_1) + a_2 h(t-\tau_2) &= \sum_{n=1}^{2} a_n h(t-\tau_n) \\ &= \sum_{n=1}^{2} a_n \psi\{\delta(t-\tau_n)\} = \sum_{n=1}^{2} \psi\{a_n \delta(t-\tau_n)\} \\ &= \psi\left\{\sum_{n=1}^{2} a_n \delta(t-\tau_n)\right\} \\ &= \psi\{a_1\delta(t-\tau_1) + a_2\delta(t-\tau_2)\}\,, \end{aligned} \tag{14.7}$$

by using the principle of superposition. Superposition is defined as

$$\psi\left\{\sum_{n=1}^{N} a_n s_n(t)\right\} = \sum_{n=1}^{N} a_n \psi\,\{s_n(t)\} = \sum_{n=1}^{N} a_n g_n(t) \tag{14.8}$$

and can be generally applied to *linear time-invariant* (LTI) systems. As the name indicates, an LTI system $\Psi\{s(t)\} = g(t)$ must meet the criteria of *linearity* toward an amplitude change a, i. e., $ag(t) = \Psi\{as(t)\}$, and *time invariance* toward a time shift τ, i. e., $g(t-\tau) = \Psi\{s(t-\tau)\}$.

Next, we analyze the system response $\Psi\{s(t)\}$ for a more complex input signal $s(t)$ by taking advantage of the fact that we can represent any signal as a series of adjacent amplitude-weighted Dirac delta functions. Because the Dirac delta has a defined area under the integral, we can use it to determine the value of a signal $s(t)$ at any time instance t we want

$$s(\tau) = \int_{-\infty}^{\infty} s(t)\delta(\tau - t)\mathrm{d}t\,. \tag{14.9}$$

The signal $s(\tau)$ represents the value of the signal $s(t)$ at time τ (Fig. 14.4).

We can also exchange t and τ and write

$$s(t) = \int_{-\infty}^{\infty} s(\tau)\delta(t - \tau)\mathrm{d}\tau\,. \tag{14.10}$$

This new equation basically describes how we resynthesize the signal $s(t)$ from many delta impulses $\delta(t-\tau)$ that are amplitude weighted with $s(\tau)$. Since we know the response of the system to every delta function in time, we can substitute $\delta(t)$ with $h(t)$ to obtain the system response to a complex time signal $s(t)$ using a process defined as *convolution*

$$g(t) = \int_{-\infty}^{\infty} s(\tau)h(t - \tau)\mathrm{d}\tau\,. \quad \textit{Convolution} \tag{14.11}$$

Convolution is often denoted as $g(t) = s(t) * h(t)$ (where the asterisk should not be mistaken for the multiplication sign). Figure 14.5 depicts the idea of the convolution process. At any time instance τ, we not only see the current signal $s(\tau)$ but also signal components back in time t_p, all weighted by the time-reversed impulse response $h(t-\tau)$, and this time reversal lends its name to convolution.

14.2 Fourier Frequency Analysis and Transformation

In 1822, *Jean-Baptiste Joseph Fourier* [14.7] described his analysis method, now known as Fourier analysis, to understand heat flow. A modern overview of the discrete Fourier transformation, which is commonly used for digital signal processing applications, can be found in [14.8]. This book also discusses the fast Fourier transformation (FFT). The FFT is a discrete Fourier transformation (DFT) method to save computational costs by using sparse matrices that contain mostly zero elements to reduce the computational load. The FFT method requires that the signal length be a power of two.

Convolution has a very interesting property: it becomes simple multiplication in the frequency domain. Since multiplication and conversion to the frequency domain are computationally less expensive than convolution, computer-based systems often take this approach. Before we can demonstrate how convolution in the time domain converts to multiplication in the frequency domain, we need to review general frequency analysis and conversion of signals based on the Fourier theorem (often referred to as *synthesis*).

Let us start with frequency analysis based on the Fourier series for periodic signals. A periodic signal $s(t)$

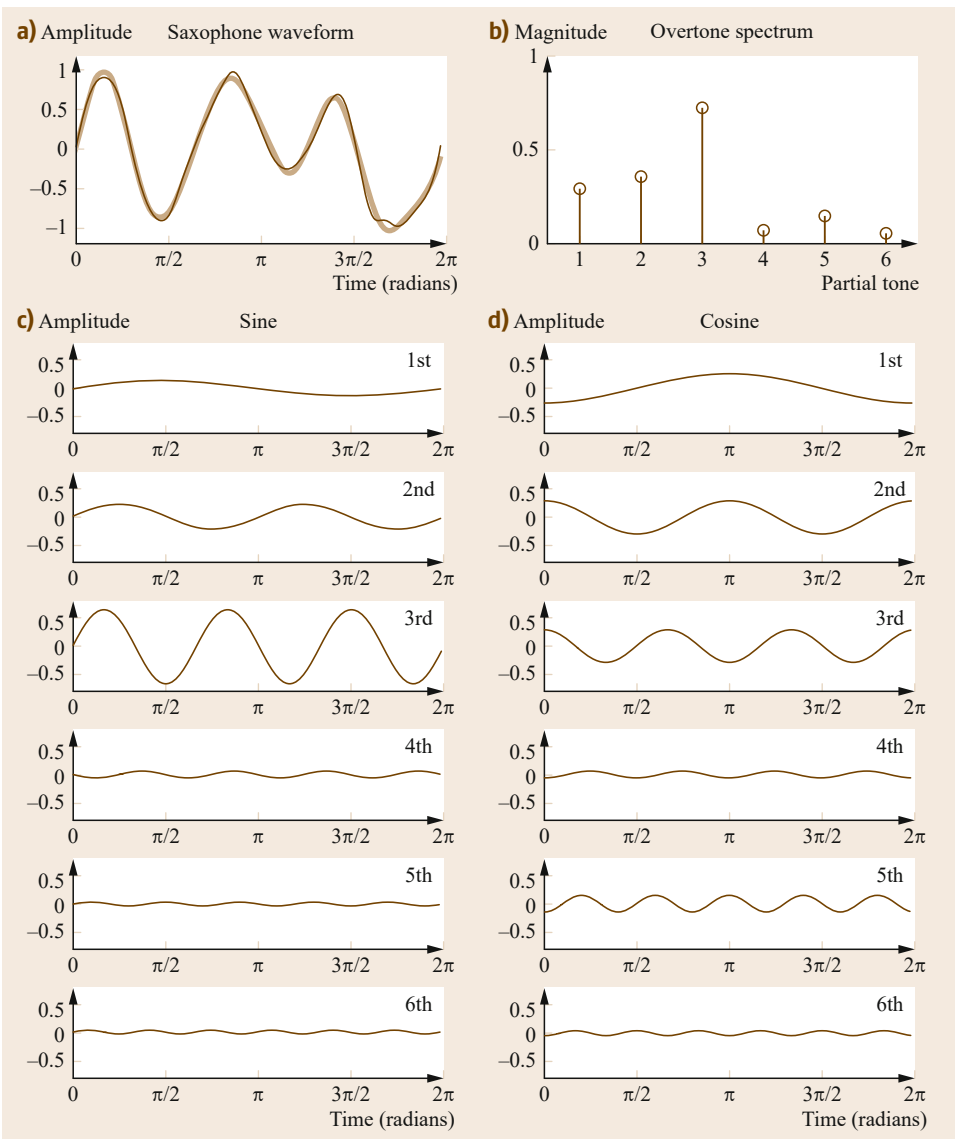

Fig. 14.6a–d The *solid black line* in **(a)** shows an example of a saxophone waveform ($f_0 = 440\,\text{Hz}$) with the individual magnitudes $c_{0n} = \sqrt{a_n^2 + b_n^2}$ of the partial tones shown in **(b)**. **(c,d)** show the periodic functions for each partial tone separated into the sine and cosine components. The *gray line* in **(a)** shows the reproduction of the saxophone waveform as the sum of the partial-tone components

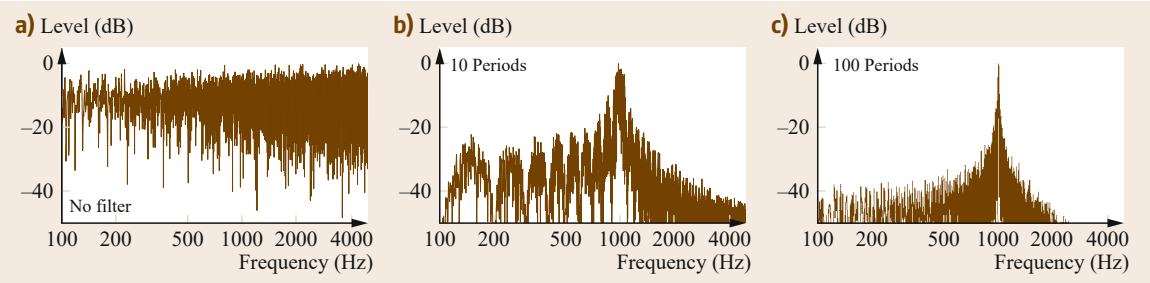

Fig. 14.7a–c Filter properties of a sine function. **(a)** shows the frequency spectrum of a Gaussian broadband noise signal. **(b)** depicts the spectrum of the same noise signal after it has been convolved with a 10-period-long 1 kHz sine tone. **(c)** shows the same condition, but this time the 100-period-long 1 kHz sine tone was used as the filter

can be defined in the time domain as

$$s(t+T) = s(t) \;\forall t \in \mathrm{Re}\ . \tag{14.12}$$

The variable T is the period of the signal, which indicates that the signal repeats itself every T seconds. For practical purposes, let us take the sample of a saxophone tone $s(t)$ shown in Fig. 14.6a (black solid line) as a periodic signal and determine the amplitudes of the tone's individual harmonics shown in Fig. 14.6b. Let us assume that we know the fundamental frequency $f_0 = 1/T$ of the tone. Since it is a wind instrument, we can also assume that the frequencies of the higher harmonics f_n are integer multiples of the fundamental tone nf_0. According to Fourier's theorem, we can now represent each harmonic s_n using a combined sine/cosine term

$$s_n(t) = a_n \cos(2\pi f_n t) + b_n \sin(2\pi f_n t)\ . \tag{14.13}$$

Remember that the sine and cosine functions are essentially the same except for a 90° phase shift. Consequently, the sine function represents the signal component for a 0° phase shift and the cosine function for a 90° phase shift with respect to the sine function. The variables a_n and b_n represent the amplitudes of each of the two trigonometric functions. Often the angular frequency ω, which is defined as $\omega = 2\pi f$, is used instead of the linear frequency f to avoid having to carry the term 2π along. We can represent the whole periodic signal as the sum over all partial tones – see gray line in Fig. 14.6a. The Fourier series is defined as

$$\begin{aligned} f(t) = a_0 &+ (a_1 \cos(\omega t) + b_1 \sin(\omega t)) \\ &+ (a_2 \cos(2\omega t) + b_2 \sin(2\omega t)) \\ &+ (a_3 \cos(3\omega t) + b_3 \sin(3\omega t)) + \ldots \end{aligned} \tag{14.14}$$

The a_0 term is the DC bias, the constant, average-valued offset of the function. Figure 14.6c,d shows the individual partial tone components of the equation above for the saxophone waveform.

14.2.1 Filter and Orthogonality Properties of Sine and Cosine Functions

The next question we must ask is how we can analyze a periodic signal $s(t)$ to determine the amplitude coefficients a_n and b_n. In this context we need to understand that a sine or cosine acts as a filter if we convolve it with a signal; For example, if we take a Gaussian noise signal and convolve it with a sine signal of frequency f_c, only the single component of the Gaussian noise at this particular frequency will remain. Figure 14.7 shows an example of a Gaussian noise signal (Fig. 14.7a) that is filtered with two sine signals of different duration but the same frequency $f_c = 1$ kHz. Figure 14.7b shows the result for the short filter (10 ms = 10 periods), which is noticeably wider in frequency than the signal for the long filter (100 ms = 100 periods) shown in Fig. 14.7c.

Based on this filter property, we can now use the sine and cosine functions to filter out each partial tone for the given fundamental frequency $f = f_0$; For example, if we multiply the saxophone sample $s(t)$ with the sine function of the fundamental frequency and integrate it over one period $T = 1/f_0$, we will obtain another sinusoidal function with an amplitude corresponding to the intensity of the saxophone tone at that frequency and phase corresponding to the sine signal. If we apply the cosine function at $f = f_0$, we also filter out the fundamental, but now obtain a sinusoidal function that corresponds with the phase of the cosine signal.

Mathematically, the filter properties of sine and cosine functions are described by their orthogonality to each other. For two sine signals, we find the orthogonality

$$\int_0^{2\pi} \sin(kx)\sin(lx)\mathrm{d}x = \pi\delta_{kl} \quad \text{for } k,l \in N^+, \tag{14.15}$$

with $x = \omega_0 t$. The variables k and l are harmonic indices in the form of positive integers, formerly denoted as n. The delta function here is the Kronecker delta, which is defined as

$$\delta_{kl} = \begin{cases} 1 & \text{for } k = l \\ 0 & \text{for } k \neq l \end{cases} . \tag{14.16}$$

Basically, two sine functions are orthogonal to each other, which means their product when integrated over one period 2π is zero, unless both signals have the same frequency. In the latter case the product is π. From a filter perspective, we can assume that the first sine function is the signal we would like to analyze and the second sine function is the filter. We will obtain a residual only if the filter is tuned to the same frequency as the signal. In all other cases, the filter is looking at frequencies where there is no energy in the signal and so there is no residual.

We also find a similar relationship for the cosine function

$$\int_0^{2\pi} \cos(kx)\cos(lx)\mathrm{d}x = \pi\delta_{kl} \quad \text{for } k, l \in N^+ . \tag{14.17}$$

For the product of a sine function with a cosine function, the two functions are always orthogonal to each other, even if they share the same frequency

$$\int_0^{2\pi} \cos(kx)\sin(lx)\mathrm{d}x = 0 \quad \text{for } k, l \in N^+ . \tag{14.18}$$

Using these three orthogonality relationships, we can determine the amplitude coefficients a_n and b_n

$$\begin{aligned} a_n &= \frac{1}{\pi}\int_0^{2\pi} s(x)\cos(nx)\mathrm{d}x \quad \text{for } n \geq 0 , \\ b_n &= \frac{1}{\pi}\int_0^{2\pi} s(x)\sin(nx)\mathrm{d}x \quad \text{for } n \geq 1 , \end{aligned} \tag{14.19}$$

with $x = \omega_0 t$. The cosine and sine functions act as phase-sensitive filters. The following relationship can be used to determine the DC component a_0

$$\int_0^{2\pi} \cos(0x)\mathrm{d}x = \int_0^{2\pi} \mathrm{d}x = 2\pi . \tag{14.20}$$

The calculated coefficients a_n and b_n can then be used to resynthesize the periodic signal $s(t)$

$$s(x) = \frac{a_0}{2} + \sum_{n=1}^{\infty} (a_n \cos(nx) + b_n \sin(nx)). \tag{14.21}$$

The requirement for periodic signals to perform Fourier analysis should also be discussed. In theory, the Fourier series applies to periodic signals, but in practice aperiodic signals can be analyzed by approximating f_0 to zero, which of course prolongs the period $2\pi f_0$ toward ∞ ($x = \omega_0 t$, $T \to \infty$). In a practical application, of course, the integration window needs to be limited and the length of the sine and cosine filters then determines the frequency bandwidth of the extracted signal.

In the next section, we will explore how convolution in the time domain transforms into multiplication in the frequency domain. In order to demonstrate this, we need to represent the Fourier series using complex exponential functions

$$s(x) = \sum_{n=-\infty}^{\infty} c_n \mathrm{e}^{\mathrm{i}nx} . \tag{14.22}$$

The complex exponential function, also called the Euler identity, is defined as

$$\mathrm{e}^{\mathrm{i}nx} = \cos(nx) + \mathrm{i}\sin(nx) , \tag{14.23}$$

with i denoting the imaginary unit. Using the definition of the complex exponential function, we can express the cosine and sine functions in the following way

$$\begin{aligned} \cos(kx) &= \left(\frac{1}{2}\left(\mathrm{e}^{\mathrm{i}kx} + \mathrm{e}^{-\mathrm{i}kx}\right)\right) \quad \text{and} \\ \sin(kx) &= \left(\frac{1}{2\mathrm{i}}\left(\mathrm{e}^{\mathrm{i}kx} - \mathrm{e}^{-\mathrm{i}kx}\right)\right) . \end{aligned} \tag{14.24}$$

Now we can insert these two terms to derive the Fourier series representation using complex exponential functions

$$\begin{aligned} s(x) &= \frac{a_0}{2} + \sum_{k=1}^{\infty} (a_k \cos(kx) + b_k \sin(kx)) \\ s(x) &= \frac{a_0}{2} + \sum_{k=1}^{\infty} \left(a_k \left(\frac{1}{2}\left(\mathrm{e}^{\mathrm{i}kx} + \mathrm{e}^{-\mathrm{i}kx}\right)\right) \right. \\ &\quad \left. + b_k \left(\frac{1}{2\mathrm{i}}\left(\mathrm{e}^{\mathrm{i}kx} - \mathrm{e}^{-\mathrm{i}kx}\right)\right)\right) \\ s(x) &= \sum_{n=-\infty}^{\infty} c_k \mathrm{e}^{\mathrm{i}kx} \\ &\quad \text{with } c_k = \frac{1}{2}(a_k - \mathrm{i}b_k) , \quad c_{-k} = \frac{1}{2}(a_k + \mathrm{i}b_k) , \\ &\quad \text{and } k \geq 0 . \end{aligned} \tag{14.25}$$

The complex amplitude coefficient c_k can then be determined using this formula

$$c_k = \frac{1}{\pi}\int_0^{2\pi} s(x)\mathrm{e}^{-\mathrm{i}kx}\mathrm{d}x\,,$$
$$s(x) = \sum_{k=-\infty}^{\infty} c_k\mathrm{e}^{\mathrm{i}kx}\,. \tag{14.26}$$

We can also describe the complex amplitude coefficient c_k using the magnitude c_{0k} and phase φ_k as

$$c_k = c_{0k}\mathrm{e}^{\mathrm{i}\varphi_k}\,, \tag{14.27}$$

with magnitude

$$c_{0k} = \sqrt{a_k^2 + b_k^2} \tag{14.28}$$

and phase

$$\varphi = \arctan\left(\frac{b_k}{a_k}\right). \tag{14.29}$$

For continuous frequency signals, the Fourier transformation is typically written as

$$S(f) = \int_{-\infty}^{\infty} s(t)\mathrm{e}^{-\mathrm{i}2\pi ft}\mathrm{d}t\,, \tag{14.30}$$

and the inverse Fourier Transformation is defined as

$$s(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} S(f)\mathrm{e}^{\mathrm{i}2\pi ft}\mathrm{d}f\,. \tag{14.31}$$

The term $1/2\pi$ is a normalization factor to ensure that a Fourier-transformed signal recovers its original amplitude when retransformed into the time domain using the inverse Fourier transformation.

14.2.2 Convolution in the Frequency Domain

In this section, we will demonstrate that convolution in the time domain becomes multiplication in the frequency domain. As mentioned above, the process of multiplication of Fourier transforms is a computationally less expensive operation than convolution. For this reason, computers typically perform convolution in the frequency domain.

Our proof starts with the convolution in the time domain

$$g(t) = s(t) * h(t) = \int_{-\infty}^{\infty} s(\tau)h(t-\tau)\mathrm{d}\tau\,. \tag{14.32}$$

In the next step, we replace the signal $h(t-\tau)$ with the inverse Fourier-transformed signal in the frequency domain $H(f)$. We will see later that this will help us to separate t and τ

$$g(t) = \int_{-\infty}^{\infty} s(\tau)\left(\frac{1}{2\pi}\int_{-\infty}^{\infty} H(f)\mathrm{e}^{\mathrm{i}2\pi f(t-\tau)}\mathrm{d}f\right)\mathrm{d}\tau\,. \tag{14.33}$$

The exponential function provides the fortunate feature that the term $(t-\tau)$ is now in the exponent of the signal and we can separate the two variables using a mathematical property of the e-function $\mathrm{e}^{(x+y)} = \mathrm{e}^x\mathrm{e}^y$, in our case substituting $x = \mathrm{i}2\pi ft$ and $y = -\mathrm{i}2\pi f\tau$. We separate the t and τ terms using the relation $\mathrm{e}^{\mathrm{i}2\pi f(t-\tau)} = \mathrm{e}^{\mathrm{i}2\pi ft}\mathrm{e}^{-\mathrm{i}2\pi f\tau}$

$$g(t) = \int_{-\infty}^{\infty} s(\tau) \times\left(\frac{1}{2\pi}\int_{-\infty}^{\infty} H(f)\mathrm{e}^{\mathrm{i}2\pi ft}\mathrm{e}^{-\mathrm{i}2\pi f\tau}\mathrm{d}f\right)\mathrm{d}\tau\,. \tag{14.34}$$

Next, we change the order of integration, which we can do as long as the double integral converges

$$g(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} s(\tau)H(f)\mathrm{e}^{\mathrm{i}2\pi ft}\mathrm{e}^{-\mathrm{i}2\pi f\tau}\,\mathrm{d}\tau\mathrm{d}f\,. \tag{14.35}$$

Then, we move out of the inner integral those terms that do not depend on τ to obtain

$$g(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} s(\tau)\mathrm{e}^{-\mathrm{i}2\pi f\tau}\,\mathrm{d}\tau H(f)\mathrm{e}^{\mathrm{i}2\pi ft}\mathrm{d}f\,. \tag{14.36}$$

It can now be seen that the inner integral is the Fourier transform of $s(\tau)$, and we substitute the term accordingly with $S(f)$

$$g(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} S(f)H(f)\mathrm{e}^{\mathrm{i}2\pi ft}\mathrm{d}f\,. \tag{14.37}$$

The inverse Fourier transform of $G(f)$ is written as

$$g(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} G(f)\mathrm{e}^{\mathrm{i}2\pi ft}\mathrm{d}f\,. \tag{14.38}$$

Since both integrals representing $g(t)$ have the same form, the integrand of the first equation $S(f)H(f)$ must equal the integrand of the second equation $G(f)$. Consequently, we have proved that

$$G(f) = S(f)H(f) \,. \tag{14.39}$$

We have shown that convolution in the time domain becomes multiplication in the frequency domain

$$g(t) = s(t) * h(t) \longleftrightarrow G(f) = S(f)H(f) \,. \tag{14.40}$$

This relationship is called the *convolution theorem for the Fourier transform.*

14.3 Cross-Correlation

The method of correlation was first introduced by *Bravais* in 1846 [14.9] to determine the error probability of a position in space. Forty years later, *Galton* [14.10] introduced the method of correlation to understand evolutionary processes, realizing that it could be applied to any set of variable pairs. *Pearson* [14.11] later proved that the method introduced by Bravais is the best fit to data with a linear relationship. Moreover, he introduced the Pearson product-moment correlation coefficient to measure the linear correlation between two variables, normalizing the degree of correlation between -1 (fully negative correlation) and $+1$ (fully positive correlation). *Pearson* [14.11] and *Stanton* [14.12] provide detailed overviews on the development of the correlation method. *Norbert Wiener* [14.13] laid the groundwork for the application of the cross- and autocorrelation functions to the analysis of time series, connecting the time-domain-based autocorrelation function to the frequency-domain-based power spectrum.

The cross-correlation method is a very powerful tool to compare the similarity of two signals. When we introduced Fourier analysis, we evaluated the similarity of two sine and cosine functions with different frequencies by multiplying them and integrating over their product. There we found that the sine and cosine functions (as well as sine and cosine functions of different frequencies) are orthogonal to each other

$$\int_0^T \cos(\omega t)\sin(\omega t)\mathrm{d}t = 0 \,, \tag{14.41}$$

with $\omega = 2\pi f$ and $f = 1/T$. However, at the same time, we agreed that cosine and sine functions are basically the same function, differing only by a phase shift of $\pi/2$

$$\cos(\omega t) = \sin\left(\omega\left(t + \frac{\pi}{2}\right)\right) . \tag{14.42}$$

In order to compensate for the phase shift, we now use a time delay τ to provide a tool to make our comparison function invulnerable to time and phase shifts between the two compared functions

$$\rho(\tau) = \int_0^T \cos(\omega t)\sin(\omega(t+\tau))\mathrm{d}t \,, \tag{14.43}$$

with the results $\rho(\tau = 0) = 0$ and $\rho(\tau = T/4 \to \varphi = \pi/2) = 1$. Now we generalize the equation above to any two input functions $x(t)$ and $y(t)$ and use the $f \to 0$ limit to define the cross-correlation

$$\rho_{x,y}(\tau) = \int_{-\infty}^{+\infty} x(t)y(t+\tau)\mathrm{d}t \,. \quad \textit{Cross-correlation} \tag{14.44}$$

For $\rho(\tau)|_{\max}$, the variable τ indicates for which time shift between the two functions they become most similar. The autocorrelation is a special case of the cross-correlation where both input signals x and y are identical

$$\rho_{x,x}(\tau) = \int_{-\infty}^{+\infty} x(t)x(t+\tau)\mathrm{d}t \,. \quad \textit{Autocorrelation} \tag{14.45}$$

The cross-correlation and the convolution are very similar functions that differ only in the sign of the second t. This becomes apparent if we use the variable convention from the previous equation for the convolution

$$g(\tau) = \int_{-\infty}^{+\infty} x(t)y(\tau - t)\mathrm{d}t = \int_{-\infty}^{+\infty} x(t)y(-t+\tau)\mathrm{d}t \,. \quad \textit{Convolution} \tag{14.46}$$

We can extend the cross-correlation function to the normalized cross-correlation function by dividing by the energies of both signals under analysis

$$\rho_{\mathrm{N}}(\tau) = \frac{\int_{-\infty}^{+\infty} x(t)y(t+\tau)\mathrm{d}t}{\sqrt{\int_{-\infty}^{+\infty} x^2(t)\mathrm{d}t \int_{-\infty}^{+\infty} y^2(t)\mathrm{d}t}} \,. \quad \textit{Normalized cross-correlation} \tag{14.47}$$

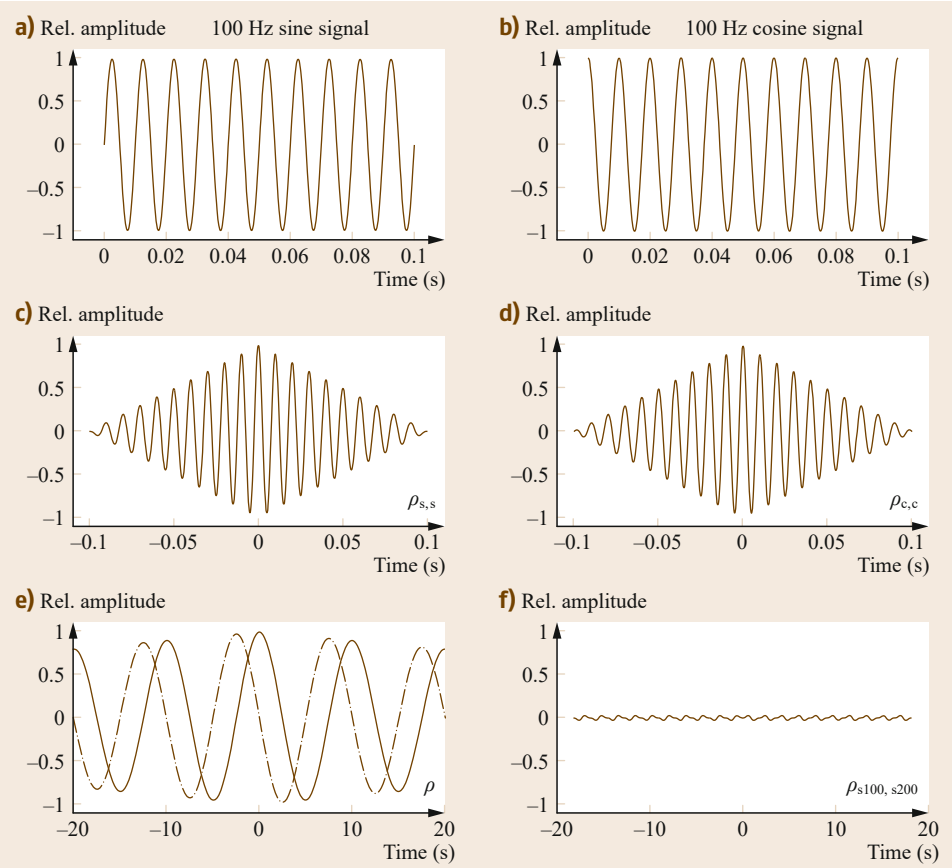

Fig. 14.8a–f Cross-correlation of two sinusoidal signals. The *top row* shows two 100 Hz signals (**(a)** sine signal; **(b)** cosine signal) that only differ by a 90° phase shift. The *center row* shows the autocorrelation function of both signals (**(c)** sine signal; **(d)** cosine signal), which turn out to be identical. Note that both functions have a peak value of 1 at an internal delay τ of 0 ms. **(e)** depicts the cross-correlation function between the sine and cosine signal (*dotted line*) versus the autocorrelation function of the sine signal. **(f)** shows the cross-correlation function of two sine signals with different frequencies (100 and 200 Hz)

For the normalized cross-correlation function, the possible range of $\rho(\tau)$ is restricted to values between -1 (fully inversely correlated) and 1 (fully correlated). A maximum value of 0 for $\rho(\tau)$ indicates that the two signals are fully uncorrelated. Consequently, a correlation value of 1 means the signals are identical at the time-shift delay τ, a value of -1 means they are identical but out of phase, and a value of 0 means they have no overlap in area.

Next, we use the normalized cross-correlation function to reexamine the orthogonality properties of trigonometric functions. Figure 14.8a,b show 100 Hz sine and cosine signals with duration of 0.1 s each. Both functions only differ in their phase. The autocorrelation function is depicted directly below each signal. Not surprisingly, the two sinusoidal signals are most identical to themselves without a temporal shift ($\tau = 0$). The reason the functions roll off to either side is because the signals no longer fully overlap in time. If the signals had been continuous, their autocorrelation functions would not roll off with τ. The autocorrelation goes to zero once one of the signals has been shifted beyond its duration ($\tau > 0.1$ s or $\tau < -0.1$ s). The local maxima in the autocorrelation functions occur each time the comparison signal is shifted by an integer multiple of the period T.

Now let us compare the sine and cosine signals with each other using the normalized cross-correlation function. The dotted line in Fig. 14.8e shows the result. Now the maximum is at 2.5 ms rather than at 0 ms. Compared with the previously discussed autocorrelation functions, the whole function is shifted by

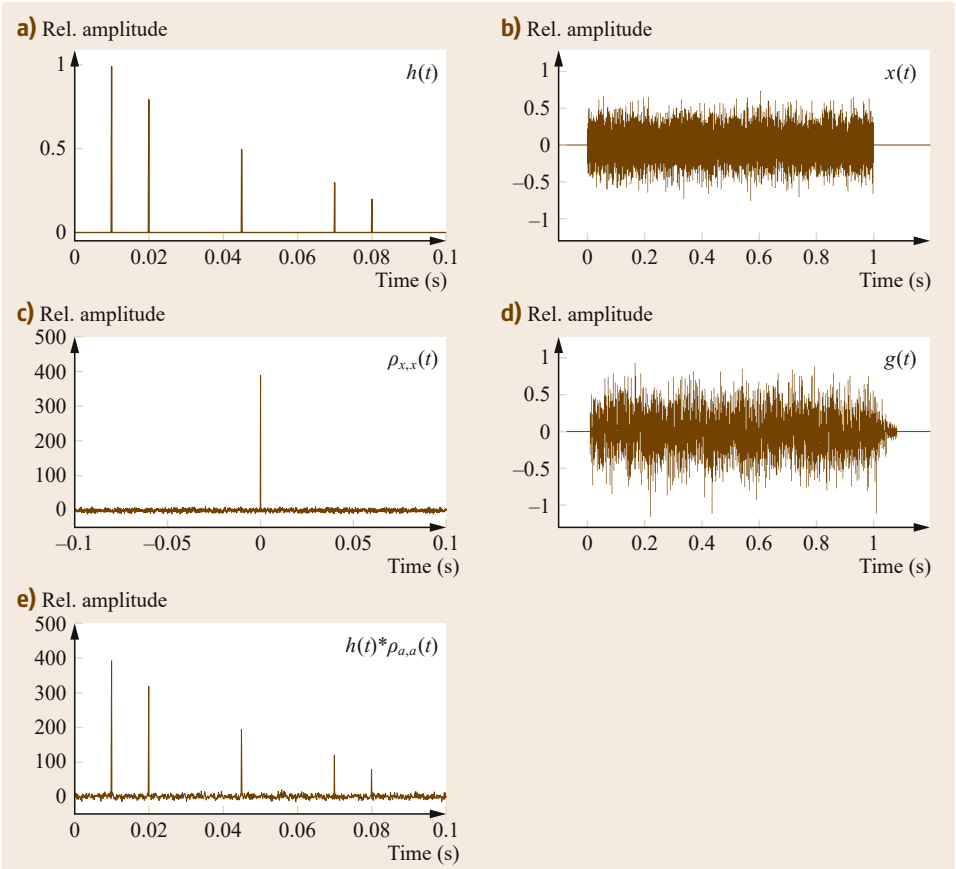

Fig. 14.9a–e Example of extracting an impulse response using the cross-correlation method. **(a)** shows an artificial impulse response with a direct sound at 0.01 s followed by four reflections. **(b)** shows the measurement signal, a 1 s Gaussian noise burst. The noise burst's autocorrelation function is basically a delta function with a peak at 0 ms and residual noise elsewhere **(c)**. **(d)** shows the measurement signal after it has been convolved with the impulse response. **(e)** shows the impulse response after it has been extracted from the convolved signals by means of cross-correlation with the original, nonconvolved measurement signal

2.5 ms, which is a quarter of the period $T = 10$ ms and corresponds to a phase shift of $\pi/2$ or 90°. Without the shift of the cosine function ($\tau = 0$ ms), the integrated product of the sine and cosine signals is 0, which explains why both signals were orthogonal to each other in Fourier analysis. However, if we consider sine signals with different frequencies (100 and 200 Hz), shifting one of the functions no longer works to obtain a significant cross-product. In fact, the latter would always remain zero if both functions were continuous.

14.3.1 Example: Extracting a Convolved Impulse Response

The main aim of this section is to understand the relationship between convolution and cross-correlation. *Stan* et al. [14.14] provide a detailed overview on standard methods to measure the impulse response of rooms and acoustic systems.

We end this chapter with a practical example of measuring an impulse response with a combined convolution/cross-correlation approach to shed more light on the properties of both methods. Let us assume that we would like to measure the hypothetical room impulse response shown in Fig. 14.9a. One way of measuring a room impulse response is to place a microphone at one position in the room as the receiver and then to excite the room with an impulse sound source (eg, a balloon pop or starting pistol) at a second position (Fig. 14.1). An alternative method that leads to better signal-to-noise ratios is to use a loudspeaker to play back a known, continuous signal such as the broadband noise signal $x(t)$ shown in Fig. 14.9a. A Gaussian noise signal has the advantage of having a delta function as its autocorrelation function for a continuous signal. Also, its power spectrum is constant, implying equal probabilistic energy at all frequencies (hence why its autocorrelation is a Dirac delta). This feature will become important for our method later on. The autocorrelation function of a Gaussian signal with restricted duration contains residual noise beside the delta peak, but is similar to the continuous signal case otherwise (Fig. 14.9c). When we record this signal coming from the loudspeaker position with the microphone at the receiver position, we obtain the source signal convolved

with the room impulse response

$$g(t) = \int_{-\infty}^{+\infty} x(\tau)h(t-\tau)\mathrm{d}\tau = \int_{-\infty}^{+\infty} h(\tau)x(t-\tau)\mathrm{d}\tau \,, \tag{14.48}$$

as shown in Fig. 14.9d. Now we cross-correlate the convolved signal with the original noise burst x that was played back from the loudspeaker

$$\rho_{x,g}(k) = \int_{-\infty}^{+\infty} g(n+k)x(n)\mathrm{d}n \,, \tag{14.49}$$

with the variables n and k also representing time, and insert the equation for $g(t)$ into this equation to substitute $g(t)$

$$\rho_{x,g}(k) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} h(\tau)x(n+k-\tau)\mathrm{d}\tau x(n)\mathrm{d}n \,. \tag{14.50}$$

We can now move $x(n)$ into the inner integral, because it does not depend on τ

$$\rho_{x,g}(k) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} h(\tau)x(n+k-\tau)x(n)\mathrm{d}\tau\mathrm{d}n \,. \tag{14.51}$$

Next, we will substitute $m = k-\tau$, which does not change the infinite boundaries of the integral. In the same step we also change the order of the integrals

$$\rho_{x,g}(k) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} h(k-m)x(n+m)x(n)\mathrm{d}n\mathrm{d}m \,. \tag{14.52}$$

Since $h(k-m)$ does not depend on n, we can move the variable out of the inner integral

$$\rho_{x,g}(k) = \int_{-\infty}^{+\infty} h(k-m)\int_{-\infty}^{+\infty} x(n+m)x(n)\mathrm{d}n\mathrm{d}m \,. \tag{14.53}$$

Now, it becomes clear that the inner integral is the autocorrelation function of our excitation signal x and we can replace it with the symbol for autocorrelation $\rho_{x,x}$

$$\rho_{x,g}(k) = \int_{-\infty}^{+\infty} h(k-m)\rho_{x,x}(m)\mathrm{d}m \,. \tag{14.54}$$

Our result shows that the cross-correlation between the convolved signal $g(t)$ and the excitation signal $x(t)$ results in the convolution of the autocorrelation function for the excitation signal x with the impulse response h. In our special case, the autocorrelation function of the excitation signal was

$$\rho_{x,x}(m) = \delta(m) \,,$$

which we can insert into our equation

$$\rho_{x,g}(k) = \int_{-\infty}^{+\infty} h(k-m)\delta(m)\mathrm{d}m \,. \tag{14.55}$$

We integrate over the delta function the same way we have done before to blend out $h(k)$ and obtain

$$\rho_{x,g}(k) = h(k) \,. \tag{14.56}$$

This result enables us to measure a room impulse response using a continuous signal and at the same time avoid potentially unstable methods such as deconvolution or division of two frequency functions. Figure 14.8e shows the practical result of this method for a 1 s Gaussian noise signal as excitation signal. The method allows us to extract the impulse response, but we have additional, residual noise between the reflections. This noise can be reduced by taking a longer excitation signal, and in practical measurements signals in the order of 1 min are often used.

Acknowledgments. I would like to thank my mentor Jens Blauert for teaching me the fundamentals of auditory signal processing. I learned the unique derivation of the convolution presented in this chapter when taking Jens' communication acoustics class in 1996. Rolf Walter at the University of Dortmund introduced me to the fundamentals of Fourier analysis and synthesis. Torben M. Pastore and Nikhil Deshpande were of great help proof-reading the manuscript.

15. Audio Source Separation in a Musical Context

Bryan Pardo, Zafar Rafii, Zhiyao Duan

When musical instruments are recorded in isolation, modern editing and mixing tools allow correction of small errors without requiring a group to re-record an entire passage. Isolated recording also allows rebalancing of levels between musicians without re-recording and application of audio effects to individual instruments. Many of these techniques require (nearly) isolated instrumental recordings to work. Unfortunately, there are many recording situations (e.g., a stereo recording of a 10-piece ensemble) where there are many more instruments than there are microphones, making many editing or remixing tasks difficult or impossible.

Audio source separation is the process of extracting individual sound sources (e.g., a single flute) from a mixture of sounds (e.g., a recording of a concert band using a single microphone). Effective source separation would allow application of editing and remixing techniques to existing recordings with multiple instruments on a single track.

In this chapter we will focus on a pair of source separation approaches designed to work with music audio. The first seeks the repeated elements in the musical scene and separates the repeating from the nonrepeating. The second looks for melodic elements, pitch tracking and streaming the audio into separate elements. Finally, we consider informing source separation with information from the musical score.

One of the great advances of the 20th and 21st centuries has been the introduction and refinement of audio recording and the audio editing techniques recording allows. Remixing, editing, and remastering in the studio has enabled the creation of new genres of music (e.g., *musique concrete*, modern hip hop). When instruments are recorded in isolation, modern editing and mixing tools allow correction of small errors in music recordings without requiring a group to re-record an entire passage (e.g., a single missed note in the flute part). This also allows rebalancing of levels between musicians without re-recording (e.g., increasing the volume of the flute compared to the trumpet) and application of audio effects to individual instruments (e.g., adding reverberation to the vocals, but not the bass).

Many of these editing techniques require (nearly) isolated instrumental recordings. One cannot edit out a missed note in the flute, if that note is also recorded on the adjacent microphone for the violin. Unfortunately, there are many recording situations (e.g., a stereo recording of a 10-piece ensemble) where there are many more instruments than there are microphones. Thus, instruments are not recorded in isolation. Also, many legacy recordings are only available in the final stereo (two-channel) or mono (one-channel) mixture and the original premixed tracks are not available. All of these situations make many editing or remixing tasks difficult or impossible.

Audio source separation is the process of extracting individual sound sources (e.g., a single flute) from

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_15

a mixture of sounds (e.g., a recording of a concert band using a single microphone). Effective source separation would allow application of editing and remixing techniques to existing recordings with multiple instruments on a single track.

There have been many source separation approaches developed for general audio signals. Examples of general source separation algorithms include independent component analysis (ICA) [15.1], nonnegative matrix factorization (NMF) [15.2], nonnegative tensor factorization (NTF) [15.3], probabilistic latent component analysis (PLCA) [15.4], and robust principal component analysis (RPCA) [15.5]. While all of these have been applied to music, most do not leverage any particular features of music to aid in the separation process.

One element of a music scene which is highly salient is the repeating structure found in the music. *Schenker* asserted that repetition is what gives rise to the concept of the motive [15.6]. *Ruwet* used repetition as a criterion for dividing music into small parts, revealing the syntax of the musical piece [15.7]. *Ockelford* argued that repetition and imitation is what brings order to music [15.8].

Computational audio researchers have found repetitive elements in music audio useful for many purposes. Common applications include music summarization, e.g., see *Bartsch* [15.9], *Cooper* and *Foote* [15.10] and *Peeters* [15.11], audio segmentation [15.12], beat estimation [15.13], finding drum patterns in the audio [15.14], and structural analysis [15.15]. For a thorough review on music structure analysis, the reader is referred to [15.11, 16, 17].

The idea that repetition can be used for source separation is supported by recent findings in psychoacoustics. *McDermott* et al. established that the human auditory system is able to segregate individual sources by identifying them as repeating patterns embedded in the acoustic input, without requiring prior knowledge of the source properties [15.18]. Given this, could repetition in music be used as a basis for automatically separating the audio into a repeating background (e.g., a salsa montuno) and a varied foreground (the lead *salsero* sala singer)?

Another salient feature of a musical scene is melody. *Bregman* [15.19] shows that humans often link together distinct sound elements (e.g., notes) in time to produce perceptually salient entities called auditory streams. These streams often correlate strongly with melodies. Many trained musicians are able to segregate several melodies into independent elements they can attend to. Can a machine do the same? Often, a musical score can aid the trained musician to perform this task better. Can a score provide similar aid to an auditory streaming algorithm?

In this chapter we will focus on a pair of source separation approaches designed to work with music audio. The first seeks the repeated elements in the musical scene and separates the repeating from the nonrepeating. The second looks for melodic elements, pitch tracking and streaming the audio into separate elements. This second approach is then informed by a musical score to improve performance.

15.1 REPET

In this work, we begin with the observation that passages in many kinds of folk and pop music can be understood as a background component that is generally repeating in time, with a superimposed foreground component that is generally variable in time (e.g., a repeating accompaniment superimposed with varying vocals or a solo instrument). On this basis the *repeating pattern extraction technique* (REPET) was proposed. REPET is an intuitive approach for separating the repeating background from the nonrepeating foreground in an audio mixture. The basic idea is to identify repeating elements in the mixture by measuring self-similarity along time, derive repeating models by averaging the repeating elements over their repetition rates, and extract the repeating structure by comparing the repeating models to the mixture.

A number of experiments have shown that REPET can be effectively applied to separate pop songs into their music accompaniment and singing voice. Unlike other approaches for source separation, REPET does not depend on special parametrizations, does not rely on complex frameworks, and does not require external information. Because it is only based on repetition, it has the advantage of being simple, fast, blind, and therefore completely and easily automatable. More information about REPET, including source code, audio examples, and related publications can be found at [15.20].

15.1.1 Original REPET

The original REPET algorithm was designed to separate the repeating background from the nonrepeating

foreground in an audio mixture (e.g., the music accompaniment from the singing voice in a pop song) by identifying a period and modeling a segment for the periodically repeating patterns [15.21, 22].

The method can be summarized in three stages (Fig. 15.1):

- Identification of a repeating period
- Modeling of a repeating segment
- Extraction of the repeating structure.

Repeating Period Identification

In the first stage, the time-domain signal (top left of Fig. 15.1) is transformed into a time–frequency representation known as the spectrogram by using the short-time Fourier transform (STFT). A spectrogram represents sound as a two-dimensional structure, where the vertical axis shows frequency from low (at the bottom) to high. The horizontal axis shows time, from left to right. The spectrograms in Fig. 15.1 use red to indicate high energy and blue to show low energy.

The autocorrelation of each frequency channel is then computed. An autocorrelation measures the similarity of a signal with a delayed version of itself given different delays. The peak of the autocorrelation function indicates the period at which the sound repeats. To identify periodicity in the mixture, the beat spectrum [15.13] is derived from the spectrogram by computing the autocorrelation over time for every frequency channel and averaging the autocorrelations over the frequency channels. This is shown in the upper right of Fig. 15.1. Here, a peak is a candidate period at which the audio may repeat.

If periodically repeating patterns are present in the mixture, the beat spectrum forms peaks that are periodically repeating at different period rates, unveiling the underlying periodically repeating structure of the mixture, as shown in Fig. 15.1. A best-fit repeating period can then be identified from the beat spectrum, manually or by using an automatic period finder [15.21, 22].

Repeating Segment Modeling

In the second stage, the repeating period is used to find the period of the underlying repeating structure in the recording. This typically correlates to a pattern a few seconds long, such as a 4-chord repeating riff in a folk song. A model of what is repeating in the music is built by segmenting the audio at the points where the pattern repeats (middle panel of Fig. 15.1). The median value of the sound across all repetitions is then used to model the canonical repeating sound, as shown in Fig. 15.1.

This approach assumes the nonrepeating foreground (e.g., vocals or an instrumental soloist) has a sparse and varied time–frequency representation compared with the time–frequency representation of the

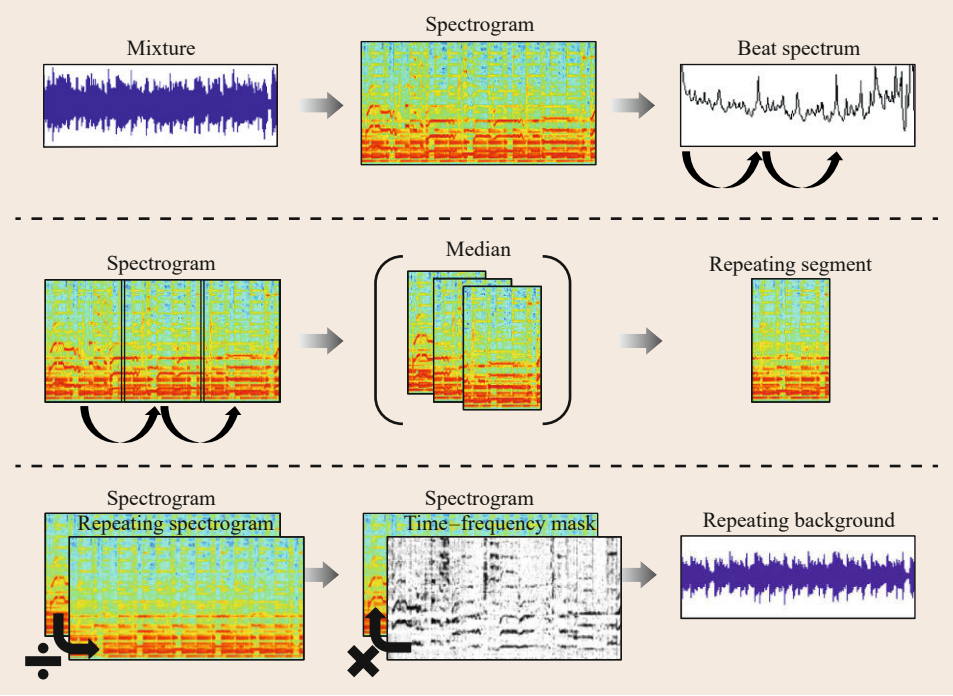

Fig. 15.1 Overview of the original REPET: (1) computation of the beat spectrum and identification of a repeating period (*top row*); (2) filtering of the spectrogram and modeling of a repeating segment (*middle row*); (3) derivation of the time–frequency mask and extraction of the repeating background (*bottom row*)

repeating background. Therefore, time–frequency bins with small deviations at their repetition rate would most likely represent repeating elements and would be captured by the median model. Conversely, time–frequency bins with large deviations at their repetition rate would most likely be nonrepeating elements (i. e., the nonrepeating musical foreground) and would be removed by the median model.

Repeating Structure Extraction

In the third stage, the repeating segment is used to derive a repeating spectrogram by taking, for every time–frequency bin, the minimum between the repeating model and the mixture spectrogram at period rate. This assumes the mixture spectrogram is the sum of a nonnegative repeating spectrogram and a nonnegative nonrepeating spectrogram. Thus, the mixture at any given time and frequency is assumed to always be as loud or louder than the individual mixture components (i. e., the repeating components are assumed not to cancel out the nonrepeating components).

The repeating spectrogram is then used to derive a time–frequency mask by dividing, for every time–frequency bin, the repeating spectrogram by the mixture spectrogram, as shown in Fig. 15.1. The rationale is that time–frequency bins that are likely to repeat at their repetition rate in the mixture spectrogram would have values near one in the time–frequency mask and would be weighted toward the repeating background. Conversely, time–frequency bins that are not likely to repeat at their repetition rate in the mixture spectrogram would have values near zero in the time–frequency mask and would be weighted toward the nonrepeating foreground.

The repeating background can then be obtained by multiplying, for every time–frequency bin, the time–frequency mask with the mixture. The nonrepeating foreground can be obtained by simply subtracting the repeating background from the mixture.

Experiments showed that REPET can be effectively applied to separate pop/rock song clips into their accompaniment music and singing voice [15.21, 22]. They also showed that REPET can be combined with other methods to improve background–foreground separation; for example, it can be used as a preprocessor to pitch detection algorithms to improve melody extraction [15.22], or as a postprocessor to a singing voice separation algorithm to improve music–voice separation [15.23]. Experiments further showed that REPET can be effectively applied to [separate the] accompaniment music and singing voice of separate full-track real-world songs, by simply applying the method along time via a sliding window [15.22]. There is, however, a trade-off for the window size in REPET: if the window is too long, the repetitions will not be sufficiently stable; if the window is too short, there will not be sufficient repetitions [15.22].

15.1.2 Adaptive REPET

Adaptive REPET is an extension of the original REPET and is designed to handle a varying periodic background, i. e., when the repeating period and/or the repeating patterns change over time (e.g., the succession of two homogenous sections in a song, such as a verse followed by the chorus), without the need for segmenting or windowing the audio [15.24].

As with the original REPET, the method can be summarized in three stages (Fig. 15.2):

- Identification of the repeating periods
- Modeling of a repeating spectrogram
- Extraction of the repeating structure.

Identification of Repeating Periods

In the first stage, the signal is transformed into a spectrogram. To identify local periodicities in the mixture, the beat spectrogram [15.13] is derived from the spectrogram by computing a beat spectrum for every time frame by sliding a window along time. In other words, each column in the beat spectrogram represents a beat spectrum at a given time.

If periodically repeating patterns are present in the mixture, the beat spectrogram forms horizontal lines that are periodically repeating vertically, corresponding to the succession of peaks in the concatenated beat spectra, unveiling the underlying periodically repeating structure of the mixture, as shown in Fig. 15.2. If variations of periodicity happen over time in the mixture, the horizontal lines in the beat spectrogram will show variations in their vertical periodicity. The repeating periods can then be identified from the beat spectrogram, for all the time frames in the mixture spectrogram, manually or by using an automatic period finder [15.24].

Repeating Spectrogram Modeling

In the second stage, the repeating periods are used to model an initial repeating spectrogram by taking, for every time frame in the mixture spectrogram, the median of the time–frequency bins at their period rate, as shown in Fig. 15.2.

The original REPET assumes that there is a single large period (e.g., the length of a measure) for all the repeating elements in the audio. The adaptive REPET considers each time frame individually (a single frame lasts roughly 20–40 ms) and tries to find similar frames separated from the current frame by some period (e.g., 2 s). If similar frames are found at this period (e.g.,

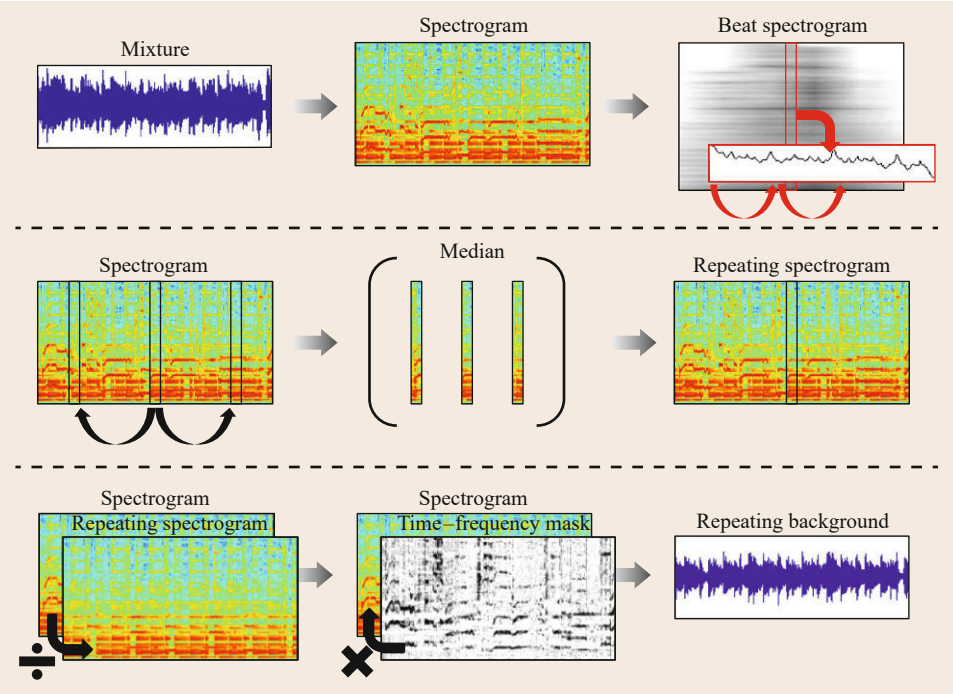

Fig. 15.2 Overview of adaptive REPET: (1) computation of the beat spectrogram and identification of the repeating periods (*top row*); (2) filtering of the spectrogram and modeling of a repeating spectrogram (*middle row*); (3) derivation of the time–frequency mask and extraction of the repeating background (*bottom row*)

similar frames at −4 s, −2 s, +2 s), the repeating spectrogram model for the current frame is built from those frames. Once this is done, it moves forward to the next time frame and tries to find a period at which the content of the new frame repeats. This period may or may not be the same as the previous time frame (e.g., a period of 1.9 s instead of 2 s). This lets it handle periodically repeating structures that vary slowly over time and also structures that are composed of interleaved repeating patterns of different periods (e.g., minimalist music).

Repeating Structure Extraction

In the third stage, the initial repeating spectrogram is used to derive a refined repeating spectrogram by taking, for every time–frequency bin, the minimum between the initial repeating spectrogram and the mixture spectrogram. The repeating spectrogram is then used to derive a time–frequency mask by dividing, for every time–frequency bin, the repeating spectrogram by the mixture spectrogram, as shown in Fig. 15.2.

The repeating background can then be obtained by multiplying, for every time–frequency bin, the time–frequency mask with the STFT of the mixture and transforming the result back to the time-domain. The nonrepeating foreground can be obtained by simply subtracting the repeating background from the mixture.

Experiments showed that adaptive REPET can be effectively applied to separate full-track real-world songs (e.g., a whole studio recording) into their accompaniment music and singing voice, unlike the original REPET which would only be meaningful for short excerpts [15.24].

15.1.3 REPET-SIM

REPET-SIM is a generalization of the REPET approach that was designed to handle nonperiodically repeating structures, i. e., when the repeating patterns happen intermittently or without a clear periodicity (e.g., repeated piano stabs in a jazz combo that use the same chord voicing, but whose rhythm varies). This is done by using a similarity matrix to identify the repeating elements [15.25].

As with the previous two methods, the method can be summarized in three stages (Fig. 15.3):

- Identification of the repeating elements
- Modeling of a repeating spectrogram
- Extraction of the repeating structure.

Repeating Element Identification

In the first stage, the signal is transformed into a spectrogram. To identify similarities in the mixture, the similarity matrix [15.26] is derived from the spectrogram by computing the cosine similarity between any two pairs of time frames.

If repeating elements are present in the mixture, the similarity matrix would form regions of high and low

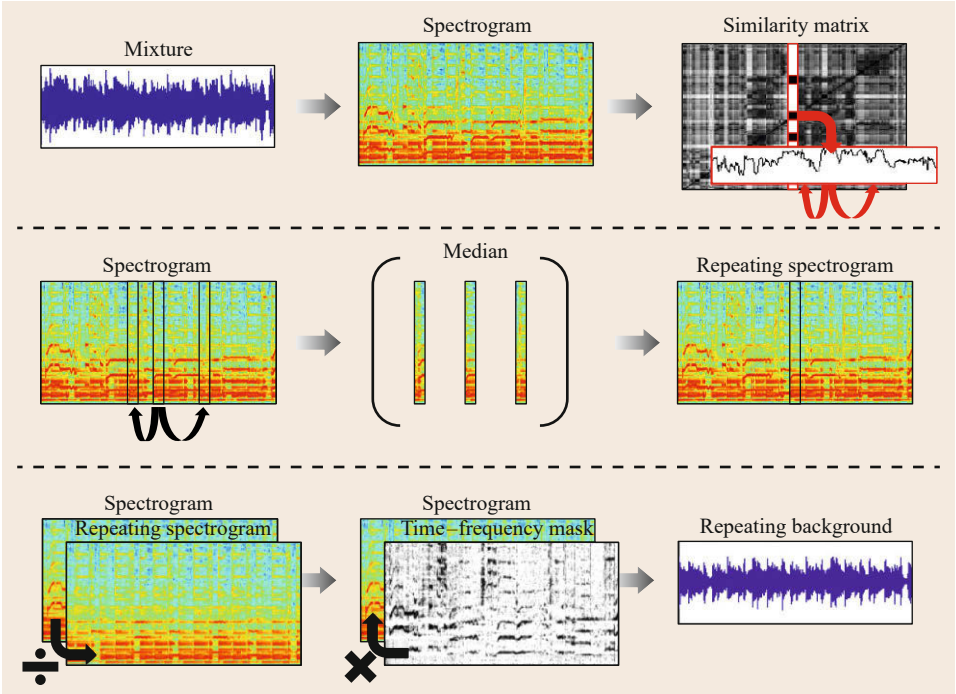

Fig. 15.3 Overview of REPET-SIM: (1) computation of the similarity matrix and identification of the repeating elements (*top row*); (2) filtering of the spectrogram and modeling of a repeating spectrogram (*middle row*); (3) derivation of the time–frequency mask and extraction of the repeating background (*bottom row*)

similarity at different time indices, unveiling the underlying repeating structure of the mixture, as shown in Fig. 15.3. The repeating elements can then be identified from the similarity matrix, for all the time frames in the mixture spectrogram, manually or by using an automatic peak finder [15.25].

Repeating Spectrogram Modeling

In the second stage, the repeating elements are used to model an initial repeating spectrogram by taking, for every time frame in the mixture spectrogram, the median of the time–frequency elements at their repetition rate, as shown in Fig. 15.3.

Compared with the other REPET methods (original and adaptive) that look for periodic similarity between events in the audio scene, REPET-SIM looks only for similarity, so that it can handle nonperiodically repeating structures, i. e., when the repeating patterns happen intermittently or without a clear periodicity.

Repeating Structure Extraction

In the third stage, the initial repeating spectrogram is used to derive a refined repeating spectrogram by taking, for every time–frequency bin, the minimum between the initial repeating spectrogram and the mixture spectrogram.

The repeating spectrogram is then used to derive a time–frequency mask by dividing, for every time–frequency bin, the repeating spectrogram by the mixture spectrogram, as shown in Fig. 15.3.

The repeating background can then be obtained by multiplying, for every time–frequency bin, the time–frequency mask with the STFT of the mixture and transforming the result back to the time-domain. The nonrepeating foreground can be obtained by simply subtracting the repeating background from the mixture.

Experiments showed that REPET-SIM can be effectively applied to separate full-track real-world songs into their accompaniment music and singing voice, also compared with the adaptive REPET [15.25]. Experiments also showed that REPET-SIM can be effectively applied to separate two-channel mixtures of one speech source and real-world background noise into their background noise and clean speech, by applying the method online for real-time computing [15.27].

Note that *FitzGerald* proposed a method very similar to REPET-SIM for music–voice separation [15.28].

15.2 Pitch-Based Source Separation

The previous sections focused on performing source separation using cues related to the repetitive, rhythmic structure of the music audio. Another fruitful approach is to use the melodic content as embodied by the pitches present in the audio. We now turn to this approach.

Pitched musical instruments (e.g., brass, woodwinds, strings, and keyboard instruments) are harmonic sound sources. Most of the energy in a harmonic sound is located at frequencies that are integer multiples of the fundamental frequency (F0). For example, if a piano plays a single note at A = 440 Hz, most of the energy in the sound will be concentrated at 440 Hz, 880 Hz, 1320 Hz, and so on. While F0 is a physical attribute and pitch is a perceptual attribute of a sound, for a harmonic sound, its pitch can be reliably matched to the F0. Therefore, we do not differentiate F0 from pitch in our discussions here.

Pitch information helps to separate harmonic sources from a mixture of sounds. In this section, we present our work on pitch-based source separation of audio mixtures composed of harmonic sound sources. Typically, this means separation of instruments from a music recording containing multiple concurrent instruments.

The first step is to estimate the pitches of these harmonic sources from the mixture [15.29]. This is called *multipitch estimation* (MPE). A frame is typically a 20–40 ms time window. MPE is typically performed in each individual time frame of the audio mixture. The second step is to connect the pitch estimates in different frames to form pitch trajectories, each of which corresponds to a source [15.30]. This is called *multipitch streaming*. The last step is to extract the harmonics from the pitch estimates of each source and reconstruct the source signal. In the following, we describe the three steps separately.

15.2.1 Multipitch Estimation

Multipitch estimation is the task of estimating pitches and the number of pitches in each frame of a harmonic sound mixture. In music information retrieval, the number of pitches is also called *polyphony*. Many methods have been proposed in the literature. Some do not employ any preprocessing of the signal and work with the full time domain or frequency domain signal [15.31–40]; others reduce the signal to a more compact representation such as employing an auditory filterbank as the front end [15.41–44] or representing the spectrum only with significant peaks [15.45–47]. Our method falls within the second category. More specifically, we represent the power spectrum of the audio mixture with both significant peaks and nonpeak regions and propose a maximum likelihood method to estimate the pitches and the polyphony from the peak–nonpeak-region representation [15.29].

Peak Detection

For harmonic sounds, significant spectral peaks ideally correspond to harmonics of the pitches. Therefore, detection of these peaks would help us infer the pitches. Taking one frame of the audio signal, we first perform a Fourier transform [15.48] to turn the audio into a spectral representation. The middle top panel of Fig. 15.1 shows a spectrogram. Here, each column of the image is the spectral representation of a single time step (typically a 20–40 ms window).

Spectral peaks at each time slice are detected by the peak detector described in [15.49]. Basically, there are two criteria that determine whether a local maximum in the spectrum should be labeled as a peak. The first criterion is global: the local maximum should not be less than some threshold (e.g., 50 dB) lower than the maximum of the spectrum across all frequencies in that time step. The second criterion is local: the local maximum should be locally higher than a smoothed version of the spectrum by at least some threshold (e.g., 4 dB). Finally, the peak amplitudes and frequencies are refined by quadratic interpolation [15.50].

We define the *nonpeak region* as those frequencies that are further than a quarter tone from any of the detected spectral peaks. Although the nonpeak region cannot tell us where the pitches should be, it can tell us where the pitches should not be. Pitches are not likely to be located at frequencies whose harmonics are in the nonpeak region.

Likelihood Function

We propose a maximum likelihood method to estimate the set of pitches from the peak–nonpeak representation of the mixture spectrum. The likelihood function is defined as the multiplication of the *peak-region likelihood* and the *nonpeak-region likelihood*, assuming conditional independence of peaks and the nonpeak region given the pitches. The peak region likelihood is defined as the probability of occurrence of the peaks, given an assumed set of pitches. The nonpeak region likelihood is defined as the probability of *not* observing peaks in the nonpeak region, given an assumed set of F0s. The peak region likelihood and the nonpeak region likelihood act as a complementary pair. The former helps find F0s that have harmonics that explain peaks, while the latter helps avoid F0s that would predict har-

monics where none are observed (i. e., in the nonpeak region).

To define the peak-region likelihood, we characterize each peak by its frequency and amplitude. We further consider the probability that each detected peak is a *normal* peak or a *spurious* peak. By *normal* we mean the peak is generated by some harmonic of the underlying pitches; and by *spurious* we mean the peak is due to other factors such as side-lobes, peak detection errors, etc.

We train the parameters of the likelihood functions using training data with ground-truth pitches and detected peaks and nonpeak regions. Two kinds of training data are used. The first kind is a set of isolated notes from the University of Iowa Musical Instrument Samples (MIS) dataset [15.51]. They are used to train the parameters of the nonpeak region likelihood model. The second kind is a set of randomly mixed chords using these isolated notes. They are used to train the parameters of the peak-region likelihood model. Ground-truth pitches are detected using the YIN [15.52] pitch tracking algorithm on isolated notes before mixing the isolated notes together. Peaks and the nonpeak region are detected using the proposed method.

Pitch and Polyphony Estimation

Given the set of detected peaks, frequencies within one semitone around each peak are considered as possible pitches (i. e., possible F0s). The underlying pitches in this frame are thus assumed to compose a subset of these frequencies. This helps to constrain the set of possible hypotheses to reasonable ones, given the data. The task of the maximum likelihood estimation is thus to find the subset of potential F0s that gives the highest likelihood to having generated the observed peaks in the spectrum.

It is, however, intractable to enumerate all these subsets. A typical scene may have 50–100 peaks. The set of all subsets of 100 peaks has 2^{100} elements and is not tractable to fully search. We therefore propose an iterative greedy search strategy [15.29]. We start from an empty subset to represent the estimated pitches. At each iteration, we add the one pitch estimate that most increases the likelihood of the subset. This strategy only enumerates a very small amount of subsets, as the choice of latter pitches depends on the choice of earlier pitches. However, the computational complexity is significantly reduced from exponential to linear with respect to the number of peaks.

An important question for this iterative greedy search process is *When should we stop*? In other words, how many pitches should we estimate in each time frame. Ideally, we hope that the likelihood function can take care of this problem and stop the process when the likelihood no longer increases on adding a new pitch. However, similar to many other maximum likelihood estimation problems, there is an overfitting problem. The likelihood typically increases with the number of pitches, although the increase becomes slower. We use a simple thresholding method to address this problem. We do not stop the iterative process until the number of pitches in the subset reaches a predefined maximally possible polyphony (e.g., 9). We then calculate the likelihood increase from 1 pitch to the maximally possible polyphony as the maximally possible likelihood increase. We then estimate the polyphony as the number of pitches that first surpasses 88% of the maximally possible increase. The threshold was tuned on a training set of musical chords with polyphony from 1–6. This simple polyphony estimation method is shown to work well on both musical chords and real music pieces.

Pitch Refinement

Pitches and polyphony estimated in individual frames may contain errors that make the pitch contours nonsmooth over time. By utilizing contextual information, it is possible to fix these errors and improve the pitch estimation accuracy.

We use a moving average to calculate the refined polyphony estimate with a triangular moving window with size of 19 frames. We also build a pitch histogram with a granularity of a semitone by counting the pitch estimates within the window and rank the pitches by their weighted counts according to the window. The top several pitches are returned as the refined pitches with equal weights, where the number is equal to the refined polyphony estimate. In experiments we show that this refinement step removes many insertion and deletion pitch estimation errors and significantly increases the estimation accuracy [15.29].

15.2.2 Multipitch Streaming

The pitches estimated in the previous section can help us separate harmonic sources in each individual frame. However, to separate the source signal over multiple frames, we need to connect these pitches into streams, each of which corresponds to a source. This is the multipitch streaming problem. Researchers have proposed using frequency–amplitude continuity to stream pitches [15.31, 36, 53, 54], but this approach only works within a note where the pitch does not change abruptly. For streaming pitches into noncontinuous pitch contours, we proposed the first method [15.30]. The basic idea is to use the timbre information. Notes performed by the same instrument have similar timbre compared to those performed by different instruments. Therefore,

we associate each pitch estimate with a timbre feature vector and perform clustering on the timbre feature vectors. Ideally, each cluster will correspond to one source and their pitches form the pitch stream of that source.

Timbre Features

We need to calculate a timbre feature vector for each pitch estimate in each frame and this feature should be calculated from the mixture signal directly. In our work we use two kinds of features. The first is called *harmonic structure* and is described in [15.49]. It is defined as a vector of relative logarithmic amplitudes of the harmonics of a pitch estimate. The harmonics are at integer multiples of the pitch. We use the first 50 harmonics to create a 50-dimensional timbre vector. We choose this dimensionality because most instruments have less than 50 prominent harmonics. For each harmonic, we use the peak-finder from [15.49] to see if there is a significant peak within a musical quarter-tone. If no peak is associated, the magnitude of the harmonic is set to 0 dB, otherwise it is set to the value of the nearest peak. Then, the representation is normalized. This feature has been shown to be similar for notes played by the same instrument within a narrow pitch range, while it is different for different instruments.

Another feature is called the *uniform discrete cepstrum* (UDC) [15.30]. It is calculated by taking the discrete cosine transform of a sparse log-amplitude magnitude spectrum where the nonzero elements are the harmonics of the pitch. This feature lies in the cepstral feature category and represents the spectral envelope of the harmonics of the target pitch. However, unlike other cepstral features such as the ordinary cepstrum or mel-frequency cepstral coefficients (MFCC), UDC can be calculated from the mixture spectrum directly for the target source, without resorting to source separation. UDC has been shown to outperform other cepstral representations and the harmonic structure feature in an instrument recognition task of musical chords [15.55].

Constrained Clustering

Given the feature vector of each pitch estimate, we perform K-means clustering on the pitches, to minimize the timbre inconsistency within each cluster. However, results show that there are two kinds of common errors. In Fig. 15.4b, a number of pitches are clustered into the wrong trajectory. For example, the pitches around Musical Instrument Digital Interface (MIDI) number 55 from 14.8 to 15.8 s form a continuous contour and are all played by the bassoon. However, in the clustering, some of them are assigned to the saxophone. In another example, from 16.8 to 17.6 s, the K-means

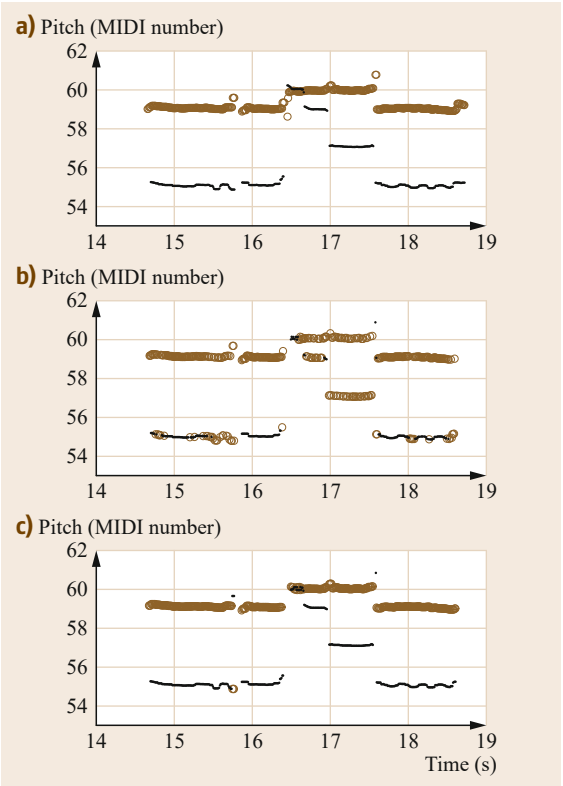

Fig. 15.4a–c Comparison of the ground-truth pitch streams **(a)**, K-means clustering ($K = 2$) results (i. e., only minimizing the objective function) **(b)** and the proposed method's results (i. e., considering both objective and constraints) **(c)**. Both the K-means and the proposed method take the ground-truth pitches as inputs, use 50 d harmonic structure as the timbre feature and randomly initialize their clusterings. Each point in these figures is a pitch. Different instruments are marked with different markers (*circles* for saxophone and *dots* for bassoon)

clustering places two simultaneous pitches into the saxophone stream. This is not reasonable as the saxophone is a monophonic instrument.

If we know that different sources do not often perform the same pitch at the same time and all sources are monophonic, we can impose two kinds of constraints on some pairs of the pitches to improve clustering: A *must-link* constraint is imposed between two pitches that differ less than Δ_t in time and Δ_f in frequency. It specifies that two pitches close in both time and frequency should be assigned to the same cluster. A *cannot-link* constraint is imposed between two pitches in the same frame. It specifies that two simultaneous pitches should be assigned to different clusters. These must-links and cannot-links form the set of all constraints. Figure 15.4c shows the result obtained from our pro-

posed algorithm, considering both the objective and constraints.

Iterative Algorithm

The formulated constrained clustering problem has two properties that mean existing constrained clustering algorithms [15.56–58] cannot be applied: 1) constraints are inconsistent with each other as they are imposed on pitch estimates that contain errors; 2) almost every pitch estimate is involved in some constraint. We therefore propose a new algorithm. It starts from an initial partition that satisfies a subset of all the constraints. Then it iteratively minimizes the objective function while incrementally satisfying more constraints. While the details of the algorithm can be found in [15.30], here we state its two important properties: 1) it always converges; 2) the timbre inconsistency objective function monotonically strictly decreases while the number of satisfied constraints monotonically increases.

15.2.3 Constructing Harmonic Masks

Given the estimated pitch stream for each harmonic source, we build a soft frequency mask around its harmonics to separate its magnitude spectrum from the mixture spectrum [15.59]. We then combine the separated magnitude spectrum with the phase spectrum of the mixture signal and perform an inverse Fourier transform to calculate the time-domain signal. Finally, the overlap-add technique [15.48] is applied to concatenate the current frame to previously separated frames.

To calculate the frequency masks for sources, we first identify their harmonics and overlapping situations from the estimated pitches. Each frequency bin is then classified into three kinds according to the number of harmonics that involve this frequency bin:

- Nonharmonic bin
- Nonoverlapping harmonic bin
- Overlapping harmonic bin.

For a nonharmonic bin, the masks are designed to evenly distribute the mixture energy to all active sources. For a nonoverlapping harmonic bin, the mixture energy is solely distributed to the source whose harmonic involves the bin.

The mask design for overlapping harmonic bins is the most difficult. One can calculate an average harmonic structure template for each source from the harmonic structures of its estimated pitches and then use the template to design the mask value at different harmonics [15.49]. This method considers the timbre model of the sources. A simpler method is to distribute the mixture energy to overlapping harmonics, in the inverse proportion to the square of the harmonic indices. This method does not model the timbre of sources, instead, it makes a general assumption that the harmonic amplitude decays at the same rate with respect to the harmonic index, regardless of pitch and instrument that produced the note. This is a very coarse assumption but it provides a simple and relatively effective way to resolve overlapping harmonics.

15.3 Leveraging the Musical Score

Previous sections described source separation algorithms that depend on repeating (rhythmic) content and pitch-based (melodic) content to perform separation. We now consider the case where one can improve a source separation algorithm by using information in addition to the audio recording. For many music pieces, music scores are widely available. In this scenario, score information can be leveraged to help analyze and separate the audio signal. More specifically, if the audio performance is faithful to the score and the audio and the score are aligned (i. e., synchronized), the score can tell us what pitches are likely being played at a time of the audio. This can greatly improve the accuracy of melodic, pitch-based source separation. We can use the score-provided pitch information to separate the harmonic sources in the audio. Such a system is called a score-informed source separation system.

In this chapter, we describe our work on an online score-informed source separation system called *Soundprism* [15.59]. Soundprism first aligns the audio with the score, then estimates the precise pitches based on the score-provided pitches in each frame and finally separates audio sources in the frame. All of these operations are performed in an online fashion, i. e., it processes the audio frame-by-frame in a serial fashion, without having the entire audio available. Figure 15.5 illustrates the system overview of Soundprism.

15.3.1 Audio–Score Alignment

The first stage of Soundprism is online audio-score alignment, also called *score following*. The score follower takes a piece of polyphonic music audio and its electronic score (e.g., MIDI) as input. It then outputs a score position for each time frame in a sequence. We

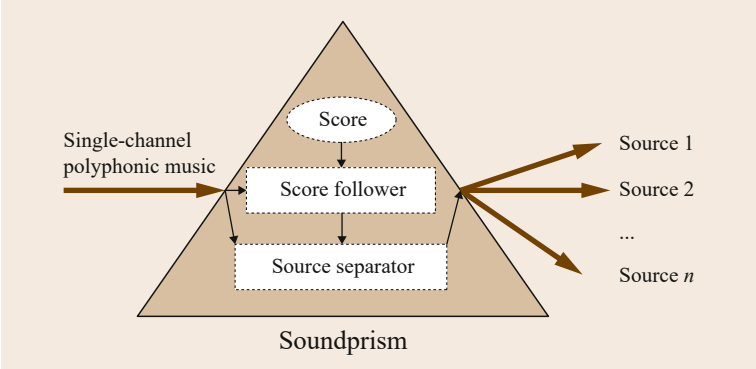

Fig. 15.5 System overview of Soundprism

propose a hidden Markov process model to do so, as illustrated in Fig. 15.6. The n-th time frame of the audio is associated with a 2-dimensional hidden state vector $\boldsymbol{s}_n = (x_n, v_n)^\top$, where x_n is its score position (in beats) and v_n is its tempo (in beats per minute [BPM]). Each audio frame is also associated with an observation variable $\boldsymbol{y}_n$, which represents the magnitude spectrum of the time frame. Our aim is to infer the current score position x_n from current and previous observations $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n$. To do so, we need to define a process model to describe how the states transition, an observation model to evaluate hypothesized score positions for the current audio frame, and to find a way to do the inference in an online fashion.

Process Model

A process model defines the transition probability from the previous state to the current state, i. e., $p(\boldsymbol{s}_n|\boldsymbol{s}_{n-1})$. This tells us how the score position and tempo changes from one frame to another and the probability of the change. We use two dynamic equations to define this transition. While the detailed equations are ignored here, the basic idea is that the change of score position is determined by the tempo and the time interval between two adjacent frames. Also the tempo changes randomly around the previous tempo assuming a Gaussian distribution if the score position just passed a note onset or offset and does not change otherwise.

Note that we do not introduce randomness directly in score position. This is to avoid disruptive changes of score position estimates. In addition, randomness is only introduced when the score position has just passed a note onset or offset. This is because it is rather rare that the performer changes tempo within a note. Second, on the listener's side, it is impossible to detect the tempo change before hearing an onset or offset, even if the performer does make a change within a note. Therefore, changing the tempo state in the middle of a note is not in accordance with music performance, nor does it have evidence to estimate this change.

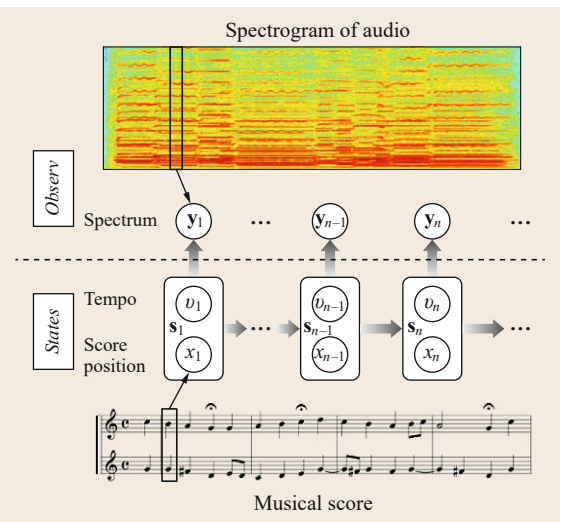

Fig. 15.6 Illustration of the state space model for online audio-score alignment

Observation Model

The observation model evaluates how well a hypothesized state (score position and tempo) can explain the observation, i. e., $p(\boldsymbol{y}_n|\boldsymbol{s}_n)$. In this work, we use the multipitch likelihood model as described in Sect. 15.2.1. The basic idea is that if the score pitches at the hypothesized score position fit well to the magnitude spectrum of the current frame $\boldsymbol{y}_n$, then the hypothesis is good. To calculate the multipitch likelihood, we just plug the score pitches into the likelihood function described in Sect. 15.2.1.

Clearly the observation model itself is not enough to estimate the hidden state (e.g., the score position), as the score may show the same pitches at different positions. In addition, the tempo dimension of the state does not play in the observation model. These problems, however, are addressed when the observation model and process model work together. The process model, con-

sidering the tempo dimension and the continuity of state changes, would only favor hypothesized states whose score position is close to the previous score position. This is the key idea of the hidden Markov process model.

Our observation model only considers information from the current frame and could be improved if considering information from multiple frames. *Ewert* et al. [15.60] incorporate interframe features to utilize note onset information and improve the alignment accuracy. *Joder* et al. [15.61] propose an observation model which uses observations from multiple frames for their conditional random field-based method. In the future we want to explore these directions to improve our score follower.

Inference

Given the process model and the observation model, we want to infer the state of the current frame from current and past observations. From a Bayesian point of view, this means we first estimate the posterior probability $p(\boldsymbol{s}_n|\boldsymbol{y}_1,\ldots,\boldsymbol{y}_n)$, then decide its value using some criterion like maximum a posteriori (MAP) or minimum mean square error (MMSE). For hidden Markov processes, this posterior probability at the current frame can be updated from the previous frame. Therefore, we can estimate the posterior probability and the hidden states in an online fashion.

Here we use a *bootstrap filter*, one variant of particle filters [15.62, 63] to do the online update of the posterior probability. The process starts from an initialization of M particles. Their score positions are all set to the beginning of the score and their tempi are uniformly distributed between half and twice of the score-notated tempo. These particles represent an initialization of the posterior probability. To update the posterior probability when a new audio frame comes in, the particles are first moved using the process model, i. e., the score positions and tempi of the particles are changed. Then the observation likelihood of each particle is calculated using the observation model, which indicates the fitness of the particle to the current audio frame. The likelihood is set as the weight of the particle. These particles are then resampled with replacement according to their weights to generate a new set of M particles. Particles that do not fit to the current frame are less likely to remain in the new particle set, while particles that are a better fit to the current frame may retain multiple copies in the new particle set. A small random perturbation is imposed on these copies to prevent degeneracy of the particles. Now the new set of particles represent the new posterior probability. The average value of these particles is output as the estimate of the hidden state in the current frame.

The set of particles is not able to represent the distribution if there are too few and is time-consuming to update if there are too many. In our work we tried to use 100, 1000, and 10 000 particles. We find that with 100 particles, the score follower is often lost after a number of frames. But with 1000 particles, this rarely happens and the update is still fast enough. Therefore, 1000 particles are used in this chapter.

15.3.2 Pitch Refinement and Source Separation

Given the aligned score position for each audio frame, we know what instrument is playing what pitch in this frame from the score. This is important information for separating harmonic sources. However, the pitches provided by the score are integer MIDI pitch numbers. MIDI pitch numbers indicate keys on the piano keyboard. Typically, MIDI 69 indicates the A above Middle C. Assuming A440-based equal temperament allows translation from MIDI pitch to frequency in Hz. The resulting frequencies are rarely equal to the real pitches played in an audio performance. In order to extract the harmonics of each source in the audio mixture, we need to refine them to get accurate estimates of pitches played in the audio.

We refine the pitches using the multipitch estimation algorithm as described in Sect. 15.2.1, but restricting the search space within a semitone of the score-notated pitches. We also assume polyphony is given by the score.

Given the refined pitches in each audio frame, we use the same method as described in Sect. 15.2.3 to construct a harmonic mask for each pitch to separate the magnitude spectrum. Finally, we apply the inverse Fourier transform with the phase spectrum of the mixture signal and the overlap-add technique to reconstruct the separated source signals.

15.4 Conclusions

In this chapter we have outlined how to perform audio source separation on music using the cues of repeating musical structure and pitch content. We then showed how one can augment the pitch-based separation algorithm by leveraging the information in a musical score, where available. Moving forward,

we envision a combination of the score-informed pitch-based separation with separation based on rhythmic structure. Combining these should allow separation of musical instruments from an audio mixture in a large variety of contexts that are currently intractable.

16. Automatic Score Extraction with Optical Music Recognition (OMR)

Ichiro Fujinaga, Andrew Hankinson, Laurent Pugin

Optical music recognition (OMR) describes the process of automatically transcribing music notation from a digital image. Although similar to optical character recognition (OCR), the process and procedures of OMR diverge due to the fundamental differences between text and music notation, such as the two-dimensional nature of the notation system and the overlay of music symbols on top of staff lines. The OMR process can be described as a sequence of steps, with techniques adapted from disciplines including image processing, machine learning, grammars, and notation encoding. The sequence and specific techniques used can differ depending on the condition of the image, the type of notation, and the desired output.

Several commercial and open-source OMR software systems have been available since the mid-1990s. Most of them are designed to be used by individuals and recognize common (post-18th-century) Western music notation, though there have been some efforts to recognize other types of music notation such as for the lute and for earlier Western music.

Even though traditional applications of OMR have focused on small-scale recognition tasks, typically as an automated method of musical entry for score editing, new applications of large-scale OMR are under development, where automated recognition is the central technology for building *full-music* search systems, similar to the large-scale full-text recognition efforts.

16.1 History

Computer-based optical recognition technologies, including both OMR and OCR, have been under development since the early days of computing technology. Computerized OCR was first developed in 1951 [16.1] and sold to large corporations, such as Reader's Digest and AT&T, to help process subscription and billing information [16.2].

Pruslin [16.3] demonstrated the first optical music recognition system. This system operated on a single measure of common Western music notation (CWMN), and was capable of recognizing a limited set of musical symbols. Several years later, *Prerau* [16.4] introduced the *DO-RE-MI* OMR system, capable of recognizing three measures of printed CWMN consisting of a single voice on two staves in a single font.

The goal of most early OMR development was a universal recognition system, capable of recognizing the entirety of music notation output, in much the same way that early OCR systems were envisioned as a tool capable of complete and accurate transcription of all textual documents [16.5, 6]. Despite understanding the limitations of the early OMR systems, Prerau concludes that the technique *should be able to be expanded to the recognition of all printed music* [16.7]. This early optimism was driven by a näive (in hindsight) understanding of the diversity and complexity of document contents. For text, page features such as

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_16

columns, figures, tables, footnotes, and even headings posed a challenge for accurate textual recognition. For music recognition, the troubles were even more acute since music notation styles and practices would vary by composer, publisher, repertoire and historical practices. By the 1990s, the goal of creating a universal recognition system had been largely abandoned in favor of repertoire and application-specific OMR systems capable of transcribing a well-defined subset of music documents [16.8]:

> [...] *in practice, composers and publishers often feel free to adapt old notation to new uses, and invent new notation, as they see fit. There are in fact national dialects of music notation, and musical works use many different levels of notational complexity. Thus it may not be possible to devise a single recognition system capable of recognizing all music notation.* [Pruslin 1966] *states that a complete solution to the music recognition problem is the specification of: which notes are present, what order they are played in, their time values or durations, and volume, tempo, and interpretation. This level of recognition suffices for only some of the applications listed* [later in this paper].

As research and development continued through the 1990s and 2000s, OMR systems were developed to specialize in transcribing specific repertoires or styles of notation. In addition to CWMN recognition systems, repertoire-specific recognition systems exist for many different music notation styles, including lute tablature [16.9–11], Byzantine chant [16.12, 13], mensural notation, both in print [16.14] and manuscript sources [16.15], and others.

Several OMR toolkits have also been developed to help assemble bespoke OMR systems. These toolkits have been used to build several of the aforementioned systems, and provide a generalized structure and toolset from which these customized OMR systems may be built. Examples of these frameworks include the CANTOR system [16.16] and the Gamera system [16.17]. While these systems present a more flexible approach to OMR, they require significantly more development expertise to create and run OMR than *turnkey* systems and, as such, are generally only used in research contexts.

16.2 Overview

The recognition process can generally be defined as identifying and contextualizing from a signal the information contained in it. It is a discriminative response to a specific stimulus that makes it possible to assign each object to a particular class. Recognizing shapes and reading are typical recognition processes performed by humans, and cognitive research has studied the complexity of this task. *Marr* [16.18], a pioneer in cognitive science, has proposed a theory of vision describing it as a bottom-up process, in which an image is first deconstructed into bidimensional primitives and then reconstructed as a spatial object. Since then, other studies [16.19] have shown that such a theory, however rational, is too restrictive and that a top-down activity is part of the human recognition processes, in particular when the subject does not easily understand the scene or the context. For example, when a human is reading a highly degraded document, the type of document and the context will be instrumental clues to deciphering its contents. For example, knowing that the document is a string quartet and reading the beginning of the bottom staff provides the reader with the information that the content to be read at that place is quite likely to be an F clef. Studies on human text reading have highlighted different reading techniques [16.20]. In most cases, the brain does not operate by letter decoding but rather by adopting a more global approach based on the linguistic context. This explains why reading known words within which letters are missing or are inverted can usually be achieved without problems. Conversely, when one has to read an unknown word, reading is performed via letter decoding and assembly.

The goal pursued in optical recognition of music scores and of documents is similar to the recognition process as described above. A major problem, however, is that it is extremely difficult to formalize this process algorithmically, especially if the aim is to design a system that can operate simultaneously with the bottom-up and top-down analysis mechanisms.

Among the various applications developed in the field of document recognition, the most advanced ones are certainly the optical character recognition (OCR) applications for which many functional and business solutions already exist. In fact, very early on, the results obtained in this field allowed complete solutions to be implemented for the recognition of typewritten texts or fonts, at least for fairly good documents having a relatively simple structure. In most systems, the recognition is performed by a sequential process of preprocessing, segmentation, classification and validation. This approach provides excellent results for two main reasons: firstly because character segmentation is

relatively easy and can be done simply by analyzing verticals projections, and secondly because classifiers such as neural networks (NN) or *k*-nearest-neighbor (*k*-NN) that are often used in these systems perform particularly well for this type of operation and on this type of data.

The results obtained in the recognition of cursive handwriting, or related tasks, are significantly less successful and it is unanimously agreed that this task is much more difficult [16.21]. In addition, it is striking to see how difficult it is, if not impossible, to adapt techniques traditionally used for recognition of printed texts to the recognition of handwritten text. In fact, the problem faced with handwriting recognition is a problem that can be summed up in a well-known paradox stated by *Sayre* [16.22]: *to recognize, we need to segment the input signal, but in order to segment appropriately we need to recognize*. The best results in handwriting recognition were obtained using other techniques than NN or *k*-NN that enable validating the recognition at different linguistic levels. The approach that has been the most widely used in recent years is hidden Markov models (HMM), especially because of their excellent noise absorption capacity and, above all, because of their linguistic context integration capacity [16.23].

16.3 OMR Challenges

OMR is a special case of document recognition. From a technical point of view, it has many similarities with OCR. Many of the challenges encountered in character recognition also arise with music. A recurring problem is the quality of documents considered. Some techniques can show promising results and yield high recognition rates when the documents considered are very clean, are straight, and show perfectly printed symbols. The difficulty of the task, however, increases dramatically with document degradation, if the document is skewed or curved, or if some symbols are poorly printed or partially deleted. In real-life cases, however, it is very rare that the documents to be processed are clean, straight, and perfectly printed. In most cases, we can expect imperfections of various types. They can be grouped into two distinct categories: the imperfections in the document itself and degradation introduced by the document acquisition phase.

Imperfections in the document can vary from one type of document to another, from one document to another, and sometimes even from one page to another. The following problems are commonly encountered:

- Printing imperfections (such as uneven absorption of ink by the paper)
- Partial erasure of symbols
- Ink bleed-through from the opposite side of the paper
- Stains
- Paper degradation (yellowing, foxing, mold and mildew etc.)
- Holes or tears.

An essential step in the recognition process is digitization, where the analog signal (an original document, a photo etc.) is converted into a digital image. This document acquisition phase is not always limited to a single capture event. In practice it is composed of several successive steps, and in the recognition stage the user may not have a clean and clear image of the original physical document but only a version that previously went through different imaging processes. In some cases for instance, the document is photographed before being digitized. A source may have been photographed and then transferred to a microfilm or microfiche, and ultimately only the microfilm is available to be digitized. Each step of the of document acquisition can introduce various types of unwanted artifacts:

- Document image skewing
- Noise
- Bulged or curved appearance of the document image
- Nonuniform lighting
- Borders around the document image
- Partial content of other pages around the document image.

An important consideration during this phase is the digitization resolution. The resolution has a direct effect on the size and definition of details that can be captured from the physical object. Musical notation contains specific features that depend on relatively small symbols, for example staccato, dotted notes and accidentals. *Ng* and *Boyle* [16.24] showed that with a document scanned at a resolution of 300 dpi, the distinction between a sharp and a natural could be ambiguous. Several studies [16.25, 26] have shown that as a result the appropriate resolution for capturing details from a music document is higher than that for text.

While OCR and OMR are similar tasks in many aspects, they also have fundamental differences that make OMR a more difficult task than OCR. The first difference concerns the placement of symbols on a page

and how they are arranged. Text is, for the most part, unidimensional. Characters and words are typically composed in a horizontal line, and each line has no vertical relationship with the parallel lines above or below it. This approach is not appropriate for music, because it is necessary in music to consider both the vertical and the horizontal dimensions simultaneously. The addition of the vertical dimension poses challenges in accurately determining the pitch of a note, for example, or the component pitches of a chord, while simultaneously information embedded in the horizontal dimension determines co-occurrences of both sounding and nonsounding events (i. e., notes that sound at the same time, or ties that control the sounding duration of a note).

Another difference is the musical characteristic that symbols are superimposed on staff lines. Superimposition of the elements is known to be a difficult problem of recognition of forms [16.27]. Many segmentation algorithms widely used in textual recognition are ineffective with music scores because they operate by edge detection. Thus, in OMR, the superposition of the symbols makes segmentation a particularly critical phase. Most musical recognition systems include the removal of the staff lines, which is particularly difficult when a musical symbol merges with a staff line, for example on top of an F clef. In practice, several factors can make staff line detection and removal difficult:

- The lines are usually not perfectly straight
- The line thickness is often variable
- The lines may be interrupted at certain points.

Many musical symbols have similar characteristics to each other (e.g., a half note and a quarter note are both made of a stem and a note head of the same size), but must be interpreted in vastly different ways. The visual difference between a note with a dotted duration and a note with a staccato is simply a slight shift in the position of the dot, but one means to lengthen the sounded note, and the other means to shorten it! This often leads to classification problems. Many musical symbols are not made of a single graphical element, but are *compound* symbols composed of two or more distinct elements. This is the case, for example, of an F clef, where the entire symbol is composed of three components: a curved line and two dots. Elements of compound symbols can belong to different types of symbols. A small dot can be the point of an F clef, a point of a dotted note, or a staccato point. Similarly, a sharp can be part of a key signature, the accidental of a note, or belong to a figured bass.

16.4 Technical Background

Several studies cover the early OMR techniques exhaustively, including *Blostein* and *Baird* [16.8], *Selfridge-Field* [16.28], *Bainbridge* and *Bell* [16.27], and more recently *Rebelo* et al. [16.21].

The nature of musical symbols has meant that from very early on OMR research had to look at structural recognition methods. The earliest research quickly showed that a functional recognition approach would work only for excessively simple cases. In general, symbols are grouped into two distinct categories: on one side, the symbolic, which can be treated as characters (keys, alterations, rests etc.), and on the other side, those that *Martin* and *Bellissant* [16.29] name the *iconic*, or assembled (e.g., note heads, stems, flags and beams), which are made of different primitives that may undergo various transformations and are assembled following certain rules.

Most OMR systems developed to date have more or less the same pipeline architecture that can be broken down into distinct phases:

1. Preprocessing of the image
2. Detection and removal of staff lines
3. Segmentation of the objects
4. Reconstruction of musical symbols
5. Classification and interpretation.

In many systems, musical rules are applied to increase accuracy. This can happen during several phases of the process, but most of the time the rules are applied during the reconstruction of the musical symbols from the primitives and during the classification of the symbols and the interpretation of the music content.

Using grammar to describe the musical notation and musical knowledge is a common technique [16.30]. Various methods have been proposed to integrate grammatical methods developed originally for languages into the bidimensional space of OMR. The transposition from one to two dimensions increases the complexity of the grammar, in both the design of the grammars and their use. This results in grammars that are either fairly simple but incomplete, or very complex but challenging to manage. One approach to simplify the problem is to have two distinct grammatical levels: low-level grammars, for describing the structure of a musical symbol constructed from primitives, and high-level grammars

for the description of the organization of musical notation itself [16.31].

16.4.1 Preprocessing

In many OMR research projects no particular attention is given to the preprocessing. The reason is that many of the problems to be solved are common to that faced by OCR, or even more generally in document recognition. In most researches a reference is made to the solutions proposed in these two research areas.

However, some more specific studies focusing on old documents looked more precisely at the thresholding problem during the binarization phase. This is the case with *MacMillan* et al. for the Levy project [16.32]. It shows that in this practical case, it is necessary to use more advanced methods of binarization. As does Ng for manuscript sources, MacMillan et al. use some locally adaptive thresholding algorithms. This technique allows the binarization to be optimized for document images with nonuniform lighting [16.33]. Furthermore, *Burgoyne* et al. [16.34] found that binarization methods that worked well for text documents did not work well for music documents and vice versa.

16.4.2 Staff-Line Detection and Removal

The detection and the removal of the staff lines is a key phase in OMR systems. This phase is often part of the preprocessing phase since usually the detection of the staff lines is used also to correct the skew of the document. Ideally, the staff lines are straight, parallel to each other, have constant thickness, and are horizontal. In reality, for various reasons, the lines may be curved, not parallel to each other, have varying thickness, and be skewed. A wide range of solutions has been proposed of tackle these challenges [16.21, 35]. These include projections, line tracing, two-dimensional vector fields, skeletonization, and graph-based approaches.

Once detected, staff lines are usually removed without removing the musical symbols. This step is critical, in particular with symbols touching the staff lines. In such cases, the removal of the staff lines may breakup the musical symbols into smaller pieces, which will then make their classification difficult without reconstruction. The difficulty of the task is therefore to find a solution that does not erase the staff line when it intersects with a symbol.

16.4.3 Recognition Architectures

The techniques used in OMR for locating and classifying symbols varies significantly from system to system and have evolved considerably since the first systems. This has been made possible by the considerable and steady increase of computational resources offered by new machines. Despite this diversity, some techniques are recurrent and are to be found similar in many approaches.

The simplest approach to locating and classifying the symbols is to look for the connected components and to classify them. This technology, already used by Prerau, generally uses simple measures such as the size of the bounding box of the symbol or the surface of the symbol. As simple as it is, this approach is still relatively effective because of the morphological diversity of some musical symbols (including in size) and can still be used today for a first classification phase.

Another approach widely used for the localization of the umsic symbols is to look for some easily detectable primitive and then to look around it for other primitives belonging to the expected symbol. For example, *Martin* and *Bellissant* [16.29] locate the note stems and then search for ellipses of note heads in the adjacent area. *Miyao* [16.36] uses a similar technique tailored for recognizing polyphonic passages. First, the note stems are located together with all the note heads and with stem flag candidates around each stem. Then, two neural networks are used to identify from the candidates those that are attached to a specific stem. With *Rossant* [16.37], vertical segments are not only used to locate the stems but also a whole series of symbols in which a vertical segment of a certain size is included: these symbols belong to various categories, such as notes, accidentals, bar lines, or certain types of rests. For the remaining symbols, Rossant performs a template correlation on limited zones: for locating whole note or half note rests, this area can be limited to a staff range, whereas the location of the whole notes, the correlation must be performed on a wider area.

Fujinaga [16.38] uses mainly vertical and horizontal projections. The symbols are located by vertical projection of the area between the upper line and the lower line. Different local projections are used to calculate the height, width, area, and the number of peaks to the vertical projection of the symbol. The data is used for classification in conjunction with some syntactic rules. For example, the first symbol on a staff is expected to be a clef; or a beam of eighth notes can contain only notes, rests or accidental; or a duration dot can be placed only after a note or rest. Classification is performed using a k-NN classifier together with a genetic algorithm.

Kato and *Inokuchi* [16.39] use a blackboard expert system where knowledge of musical notation is used in the process to remove ambiguities. The recognition is performed measure by measure once the clef, the

key signatures and the time signatures have been recognized. To allow optimal recognition of the different musical symbols that differ significantly in their size, their position, and their possible appearance frequency or importance, a wide variety of recognition methods are used. The architecture consists of four separate modules, which communicate with each other through a shared common data structure representing a measure. The role of the various modules is as follows:

1. Extraction of the primitives
2. Reconstruction of the symbols
3. Recognition of the symbols
4. Semantic analysis.

The memory shared by the four modules consists of five distinct layers representing five different levels of abstraction for a measure:

1. Pixels of the image
2. Primitives (note heads, stems, accidentals etc.)
3. Musical symbols (reconstituted notes, rests etc.)
4. Musical meaning of symbols (pitch, duration etc.)
5. Possible interpretation of the content of the measurement.

The recognition process is guided by a variable threshold that controls the recognition. Each layer makes assumptions that are verified by the upper layer from a tight line. If an upper layer considers a hypothesis unacceptable, the threshold is released and the treatment is reperformed at the lower level with the new threshold. For example, an unrecognized primitive will be put back in the pixels of the image. A document of good quality will be recognized with tighter thresholds and faster than poor-quality paper.

Ng and *Boyle* [16.24] use an iterative process of segmentation and recognition. Recognition is performed at different phases of the segmentation process, rather than requiring all the symbols to be segmented into primitive or broken signs prior to recognition. The purpose of this method is to avoid over-segmentation of the symbols. A first pass of recognition is performed directly after the removal of staff lines based on simple rules and using a *k*-NN classifier. For nonrecognized symbols, different types of subsegmentation and heuristics are performed.

Coüasnon [16.40] proposes a solution that uses the syntactic structure of musical notation. The idea is to use the a priori knowledge given by the music writing rules in order to guide the process of segmentation and labeling of objects. Coüasnon distinguishes between two types of information: the *physical* information corresponding to the arrangement of notes and attributes on the partition, and the *logical* information corresponding to the transformation of the notes in music writing. He defines a grammar that models this separation into two levels. The terminals of this grammar are the basic entities of the document description and are recognizable without contextual information in order to have information on which the recognition process can be based. They consist of terminal segments and symbols. The recognition process is performed in two phases corresponding to the two levels of information: graphic recognition and syntactic recognition. The first phase deals with the notes and recognizes the relative positioning of the attributes, while the second phase recognizes the symbols connected with a voice (slurs, dynamics etc.) and assigns the notes to the different voices depending on the vertical alignment and the number of beats per measure. The method specifically targets orchestral scores, where a distinction must be made between voices and staves: there may be up to three voices per staff and, conversely, a voice may be written on more than one staff.

Bainbridge and *Bell* [16.31] provide an extensible solution also based on the use of a grammar. The solution is meant to allow the recognition of different types of music notations and not be limited to CWMN. The system, named CANTOR, consists of distinct modules to be applied after the removal of stave lines:

1. Primitive recognition
2. Primitive assembly
3. Musical semantics.

Recognition of primitives is defined through a language specifically designed for the task. The idea is to accommodate a wide range of music writing by easily assigning a primitive recognition for each shape (e.g., projections, Hough transform etc.). Assembly of the primitive, the second module, is based on a slightly modified definite clause grammar, which has the limited scope of describing the taxonomy of musical notation. The purpose of keeping the scope of the grammar limited is to prevent it from becoming too complex and difficult to manage. The purpose of the last phase is to combine the symbols recognized by looking at their position in order to produce a structure representing the musical content of the image.

16.4.4 OMR Aggregation

Several researches have tried to improve OMR results by aggregating multiple commercial OMR tools. This approach relies on the fact that the commercial OMR tools all have their strengths and weaknesses and thus it should be possible to improve the overall recognition results by comparing the output of several tools. The first attempts were made by *Knopke* and *Byrd* [16.41]. Their approach involves two steps. First, the strengths

and the weaknesses of each tool that will be used are evaluated. Then the results of this evaluation are used for weighting the output of each tool when comparing their output and when the tools do not agree. *Bugge* et al. [16.42] propose a similar approach together with the definition of a dedicated format (MusicXiMpLe), a subset of the MusicXML file format used for the alignment of the tool's output and that is meant to facilitate the alignment of the data. More recently, *Church* and *Cuthbert* [16.43] have proposed a different approach that integrates rhythmic analysis in the alignment process.

16.5 Adaptive OMR

A wide range of music printing techniques have been used throughout history [16.44, 45], each having their own graphic particularities. This has led to the creation of highly varied music document symbols and notation practices. For each printing technique, publisher, editor, composer, or musical repertoire, the appearance of the notation can vary significantly. Printers often had their own distinctive font. The font shapes also vary depending on the size of the book, ranging from small in-octavo formats to larger in-folio or even in-plano formats. Font designs also have trends and changes occur over time. For example, the shape of the note heads in music fonts of the 16th and 17th centuries was generally diamond shaped. It then gradually changed and by the 18th century round note heads had become the trend.

In many OMR systems, the recognition of symbols is performed using supervised machine-learning algorithms. Supervised learning algorithms require ground-truth datasets of symbols in order to be trained. For each ground-truth symbol (e.g., a note head), features are extracted and fed to the algorithm for training. Once trained, the system will be able to identify similar symbols of the same category. When building an OMR system, gathering the ground-truth data for training is a highly time-consuming task since the amount of data required can be quite high, the data should ideally come from a wide range of sources, and each symbol needs to be correctly labeled. The high variability in the data makes it unrealistic to build an OMR system optimized for recognizing any document, even if targeting documents from a reduced historical period or one of restricted type.

A solution for tackling this issue is adaptive OMR [16.38, 46]. The assumption with adaptive OMR is that the system is not likely to consistently reach 100% accuracy and that most of the time, OMR workflows require human verification and correction to achieve usable results. In this context, adaptive OMR uses these correction results as further training data, feeding them back to the system and retraining the recognition system. As a result, systems will *learn* from their previous mistakes, correctly identifying previously misrecognized symbols through the expansion of its training data.

Pugin et al. [16.47] describe how this can be achieved using maximum a posteriori (MAP) adaptation, a technique widely used in handwriting and speech recognition. In a preliminary phase, a book-independent (BI) model is trained using ground-truth data taken from a selection of different books drawn from different printers and featuring variations in font shape and size, and is used as a seed for the recognition system. Thus the BI model gives acceptable results in general but is not specifically optimized for a particular source. In real-world usage, as each page of a book is recognized and corrected, the BI model is amended and optimized with MAP adaptation for the symbols in that book. As soon as the user has corrected the recognition errors on a newly processed page, that page is used as ground-truth to adapt the BI model. Eventually, after a user has corrected a number of pages, a book-dependent (BD) model emerges that is optimized for a particular set of sources (e.g., from a specific printer). The BD model can be saved and used for recognizing similar documents, creating a more optimal *bootstrap* than the general BI model.

16.6 Symbolic Music Encoding

The output of an OMR process is a machine-readable encoded music score. Whereas for text recognition, unformatted text files can serve as a basic encoded output of OCR processes, there is no equivalent for music encoding. There is no uniformly recognized basic music encoding scheme equivalent to unicode or to ASCII (American Standard Code for Information Interchange). For OMR applications, this means that

the encoded output has to be structured according to a defined music code, be it designed specifically for the OMR application, such as the Liszt format for the SharpEye commercial application, for example, or a more generic musical code.

Over the years, hundreds of musical codes have been proposed, illustrating both the complexity of music notation and the wide range of applications codes can serve [16.48]. Selfridge-Field groups them into three categories:

1. The codes targeting sound applications
2. The codes targeting notational applications
3. Those targeting analytical or more abstract applications.

Looking at how note pitches are handled is a simple way to help understand the difference between these code categories. In the first category, the most widely used code is undoubtedly MIDI (Musical Instrument Digital Interface), whose primary goal was to allow sound information to be exchanged between instruments. One particularity of MIDI regarding pitches is that it does not make the difference between, say, an F-sharp and a G-flat even if they were noted differently in the score. The second category of codes is meant to capture visual characteristics of music notation. Musical codes that belong to this category include DARMS (Digital Alternative Representation of Music Scores), one of the oldest computer codes; SCORE, the code used by the Score music notation software application developed by Leland Smith; or the notation interchange file format (NIFF). One particularity of the codes for notational applications is that they often do not have a concept of pitch. They do not store the notes by referring to the pitch name and the octave but instead by referring to the staff line on which they appear. The C_4 (C of the fourth octave) with the treble G-clef will be coded with the same staff line parameters as an E_2 with the bass F clef. Codes from the later category that target analytical applications, such as the plain and easy code, the kern representation, or the Essen associative code (EsAC), to mention only a few, store the note information through its pitch name and its octave.

Codes for notational applications are well suited to OMR applications. In fact, NIFF was developed with OMR in mind and is still used by some commercial software applications. NIFF was designed in the mid-1990s and subsequently came to be supported by a fair range of commercial OMR systems, including SharpEye, SmartScore, and PhotoScore. The use of NIFF remained limited, however, and it never really took off beyond its use by commercial OMR applications, which eventually abandoned it. Nor did another attempt in music code definition that was to extend MIDI for OMR with the expressive MIDI [16.48].

One reason NIFF failed to establish itself as a standard file format may be that it is a binary format. (Binary codes had the advantage of being more compact than ASCII codes, but disk space is no longer an issue for this type of data). But another reason might be that it is a notational code, with the limitation that only the graphical component of music notation is taken into account. In OMR, the recognition task acts as an encoding process that moves from a graphical domain to a logical domain. With a notational code such as NIFF, the processing of the data remains limited. For example, the pitch name and the octave of a note can remain unknown since only the position on the staff line is stored. In many uses of OMR data, however, further processing will be desirable in order to move to a code of the third category, the codes for an analytical or more advanced application. Typically, this will mean further processing the data in order to determine the pitch names and the octaves by taking into consideration the clef of the staff (or possible intermediate clef changes) and the key signature (or possible accidentals appearing previously in the measure). When the goal of the OMR process is the reediting of the original image, then a notational code can suffice, assuming that the editing tool can read the notational code produced by the OMR process. (It should to be noted that such an approach can have advantages regarding the impact of some recognition errors. For example, if a clef of a staff was wrongly recognized, it will have no impact on the accuracy of the content of the staff itself). This is, however, only one possible use case of OMR. Typical use cases of OMR require analytical data, for example to make an arrangement or transposition of the musical content. The analytical data can be derived from notational codes, but this is not necessarily trivial to do. It is one reason why encoding output formats other than NIFF were desirable and why it eventually became obsolete.

One analytical format that is widely used as an output of OMR processes is MusicXML, which is a code that started as an XML (extensible markup language) representation of MuseData [16.49]. It was developed by Michael Good and is now owned by MakeMusic. MusicXML is primarily an interchange format for exchanging music data between computer applications. This makes it well suited for exporting data from an OMR system to other types of applications, but it is not designed to represent and store the information of an OMR process.

Some XML alternatives to MusicXML were proposed for encoding music notation. One targets a wide range of applications, including OMR: the IEEE 1599–2008 standard designed by the IEEE 1599 Working

Group for XML Musical Application [16.50]. To our knowledge this standard is not currently used by any OMR systems.

16.6.1 The Music Encoding Initiative (MEI)

Over the last few years, a community-based project began to occupy an increasingly important role: the Music Encoding Initiative (MEI) [16.51]. The project was started around 2000 by Perry Roland from the University of Virginia. It was directly inspired by the Text Encoding Initiative (TEI), a leading project in text studies that became over the years the commonly accepted standard for representing and encoding texts. MEI pursues similar goals for musical documents. It is expressed in the form of an XML schema that defines the structure of the corresponding XML musical data. The first version of the MEI schema was released in 2010 in ODD (one document does it all), which is a schema definition solution developed by the TEI community that regroups in one document the schema definition and all the documentation related to it. The MEI schema is regularly updated to incorporate the latest improvements.

One feature of MEI in contrast to many attempts to define a musical code is that it is driven by an open community of contributors representing a wide range of backgrounds and interests. They include technologists, musicologists with various repertoires of expertise, and librarians. Beside the fact that MEI is community driven, it also has the particularity of accommodating a wide range of music notation and not being limited to CWMN – even though this is its first target. This flexibility is greatly facilitated by its modular approach and its nonmonolithic design. Each music notation type can be defined as a separate module, for example, MEI already includes in its core set of modules specialized modules for mensural and neume notations. The modularity of MEI does not serve only the separation of music notation types. MEI includes distinct modules for the metadata, for pointers and references, for linking with facsimile or for the definition of graphics, shapes, and symbols. Furthermore, each module can be modified or new modules added, should the default settings of MEI not be appropriate. This can happen when encoding a different notation type or when another type of application is targeted by the encoding. MEI includes a so-called customization service that allows part of the schema to be redefined or new encoding concepts to be introduced [16.52].

Even though MEI was not designed specifically for OMR applications, its richness and flexibility makes it perfectly appropriate for them [16.53]. The aforementioned module for linking with facsimile images is of particular interest. It makes it possible to easily and precisely refer from the encoding to zones in an image. This is similar to what is achieved with the hOCR format developed by Google for their open-source OCR project OCRopus. Since the output is text with OCR, they can use HTML (hypertext markup language) to mark up the text output [16.54]. However, the hOCR format enriches the HTML with additional information on layout, referring to an image, and data such as character recognition confidences. This is done in a way that does not affect the structure of the HTML content, which remains standard HTML. In a similar (though not identical) way, the MEI can include additional information, including references to image zones without the logical structure of the MEI to be modified. With MEI, references to images work by defining a facsimile subtree in the MEI file that regroups a set of surfaces (typically each one representing a page) that will contain a reference to an image and a list of zones in it. Each zone is identified with a unique identity to which any element in the encoding (a clef, for example) can refer. This not only enables robust linking between the encoding and the image to be generated, but it also has the advantage of keeping the information concerning the references to the images separate from the logical musical data.

16.7 Tools

16.7.1 Commercial OMR Software

Although several commercial OMR software packages have been marketed, currently only a handful products have stood the test of time. One of the survivors is also the first commercial OMR software ever published. Initially under the name MIDISCAN, Musitek released its product in August 1993 [16.55]. It was renamed later as SmartScore and its Lite version was bundled with a music editing software Finale 2003 in the spring of 2002. Another popular music editing software Sibelius (now owned by Avid Technology) uses Photoscore [16.56], which was originally released by Neutron for the Acorn system in 1997 (for Windows in 1999 and for the Mac in 2000). The ScoreMaker by Kawai has been available on the Windows system (in Japanese only) since 1995 and the capella-scan [16.57] from Germany has been around since about 2000 [16.58]. According to the developer, Graham Jones, the development of SharpEye started in 1996 [16.59], but it has not been updated

since 2006 (version 2.86) when he *transferred rights in SharpEye to another company* [16.60]. All of the commercial OMR software mentioned above are designed to work with CWMN.

16.7.2 Open-Source Tools and Toolkits

A few OMR tools are available as open-source. We can make the distinction between end-user ready-to-use desktop applications and toolkits available for creating custom OMR applications.

Desktop Applications

For CWMN, the only open-source tool available is Audiveris [16.61]. It is written in Java and is available under the General Public License (GPL) v2 open-source license. For text recognition, Audiveris uses the Google OCR Tesseract engine. The recognition engine is based on neural networks that can be retrained for specific sources. Audiveris includes a user interface for data correction and exports to MusicXML. Version 5 is currently in preparation.

One open-source OMR project specifically targets Renaissance music prints: the Aruspix project [16.62]. The project focuses on the development of techniques and tools for processing early typographic music prints from the 16th and 17th centuries. The Aruspix software application is a desktop application written in C++ (cross-platform) and is available under the GPL v3 license. Aruspix uses HMM (hidden Markov models) for the recognition with an original approach without staff removal [16.14]. It includes a user editor for correcting the results and an adaptive feature based on MAP adaptation [16.47]. Aruspix uses MEI as internal and output format.

Toolkits

The most widely used toolkit for building OMR systems is Gamera [16.17, 63]. Gamera is written in C++ and Python and is available under the GPL v2 license. It is designed as a toolkit for building pattern recognition systems with a strong focus on document recognition and OMR in particular. It includes a whole range of image processing algorithms together with a *k*-NN classifier. With this tool, the users can build their own recognition system by putting together scripts that will perform selected operations. These can include various preprocessing operations, such as noise removal, blurring, deskewing, contrast adjustment, sharpening, binarization, and morphology, for example. At the core of the Gamera system is the segmentation and the classification. Several algorithms are provided for these tasks together with a user interface for labeling the data. Both the image processing and the classifier parts are easily extendable, if necessary, with either C++ or Python extensions.

Gamera is distributed with add-on toolkits specifically designed for building OMR applications. The MusicStaves toolkit implements various algorithms for removing the staff lines [16.35]. It can be used in an interactive mode through the Gamera graphical user interface or in a noninteractive mode from the command line or scripts. The OTR (optical tablature recognition) toolkit is a package for the recognition of lute tablature [16.9, 11]. It includes scripts for the recognition of French, German, and Italian tablatures, all being slightly different tablature notations. Gamera also includes a Psaltiki recognition toolkit for the recognition of Byzantine chant notation used in chant notation of the Eastern churches [16.13]. It also distributes an OCR toolkit with custom page segmentation algorithms and heuristics rules for dealing with diacritics.

Gamera has been used for projects on other music notation, including neumes [16.64]. Gamera is also often used for evaluating research techniques, such as with Aruspix [16.65] where two OMR approaches are compared, or on more specific OMR steps such as staff line removal [16.66–68].

16.8 Future

Recent directions taken in OMR developments together with changes in technology make it possible to envisage completely new OMR paradigms. For decades, the goal of OMR has focused almost exclusively on providing image transcriptions for further processing with external software applications. Commercial OMR applications are usually desktop software applications that take an input image and output an encoded score without making further use of the link established between the image and its content.

Recent advances that can change this paradigm are manifold. First of all, open-source developments, such as Gamera, open new perspectives. The OMR technology is no longer embedded in a black box but instead remains open in modules that can be modified and assembled differently according to the needs and type

of documents to be processed. Many music documents raise similar though not identical challenges, and being able to adjust the tools is essential. The aforementioned Gamera MusicStaves toolkit is a perfect example in that regard.

Adaptive-OMR design is another direction that opens new perspectives and that also differs from the design of most commercial OMR desktop applications. Having systems that improve themselves over time is essential for bringing OMR to a next level. Correcting OMR errors is a highly time-consuming task, and the advantages gained by being able to feed this knowledge back into the system appear self-evident. Nonetheless, for years users have been using OMR systems and correcting their output without exploiting this data goldmine. This wasteful practice can be changed, but only if the output of the OMR process preserves the link between the output data and the image. It appears that the developments of MEI will play a key role in this endeavor. Having a standard format for preserving OMR data will allow the creation of large datasets. They will be usable for training or improving any OMR systems, which in turn will greatly facilitate the development and improvement of OMR technology.

One significant technological change that has occurred over the last few years is the emergence of online applications that can run in web browsers. It is now possible to develop software applications that run online without any application or plugin to be downloaded and installed locally. This radically changes the way software applications can be made available to the users. Over the next few years we can expect to see online OMR tools appearing that will be a significant breakthrough from the desktop applications currently available. In this context, the development of MEI engraving tools, such Verovio [16.69, 70] will be essential for making the OMR output editable online. For OMR, having online tools will also make it possible to develop adaptive systems where the corrections of one user can be immediately incorporated into the system and benefit all users, not only the one who made the corrections.

Online technology also transforms the way data can be made available. We now have access to thousands of images of music sources that are being digitized and made available by music libraries and archives all around the world. These images are an unparalleled resource for musicians, musicologists, and other scholars alike. However, only OMR technology can fully revolutionize the way they are made available to the user. The recent developments of Diva.js [16.71, 72] offer a glimpse of the future, where the output of the OMR process in MEI is displayed on top of high-resolution images directly in the web browser. This is a setup that is widely known for books but is still lacking for music, and large-scale online OMR technology is the key to fill this gap.

As large amounts of score data become available in symbolic formats, the next challenge is how to effectively use these large corpora of musical data. There are two basic issues: searching and analysis. Searching music is complex: there are pitches, rhythms, text, multiple voices sounding simultaneously, chords, different instruments etc. Linking metadata for sources and works (e.g., date of composition, location, or genre) and musical content is also essential. Analyzing music is also challenging given the large amounts of symbolic data that were not available previously. Thus, there will be questions such as what are the best ways to search through these corpora? What should the queries look like? What kinds of user interfaces are needed for queries and displays? What types of analysis of music are possible given these large datasets? The answers to these and other questions will create new research avenues paved with the aid of OMR technology.

17. Adaptive Musical Control of Time-Frequency Representations

Doug Van Nort, Phillippe Depalle

In this chapter we consider control structures and mapping in the process of deciding upon the underlying sonic algorithm for a digital musical instrument. We focus on control of timbral and textural phenomena that arise from the interaction and modulation of stationary spectral components, as well as from stochastic elements of sound. Given this observation and general design criteria, we focus on a family of sound models that parameterize the stationary and stochastic components using a spectral representation that is commonly based on an underlying short-time Fourier transform (STFT) analysis. Using this as a fundamental approach we build a dynamic model of sound analysis and synthesis, focusing on a design that will simultaneously lead to musically interesting transformations of textural and noise-based sound features while allowing for control structures to be integrated into the sound dynamics. Building upon well-established adaptive algorithms such as the Kalman Filter, we present a recursive-exponential implementation, and exploit a fast algorithm derivation in order to process both additive data and the full underlying phase vocoder. The model is further augmented to allow for nonlinear adaptive control, pointing towards new directions for adaptive musical control of time-frequency models.

At this point in the field of digital music synthesis and control, there are many high-quality algorithms available for sound synthesis and transformation. Similarly, the issue of mapping and control structures to expressively manipulate these algorithms is also a well established field [17.1, 2]. The dominant control paradigm thus far has been to impose structures onto synthesis algorithms in a top-down fashion, following established paradigms such as continuous timbre space navigation [17.3]. However, there exists a largely unexplored territory that can advance the design of systems for digital, expressive musical control: the concurrent design of sound synthesis and control algorithms from a very low level. Such an approach can allow for nuanced manipulation that deeply integrates sonic and expressive goals, by expressing both the temporal dynamics of input gestures as well as how this control affects the sound over time. This requires one to consider control in a lower-level part of the instrumental design hierarchy, and to *embed this in the description of the underlying sound process*. Such an approach can become particularly powerful in the case of analysis/transformation/synthesis systems based on spectral models. In this chapter we present a particular class of adaptive analysis/synthesis systems whose representation can function as a hybrid between signal

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_17

and physical modeling approaches, as well as between source-filter and additive models. The models we develop for sound transformation are novel and interesting in their own right, allowing for various textural and spectral effects. However we further reconsider classic techniques in a new framework not simply for new transformation possibilities, but extend this by building the normally *higher-level* control layer into the model itself, showing how mapping and control can be considered at the most atomic level, so that the design of musical control is deeply tied into the very definition of the system.

When one considers the type of sound they want to control they are, at least to some extent, imagining the space of possible transformations of this sound. Therefore, it is beneficial to consider the transformations afforded by a given sound model, in conjunction with the myriad ways that this model may be controlled. This chapter will focus on a family of sound models that parameterize the stationary and stochastic components using a spectral representation that is commonly based on an underlying short-time Fourier transform (STFT) analysis [17.4]. Using this as a fundamental approach the chapter presents a dynamic model of sound analysis and synthesis, focusing on a design that will simultaneously lead to interesting transformations of spectral, textural and noise-based sound features while allowing for control structures to be integrated into the sound dynamics. This is achieved through a novel approach based on a recursive-exponential implementation, augmented to allow for nonlinear adaptive control.

17.1 State-Space Analysis/Synthesis

The dominant paradigm for understanding a linear system (audio filters, the Fourier transform, etc.) typically lies in the frequency domain through a transfer function representation, which describes the input/output relationship that the system will produce. Any such system can also be represented as a recursive difference equation that expresses not just the out-of-time effect of the system, but the dynamics of this system over time [17.5]. This is achieved through a state-space representation (SSR): rather than model a system in terms of its transfer-function representation one can express its actions on a stochastic process $\boldsymbol{y}[n]$ by way of the two state-space equations

$$\begin{aligned} \boldsymbol{s}[n+1] &= \mathbf{A}\boldsymbol{s}[n] + \boldsymbol{w}[n] \quad \text{and} \\ \boldsymbol{y}[n] &= \mathbf{B}\boldsymbol{s}[n] + \boldsymbol{v}[n]\,, \end{aligned} \tag{17.1}$$

where the sequence $\boldsymbol{s}[n]$ is the state of the process at time n, and the upper equation represents the internal dynamics of the process as governed by dynamics matrix $\mathbf{A}$. The lower equation projects the state vector, which may be hidden, into a vector of observable output variables using observation matrix $\mathbf{B}$. Both $\boldsymbol{w}$ and $\boldsymbol{v}$ are assumed to be zero-mean, Gaussian white-noise processes. The first affects the progression of the state while the second is additive noise present in the output process $\boldsymbol{y}$.

Using the SSR, one can express and modify the dynamics of a sound transformation system, building a control structure around this representation. As we will see, methods for statistical estimation can be applied to this framework, and can be extended to modeling in nonstationary and nonlinear environments. A further advantage is that a physically inspired model of a control/sound system can be used to constrain the interaction, so that physical and more abstract signal models can be used in a hybrid fashion. The approach presented here takes advantage of this potential for parameter estimation, accounting for nonlinearity and model hybridity.

17.1.1 The State-Space Phase Vocoder

In general, the phase vocoder is a widely used tool for the analysis, transformation and synthesis of audio signals. It began as an attempt to efficiently code and transmit voice signals using filter banks [17.6], was later represented by the STFT [17.7] and then began to find use in musical applications [17.8, 9]. The most common effects generated by the use of the phase vocoder are pitch shifting and time scaling, which are achieved through altering the time/frequency block increment size between the analysis and synthesis step and then interpolating. If the step increment for both analysis and synthesis is subjected to certain constraints based on the type of windowing function used in the STFT, then the input signal is perfectly reconstructed upon resynthesis. However the phase vocoder becomes musically interesting when the signal is distorted by transformations such as pitch/time scaling, cross-synthesis and others in which the amplitude and phase of each frequency bin are modified over time. As the representation itself is purely deterministic and able to capture the signal entirely, these distortions are externally applied to the spectral data in an intermediate (i. e., between analysis and synthesis) step.

Now, the creation of an SSR-based phase vocoder is possible by exploiting a recursive description of the discrete Fourier transform (DFT), as was presented in [17.10]. The approach exploits the fact that the complex exponentials of the DFT can be expressed as

$$e^{jn\theta} = e^{j\theta} e^{j(n-1)\theta} , \tag{17.2}$$

for time n and frequency θ. Thus the DFT matrix and its inverse can be expressed as a first-order recursion, which from the above equations we can see is a necessity in order to work within this SSR framework. Therefore the DFT matrix may be represented by the state matrix $\mathbf{A}$, which becomes a block diagonal matrix consisting of 2×2 rotation submatrices, and can be thought of as expressing the *process of the Fourier transform* in the way one might imagine a heterodyning filter to act over time in an analog filter-bank DFT implementation [17.11]. The state $\boldsymbol{s}$ in this case is a vector representing the spectral frames acted on by the DFT matrix at each time step, while $\boldsymbol{v}$ can be thought of as an additive output noise similar to the residual found in the spectral modeling synthesis (SMS) approach [17.4]. This basic representation forms the foundation for the control/sound models that are derived throughout this chapter. In [17.12] we presented musically inspired effects created by exploiting its explicit representation of spectral dynamics and a stochastic component, known as the stochastic state-space phase vocoder (SSSPV). We extended the generic structure of (17.1) by introducing noise into the state matrix $\mathbf{A}$. This resulted in modifying the dynamic of the process, which led to more dramatic effects. Indeed, adding such noise in the dynamic of the synthesis with different time-varying behaviors allows for effects such as concurrent random modulations between partials that can induce jitter and lead to an influence of a given sound's texture [17.13].

17.1.2 Related Work

A state-space approach to analysis/synthesis was presented in [17.14] in which the real and imaginary components of p sinusoidal partials, tracked over time, were represented in the state vector. The observation matrix summed across the real components of the partials, and the addition of observation noise generated a sinusoid+noise resynthesis. The same underlying model was also used in [17.15], though the spectral components that were tracked did not necessarily represent partials. Similarly, a recursive state-space formulation is presented in [17.16] wherein the state is comprised of the real and imaginary components for N evenly spaced frequency bins. Thus, this implementation maintains all of the data from the phase vocoder while the aforementioned work directly tracks partials and so is a sinusoidal model. The motivation differs in [17.16] as well, with the goal being the interpolation of missing audio samples whereas the former two projects were concerned with building an analysis/synthesis scheme for audio transformations. The work presented in this chapter is situated between these two as the motivation is towards musical transformations, yet preserves the lower-level representation given by the complete Fourier spectral frames.

Each of these approaches utilizes adaptive filtering and estimation to jointly estimate and predict spectral models of a musical signal that spans from the low level of spectral envelope and partials up to musical structure. The unifying characteristics across each is that they rely on a state-space modeling framework. This approach to signal representation allows for hybrids between a signal model and a physical model, as was shown by [17.17] and [17.18].

17.1.3 Beyond SSSPV: From Effect to Transformation

The SSSPV can be considered as a phase vocoder in which a stochastic element has been built into the representation via a state-space framework. The focus with this implementation is on the fact that through the embedding of noise within the system representation itself (rather than as input to the state or observation equations) a sound can be resynthesized with an added textural or roughness quality. While this approach can provide a family of interesting effects, there are some limitations with this implementation. Primarily, this state-space representation diverges from a classic phase vocoder in that it is actually a recursive implementation of the DFT. In other words, it is only defined for a single analysis window, and the input signal must be reintroduced at the boundary between windows. This is not a problem for this set of noise-based effects, but it inhibits the implementation of deeper transformations based on time stretching and pitch shifting across large time scales.

The use of the state-space representation is interesting with the SSSPV in that it gives access to the internal dynamics of the analysis/synthesis process for control and processing. However a deeper reason for using the state-space approach is that it allows for the use of tools such as the Kalman filter for parameter estimation. To this end, we build upon the state equations from (17.1), and using the same underlying spectral model as in SSSPV, design an STFT-based recursive implementation that functions as a *true* phase vocoder, capable of deeper transformations than noise-based effects.

17.2 Recursive, Infinite-Length Windows

Creating a state-space recursion based solely on (17.2) defines a DFT that implicitly assumes a periodic input signal whose fundamental period is defined by the N input samples. It is further an implicit rectangular windowing, and by reintroducing the input each N samples (as in SSSPV) there is no overlap in the analysis. In order to extend this, we will illustrate how the STFT can also be expressed with a one-step recursion. In the process, this will introduce an infinite-length window into the definition, which provides certain beneficial time-frequency properties; in particular, through a single-sided exponential window [17.19] $h[m]$ defined as

$$h[m] = \mathrm{e}^{\lambda m} u_+[-m] \,, \tag{17.3}$$

where $u_+[m]$ is the unit step function. The use of this window allows one to accurately detect the beginning of signals (due to the discontinuous front edge of the window) as well as to tune the influence of the past samples through changing the damping value $\lambda > 0$. Following this, the STFT

$$X_{n,k} = \sum_{m=-\infty}^{\infty} x[m]h[m-n]\mathrm{e}^{-\mathrm{j}\omega_k m} \tag{17.4}$$

for real input signal $x[m]$ becomes

$$X_{n,k} = \sum_{m=-\infty}^{n} x[m]\mathrm{e}^{\lambda(m-n)}\mathrm{e}^{-\mathrm{j}\omega_k m} \,. \tag{17.5}$$

The one-step recursion can be derived by looking at the value

$$X_{n+1,k} = \sum_{m=-\infty}^{n+1} x[m]\mathrm{e}^{\lambda(m-(n+1))}\mathrm{e}^{-\mathrm{j}\omega_k m} \,, \tag{17.6}$$

which expands to

$$X_{n+1,k} = \sum_{m=-\infty}^{n} x[m][\mathrm{e}^{\lambda(m-n)}\mathrm{e}^{-\lambda}]\mathrm{e}^{-\mathrm{j}\omega_k m} + x[n+1]\mathrm{e}^{-\mathrm{j}w_k(n+1)} \tag{17.7}$$

and thus

$$X_{n+1,k} = \mathrm{e}^{-\lambda} X_{n,k} + x[n+1]\mathrm{e}^{-\mathrm{j}\omega_k(n+1)} \,. \tag{17.8}$$

Therefore the STFT at any given time – when using this window function – is a product of the exponentially damped previous time step and the Fourier transform component from the current time-series value. In light of the state-space representation developed in the previous section, we can now rewrite the state equation as

$$\boldsymbol{s}[n+1] = \hat{\mathbf{A}}\boldsymbol{s}[n] + \mathbf{D}_n \boldsymbol{u}[n+1] + \boldsymbol{w}[n] \,, \tag{17.9}$$

where

$$\hat{\mathbf{A}} = \mathrm{e}^{-\lambda}\mathbf{A} \quad \text{and} \quad \mathbf{D}_n = (\bar{\mathbf{A}})^n \,, \tag{17.10}$$

with $\bar{\mathbf{A}}$ defined as the block diagonal from $\mathbf{A}$ extracted and collapsed in order to form a $2N\times 2$ matrix. Finally $\boldsymbol{u}[n] = [x[n+1]\ 0]^{\mathrm{T}}$ is the real-valued time series at time $n+1$ and functions as the *input vector* in terms of the state-space formalism.

Now, this implementation is an adaptive version of the STFT in which the infinite-length exponential window acts as a forgetting factor. This smoothing extends the previous recursive DFT into an STFT through a consideration of all past sample values. From this point onward, let us refer to this implementation as the recursive exponential STFT, or RESTFT (RESTFT). Note that this differs from a standard STFT wherein window length N is directly related to time-frequency resolution in that this gives rise to N frequency bins. Instead, in this case frequency resolution is not directly tied to window duration [17.20], but rather is a factor both of the window overlap as well as the damping value λ. These can therefore be adapted based on the transformation and synthesis requirements.

Now, we may build an adaptive framework on top of RESTFT using the Kalman filter, in order to parameterize the relative sine/noise quality of both attack and sustain such that one may reestimate these trajectories under time stretching and other time-varying transformations. Several algorithms were created in order to reach this goal, beginning with the creation of the initial Kalman framework.

17.3 Kalman Filter-Based Phase Vocoder

Taking full advantage of deeper sound transformations and control parameter estimation with the RESTFT representation requires the implementation of a Kalman filter (KF). The KF is an algorithm developed in order to optimally estimate the state of a linear dynamical system perturbed by Gaussian noise [17.21, 22]. Many variants have been established in order to extend the tracking, estimation and prediction properties of this filter to nonlinear and non-Gaussian systems [17.23]. As the STFT is a linear transform, the standard form of the KF suffices in order to model the sound process. The result is a model that allows one to estimate the magnitude and phase of each bin for every time step, and to extract *both the state and observation noise* for individual control and processing. As is noted in [17.24], in which the author creates a similar Kalman-based additive model specialized to damped percussive sounds, the state and observation noise sources relate to the transient noise and sustain noise (respectively) of the underlying sound signal. In this chapter we focus on these noise values, in order to define novel transformations of the noise component that adapt to varying time-stretching, such as one finds in scrubbing-based gestural control.

Now, the Kalman filter is a recursive process that consists of a time update and a measurement/observation update. The former first predicts future values of the state, and the latter then modifies this in order to provide an adjusted estimate for the current time step. More precisely, the a priori state estimate $\hat{\boldsymbol{s}}_n^-$ and the state covariance estimate $\mathbf{P}_n^-$ are conditioned on all prior values as

$$\begin{aligned}\hat{\boldsymbol{s}}_n^- &= \hat{\mathbf{A}}\hat{\boldsymbol{s}}_{n-1} + \mathbf{D}_{n-1}\boldsymbol{u}_{n-1} \quad \text{and} \\ \mathbf{P}_n^- &= \hat{\mathbf{A}}\mathbf{P}_{n-1}\hat{\mathbf{A}}^{\mathrm{T}} + \mathbf{Q}\,. \end{aligned} \tag{17.11}$$

These are the *time update* equations. Recall that the underlying system is perturbed by process and observation noise $\boldsymbol{w}_n$ and $\boldsymbol{v}_n$, which are zero-mean Gaussian white noise with variance $\mathbf{Q}$ and $\mathbf{R}$ respectively. The values $\hat{\boldsymbol{s}}_n$ and $\mathbf{P}_n$ are the a posteriori state and state covariance values, acquired from the following *measurement update* equations

$$\begin{aligned}\mathbf{K}_n &= \mathbf{P}_n^-\mathbf{B}^{\mathrm{T}}(\mathbf{B}\mathbf{P}_n^-\mathbf{B}^{\mathrm{T}} + \mathbf{R})^{-1}\,, \\ \hat{\boldsymbol{s}}_n &= \hat{\boldsymbol{s}}_n^- + \mathbf{K}_n(\boldsymbol{y}_n - \mathbf{B}\hat{\boldsymbol{s}}_n^-)\,, \end{aligned} \tag{17.12}$$

and

$$\mathbf{P}_n = (\mathbf{I} - \mathbf{K}_n\mathbf{B})\mathbf{P}_n^-\,. \tag{17.13}$$

A heuristic understanding of these equations would be to first consider the a priori state and covariance estimates as predictions based on all past values, with no noise disturbance; the updated estimates are defined by adjusting this initial estimate based on the influence of the *innovations sequence* $\boldsymbol{\epsilon}_n = (\boldsymbol{y}_n - \mathbf{B}\hat{\boldsymbol{s}}_n^-)$, which represents the difference between the observed value and the ideal noise-free observation. The degree of influence from the innovation is *tuned* by the so-called Kalman gain $\mathbf{K}_n$.

Following [17.24] we extract the residual from the state-space model in order to drive the resynthesis, though the extraction method differs as does the underlying representation (exponential STFT versus damped sinusoidal model). Thus the estimated process and observation noise sources are defined as

$$\hat{\boldsymbol{w}}_n = \hat{\boldsymbol{s}}_n - \hat{\mathbf{A}}\hat{\boldsymbol{s}}_{n-1} \quad \text{and} \quad \hat{\boldsymbol{v}}_n = \boldsymbol{y}_n - \mathbf{B}\hat{\boldsymbol{s}}_n\,. \tag{17.14}$$

We therefore have an estimate of the state $\hat{\boldsymbol{s}}_n$ – providing instantaneous estimates of magnitude and phase values – which gives rise to estimates of the excitation noise $\hat{\boldsymbol{w}}_n$ and the additive output noise $\hat{\boldsymbol{v}}_n$.

Finally, in order to provide the first a priori estimates, the model must be given initial conditions for the state and state covariance matrix. In the absence of any specific knowledge about the signal, we may safely define these such that

$$\hat{\boldsymbol{s}}_0 = \mathbf{0}_{2N\times 1} \quad \text{and} \quad \mathbf{P}_0 = \sigma^2\mathbf{I}_{2N\times 2N}\,. \tag{17.15}$$

The value $\sigma^2 \ll 1$ is the state covariance – it reflects the level of uncertainty in our initial state and governs the rate of convergence of the filter. If we were absolutely certain that the initial state was identically zero, we could let $\sigma^2 = 0$ as well. When the state of the input at time zero is unknown, one may include σ^2 as a model parameter that must be tuned. The other parameters are the noise covariance for the state and process noise values, the damping value λ for matrix $\hat{\mathbf{A}}$ and the state size N. The three noise covariance values $(\sigma^2, \mathbf{Q}, \mathbf{R})$ influence the ability of the tracking of spectral data, changing the relative amount of energy that will be present in the residual signals $\hat{\boldsymbol{w}}_n$ and $\hat{\boldsymbol{v}}_n$ as compared to the state estimate $\hat{\boldsymbol{s}}_n$. Meanwhile, the values λ and N together define the time/frequency resolution of the analysis as well as the computational power required (in the case of N). Therefore, while the Kalman-based RESTFT will produce a *perfect reconstruction* of an input signal if there are no modifications to the spectral or residual data, this is a parametric approach in which the relative contribution of each time-series $\hat{\boldsymbol{s}}_n$, $\hat{\boldsymbol{w}}_n$ and $\hat{\boldsymbol{v}}_n$ can be tuned by altering these model parameters.

17.3.1 Discussion

This KF-based RESTFT framework becomes musically interesting when used to reestimate state and noise values after applying time/frequency transformations such as pitch shifting or time stretching, or when one controls the relative level of each as well as the variance of the noise processes over time.

By adding a layer of control for such adaptive signal behavior, one is providing a bottom-up definition of mapping in which the general dynamic rules are described, rather than a static parametric mapping function. In this way, control and mapping are embedded in the signal definition, and happen *at the level of the sound transformation*.

Again, the RESTFT state size is defined by the number of phase vocoder spectral bins. This state size is a strong limiting factor for computation of the analysis, and so we have developed an algorithm adapted from the control theory literature, the so-called Chandrasekhar-type recursions [17.25], in order to make high-quality transformations more feasible by allowing for more reasonable window (i. e., state matrix) sizes, and therefore higher frequency resolution. The details of that algorithm may be found in the appendix.

17.4 Additive Layer and Higher-Level Architecture

The advantages gained by having an adaptive framework based on the Kalman filter can be extended from the phase vocoder to a higher-level, additive framework as well. In this implementation, rather than tracking the state of N evenly spaced frequency bins, we can model L sinusoidal partials ($L \ll N$ in general) so that

$$x_n = \sum_{k=1}^{L} \left[a_{k,n} \cos\left(\sum_{r=0}^{n} \omega_{k,r} + \phi_k \right) \right] . \qquad (17.16)$$

In terms of the underlying state-space representation, rather than the time-invariant state matrix defined by (17.10), the system here is nonstationary with time-varying state matrix $\mathbf{A}_n$ where the frequency values to each block diagonal component are given from the L frequencies $\{\omega_{1,n}, \ldots, \omega_{L,n}\}$. Therefore the matrix is of size $2L \times 2L$, where L is generally below 100. Note that the time resolution is therefore not bound implicitly to N samples in the same way as with the phase vocoder. Rather, the time-varying matrix $\mathbf{A}_n$ can be updated as much (i. e., each sample) or as little as desired, and commonly every H samples (i. e., hope size).

Now, note that the infinite-length exponential windows are still used in this analysis, preserving the time-frequency properties that exist with the RESTFT. This analysis stage does not do any partial tracking itself. Rather, peaks of interest are given to the analysis system at any time stamp deemed appropriate. Therefore, another method may be used in order to provide high-quality partial tracking (e.g., [17.26]) and this information can be fed to the Kalman-based system in order to provide a complete set of data on the suggested location of each partial. The additive Kalman layer, then, computes a *reanalysis* that extracts specific magnitude and phase values at each partial while producing the residual in the process. As with the KF-RESTFT, the sound's transient noise is captured by the process $\hat{\boldsymbol{w}}_n$ while the additive noise is represented by $\hat{\boldsymbol{v}}_n$. Therefore, rather than providing an improved partial-tracking algorithm, this additive implementation is geared towards providing a more refined analysis of the sine/noise energy decomposition. This serves the ultimate goal of improved noise-based transformations, in this case relative to a parametric additive framework. The overall sound processing architecture is depicted in Fig. 17.1, which shows the two analysis/synthesis schemes – KF-RESTFT and the Kalman-additive model – in parallel. It is not necessarily suggested that both schemes must be used in tandem, but rather this illustrates the manner in which they relate to one another in terms of model, input and control parameters. In each case, the input value x_n is sent into the analysis. In terms of the additive model, it is assumed that some other method is used for determining the list of peaks $F_\tau = \{\omega_{0,\tau}, \ldots, \omega_{L-1,\tau}\}$ in the *peak tracking* step. For both the additive and phase vocoder implementations, a set of model parameters must be provided. With the phase vocoder, these parameters are

$$\theta = \{\lambda, N, r, \sigma^2, q\} , \qquad (17.17)$$

where again the first two influence the time-frequency resolution and the latter three are the noise covariance values for the state, process and observation. For the additive model, the parameter set $\bar{\theta}$ varies slightly

$$\bar{\theta} = \{\lambda, L, H, r, \sigma^2, q\} , \qquad (17.18)$$

where L is the number of partials, and H is the hop size of the peak-tracking analysis. In general, these model parameters are not controlled online (and so have no inputs in this diagram), but they may potentially be changed in an adaptive fashion [17.27]. Once the Kalman-based additive or phase vocoder analyses are complete, they produce state estimates $\hat{\boldsymbol{s}}_n$ as

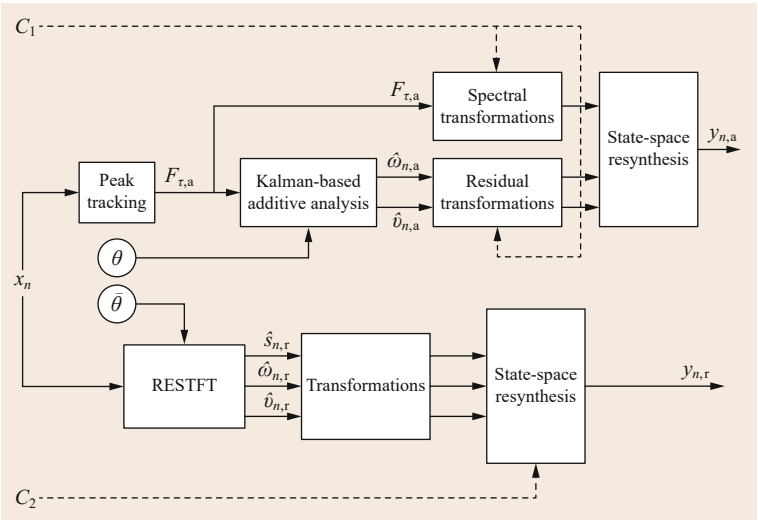

Fig. 17.1 Model architecture for Kalman-based additive and recursive exponential STFT models, shown here in parallel. Amplitude or phase values may be extracted for processing during the respective transformation stages

well as residuals $\hat{\boldsymbol{w}}_n$ and $\hat{\boldsymbol{v}}_n$. These are the values that are more likely controlled, or otherwise transformed before resynthesis. Thus, any possible control input would map directly into these values. In the case of the additive model, the frequency values F_τ may be transformed separately, so that partials may be independently processed. After time/frequency transformations are applied to the spectral frames of the state or to the residual values, the entire process is resynthesized using the state-space model, by (17.14).

17.5 Sound Transformations

Depending on the type of input signal, these two models are fairly robust to changes made simply to the noise covariances. However these values do exhibit an influence when the signal in question is time stretched, and so become indirect tuning parameters in adding textural qualities to the signal. It is shown in [17.24] that in fact it is only the *ratio* of the state/observation noise covariances that affect the resultant sound. This ratio changes the relative influence of the state or observation noise process over the output, and so this must be tuned in conjunction with the transformations – whether applied primarily to the input (state) or output (observation) residual. At the same time, time-varying modifications of the partials (in the case of the additive model) can be achieved without time stretching by focusing on the frequency trajectories and even the window damping value λ. Therefore, the transformations made possible with this approach can be broken down into three broad categories defined by:

- Textural effects achieved through a combination of processing the two noise time series and time stretching.
- Spectral effects achieved through modifying the state matrix.
- Cross-synthesis by combining the noise time series and state matrix values from different input signals.

As noted previously, the underlying sound model introduced in this chapter is a combination of a source-filter and an additive/phase vocoder approach. This fact is embedded in the above classification of transformations: the first can be considered a source-filter type of processing where the noise excitation is transformed and conditioned by the state matrix filter, while the second is primarily focused on additive transformations such as transposing all or certain partials over time by altering the damping parameter for the state matrix. This second class can also exhibit source-filter-type processing if blocks of the state matrix itself are processed (rather than its frequency/damping parameters), thereby changing the filter response of the model. The third class combines both of these approaches: the excitation of one sound may be altered and crossed with another sound whose spectral content has likewise been processed by altering its state matrix parameters. A full treatment of these classes is beyond the scope of this chapter, but the reader can see [17.28] for an expanded discussion.

17.6 Adaptive Control of Sound Transformations

The model developed here for sound transformation is novel and interesting in its own right, allowing for various textural and spectral effects. However another reason for reconsidering classic techniques in a new framework is not simply for new transformation possibilities, but also to build the normally *higher-level* control layer into the model itself, showing how mapping and control can be considered at the most atomic level. The use of the estimation framework afforded by the Kalman filter was chosen not only for residual estimation, but because it can allow for *consideration of control dynamics* during the analysis stage in parallel with sound dynamics. In this way, mapping becomes an expression of the way control dynamics covary with and influence sound dynamics, and vice versa. Therefore we will illustrate an augmentation of the sound model to include control dynamics. We will first look at an example based on a simple source-filter model to make the process clear and to illustrate the modeling of a time-domain autoregressive moving average (ARMA) process; a basic control system that can be used modularly to build more complex designs. After this we will return to a more musically motivated example based on the RESTFT and physically inspired control dynamics.

Recall that the RESTFT/additive model is based on a linear state-space equation, which expresses the temporal evolution of the STFT. While it is sufficient to use a linear model in order to describe the underlying analysis/synthesis system and certain sound transformations, as soon as one wishes to express musically interesting control of the spectral state-evolution, the system becomes nonlinear very quickly. In this case, one must expand to a nonlinear state space, and extend the modeling approach applied to RESTFT accordingly. This augmentation process begins with the modeling assumption that the state evolution and observation equations are governed by some nonlinear functions f and g such that

$$\begin{aligned} \boldsymbol{s}[n+1] &= f(\boldsymbol{s}[n], \boldsymbol{u}[n], \boldsymbol{w}[n]) \quad \text{and} \\ \boldsymbol{y}[n] &= g(\boldsymbol{s}[n], \boldsymbol{u}[n], \boldsymbol{v}[n]) \,, \end{aligned} \tag{17.19}$$

where all input/output parameters maintain their meaning from the previous state-space equations. A direct application of the previous model is not possible, as the Kalman filter is defined only for a linear system. However, several nonlinear extensions to this technique have been developed, with one of the more popular variants being the extended Kalman filter (EKF) [17.22]. The EKF has been used in many applications for nonlinear state estimation and control, making it a standard for certain areas such as in design of navigation systems.

The essential idea of this technique is to create a nominal linear trajectory $\bar{\boldsymbol{s}}_k$ in state space around the true state trajectory. This is calculated from the a posteriori estimate $\hat{\boldsymbol{s}}_{k-1}$ at a previous time step and without input noise via

$$\begin{aligned} \bar{\boldsymbol{s}}_k &= f(\hat{\boldsymbol{s}}_{k-1}, \boldsymbol{u}_{k-1}, \boldsymbol{0}_{N\times 1}) \quad \text{and} \\ \bar{\boldsymbol{y}}_k &= h(\bar{\boldsymbol{s}}_k, \boldsymbol{u}_k, 0) \,. \end{aligned} \tag{17.20}$$

Once this trajectory is calculated, a local linear estimate of the nonlinear state evolution is computed at each sample and the standard Kalman equations are applied to this linearized form. To achieve this, a Taylor series approximation of the nonlinear functions f and g are calculated as

$$\boldsymbol{s}_k \approx \bar{\boldsymbol{s}}_k + \bar{\mathbf{A}}_k(\boldsymbol{s}_{k-1} - \hat{\boldsymbol{s}}_{k-1}) + \bar{\mathbf{W}}_k w_{k-1} \,, \tag{17.21}$$

$$\boldsymbol{y}_k \approx \bar{\boldsymbol{y}}_k + \bar{\mathbf{H}}_k(\boldsymbol{s}_k - \hat{\boldsymbol{s}}_k) + \bar{\mathbf{V}}_k \boldsymbol{v}_{k-1} \,, \tag{17.22}$$

where $\bar{\mathbf{A}}$ and $\bar{\mathbf{H}}$ are the Jacobian matrices for functions f and g respectively, taken with respect to the state input. $\bar{\mathbf{W}}$ and $\bar{\mathbf{V}}$ are similarly computed, with respect to the input noise processes. Finally, with this local linearization at each instance – using the nominal state trajectory and Jacobian matrices – we may use the classic Kalman algorithm to produce state, residual and output estimates with appropriately modified versions of (17.11) through (17.13).

17.6.1 Example 1: Control of Modulated Source–Filter Model

In order to understand the paradigmatically different nature of this approach to control in comparison to standard views on parameter mapping, consider the following example system, which begins from the desire to design a Wacom tablet-based control of a modulated source-filter model. The first step is to express a second-order infinite impulse response (IIR) filter in a first-order recursion as a time-domain autoregressive (AR) process. The initial second-order expression begins with output $y[n]$ and filter coefficients $b_1[n], b_2[n]$ that relate to each other as

$$y[n] = b_1[n]y[n-1] + b_2[n]y[n-2] + a_0 x[n] \,, \tag{17.23}$$

where $x[n]$ is the input source signal and a_0 is an input gain. We may then express the state vector as

$$\boldsymbol{s}[n] = \begin{pmatrix} x_1[n] \\ x_2[n] \\ x_3[n] \\ x_4[n] \end{pmatrix} = \begin{pmatrix} y[n] \\ y[n-1] \\ b_1[n] \\ b_2[n] \,, \end{pmatrix} \tag{17.24}$$

which gives rise to the following state equation

$$\boldsymbol{s}[n+1] = \begin{pmatrix} x_3[n+1]x_1[n] + x_4[n+1]x_2[n] \\ x_1[n] \\ x_3[n] \\ x_4[n] \end{pmatrix} + \begin{pmatrix} a_0 x[n] \\ 0 \\ 0 \\ 0 \end{pmatrix} + \boldsymbol{w}[n]\,, \tag{17.25}$$

where again $\boldsymbol{w}[n]$ is a white noise process. Note that computing the state at time n requires knowledge of the state itself, and so a priori values $\hat{x}_3$ and $\hat{x}_4$ are used in practice.

While this equation already introduces nonlinearities due to the interaction between state values, it is more intuitive from a musical point of view to control the center frequency (f_c) and bandwidth (B_w) of the filter. Therefore, using knowledge of the relationship between these parameters for a second-order IIR filter, we can rewrite the state equation in a more intuitive manner – though at the cost of introducing more nonlinearities. Further, a two-dimensional control input $u[n] = \{u_1[n], u_2[n]\}$ is introduced to influence these two parameters, so that bandwidth changes linearly and the center frequency is sinusoidally modulated. To achieve this mapping we may include the control inside the state dynamics function. The state vector then becomes

$$\boldsymbol{s}[n] = \begin{pmatrix} y[n] \\ y[n-1] \\ f_c[n] \\ B_w[n] \end{pmatrix}, \tag{17.26}$$

while the new state equation is

$$\boldsymbol{s}[n+1] = \begin{pmatrix} -\phi(\hat{x}_3[n+1], \hat{x}_4[n+1])x_1[n] + \psi(\hat{x}_3[n+1])x_2[n] \\ x_1[n] \\ x_3[n] + c_1[n] \\ x_4[n]\cos(2\pi u[n]n) \end{pmatrix}, \tag{17.27}$$

where

$$-\phi(a,b) = -2\mathrm{e}^{\frac{-a\pi}{f_s}}\cos\left(\frac{2\pi b}{f_s}\right), \tag{17.28}$$

and

$$\psi(a) = \mathrm{e}^{\frac{-2a\pi}{f_s}}, \tag{17.29}$$

for any real value a, b where f_s is the audio sampling rate. This new state space has several aspects that a traditional Kalman filter cannot handle: nonlinear state dynamics, use of the a priori state values in the state vector and the inclusion of control input in the state dynamics function itself. However, with the use of an EKF variant, we can estimate the state and control, driving the system as desired.

Now, with all of the complexity embedded in the state dynamics, the observation on this state is a simple projection of $x_1[n]$ onto output $z[n]$

$$z[n] = \begin{bmatrix} 1 & 0 & 0 & 0 \end{bmatrix} \boldsymbol{s}[n]\,. \tag{17.30}$$

For this example, the input *source* $x[n]$ is white noise, and so to align with our previous notation let $x[n] = w[n]$, while again the control input $u[n]$ comes from an external control source: the two-dimensional position data from a graphics tablet (though any continuous control could be used). Given this representation, the EKF derivation begins with the Jacobian matrix for the state equation f, which becomes

$$\bar{\mathbf{A}}_n = \begin{pmatrix} -\phi(\hat{x}_3[n], \hat{x}_4[n]) & \psi(\hat{x}_3[n]) & \frac{\partial f}{\partial x_3} & \frac{\partial f}{\partial x_4} \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \tag{17.31}$$

where

$$\frac{\partial f}{\partial x_3} = -2\hat{x}_1\mathrm{e}^{\frac{-\pi\hat{x}_3}{f_s}}\cos\left(\frac{2\pi\hat{x}_4}{f_s}\right) - \frac{2\pi\hat{x}_2}{f_s}\mathrm{e}^{\frac{-2\pi\hat{x}_3}{f_s}}, \tag{17.32}$$

and

$$\frac{\partial f}{\partial x_4} = \frac{4\pi}{f_s}\mathrm{e}^{\frac{-\pi\hat{x}_3}{f_s}}\sin\left(\frac{2\pi\hat{x}_4}{f_s}\right). \tag{17.33}$$

After estimating the linearized state matrix, one can further estimate the state by the linear approximation as in (17.21), centered about the nominal state trajectory defined by (17.27). The matrices $\bar{\mathbf{W}}$ and $\bar{\mathbf{V}}$ are simply the identity multiplied by their initial noise covariances, and the matrix $\mathbf{H}$ remains a simple projection. At this point, we can use the Kalman filter loop in order to estimate the state and output, given the control input values c_1 and c_2. The a priori prediction at the next step is computed, in order to be used in the future calculation of the Jacobian matrix for the nonlinear state dynamics. Therefore, in practice we use a one-step prediction in order to drive the nonlinear control dynamics, rather than directly affect the B_w and f_c parameters. In this sense the system implements predictive control.

17.6.2 Example 2: Dynamic Control of Partials/Residual

We now return to the time-frequency models developed in this chapter in order to embed control dynamics within them, towards a more musically inspired example. The classic view of analysis/synthesis methods would consider control input to act on an intermediate transformation stage, between analysis and synthesis, as depicted in Fig. 17.1. However, if one were to consider control dynamics in the model during the analysis stage, then the process would be modeled as the outcome that occurs from the particular control input that is enacted at the time of analysis, such as in the previous example in which the process was considered as a frequency-modulated source-filter model. This difference must be considered when planning for the transformation stage in the context of analysis-synthesis modeling. In the original Kalman implementation, the analysis stage was simply modeled as a linear STFT, and the parameters were modified or substituted afterwards. Instead, we can *augment* the initial model to include potentially nonlinear control dynamics, which are then estimated during the analysis stage.

Control of State-Space Additive Model

In order to explore an implementation of this instrument design methodology, we draw upon the first author's performance practice of using a Wacom graphics tablet as an input control device for *scrubbing* type of interactions [17.1]. This example combines the ARMA modeling approach and an EKF estimator for control dynamics (as in Example 1, Sect. 17.6.1) with the Kalman-based additive sound model. That is, the latter model is used for the sound analysis/modeling stage, and is augmented with temporal dynamics for the control analysis/transformation stage. Therefore this approach can properly be considered as *analysis-augmentation-transformation-synthesis*.

While the full example is beyond the scope of this chapter (see [17.28] for more), the basic intent is to build a system that controls timbral/textural characteristics through gestural dynamics that are built into the control structure. We can work with the low-level spectrotemporal model as expressed by (17.9) in order to add a control for the separate levels of the sine versus residual level such as

$$\boldsymbol{s}[n+1] = \hat{\mathbf{A}}\boldsymbol{\alpha}\boldsymbol{s}[n] + \mathbf{D}_n\boldsymbol{u}[n+1] + \boldsymbol{\beta}\boldsymbol{w}[n]\,. \quad (17.34)$$

where $\boldsymbol{\alpha}$ is a $1\times N$ weighting for the partial values and $\boldsymbol{\beta}$ is similarly a $1\times N$ weighting for the input residual value. The overall perceptual effect depends heavily on the choice of the distribution of the individual weight values. For example, the individual $\boldsymbol{\alpha}$ weights can target certain partials, be drawn from another spectral envelope to create cross-synthesis, or control the odd/even balance, which can have a strong effect on the perceived timbre. Similarly, the relative balance of the partial/residual magnitude spectrum over time can strongly affect the dynamic textural properties of the sound.

Implementing Control Gestural Dynamics

Consider the use of the velocity from the Wacom tablet x-y values, conditioned by a leaky integrator, to guide certain aspects of a sound's resynthesis. This sort of gesture requires a sustained motion at a fairly high speed (which is a function of the integrator's response time) in order to maintain the influence. Therefore, oscillatory motion at regular speeds will result in a sustained value of the control output. A perceptually coherent mapping arises when this controls the stable part of the spectra, represented by the partial values of the state vector. For musical reasons, we will also map this motion to the playback time of the sample being scrubbed. For this example, assume we condition these dynamics on the x-position input, and call it c_1. In classic instrument design cases, the differentiator and integrator are thought of as *black boxes*, only considered in terms of their input/output effects. However, we can represent their dynamics as a recursive difference equation as well, with the velocity found simply by

$$\delta[n] = k_\mathrm{r}(c_1[n] - c_1[n-1])\,, \quad (17.35)$$

where k_r is the rate of the control signal. At this point, we can apply the leaky integrator to the velocity, which can be expressed as

$$L[n] = \frac{1}{k_\mathrm{r}}\delta[n] + L[n-1]\,2^{\frac{-1}{k_\mathrm{r}\lambda}}\,, \quad (17.36)$$

where λ is the response time of the integrator. Therefore, from a signal processing point of view, this system is a first-order filter acting on the velocity of control input c_1. In order to design another expressive control gesture for y-position input c_2 that has considerably different dynamics, we can extend to a second-order filter and add resonance to the system. Generally speaking we can condition this input by the equation

$$z[n] = b_1 z[n-1] + b_2 z[n-2] + b_0 c_2[n]\,, \quad (17.37)$$

where z is the system output and b_1 and b_2 are general filter coefficients while b_0 is the input gain. The temporal behavior of this system depends heavily on these latter three coefficients. Further, to leverage the dynamics of this system we need to express it in a one-step

recursion, which we can do by defining an intermediate equation as

$$z[n] = z[n-1] + \frac{1}{k_\mathrm{r}} d[n] \,, \tag{17.38}$$

with new intermediate variable d. Taking this further, define the general filter coefficients as

$$b_0 = \frac{a_1}{k_\mathrm{r}^2} \,, \quad b_1 = 2 - \frac{a_1 - a_2}{k_\mathrm{r}^2} \,,$$
$$b_2 = \frac{a_2}{k_\mathrm{r}^2} - 1 \,, \tag{17.39}$$

where again a_0, a_1 and a_2 are tunable filter coefficients. Inserting (17.38) and (17.39) into the general second-order equation results in a first-order recursion of two variables defined as

$$d[n] = d[n-1] + \frac{1}{k_\mathrm{r}} (a_1 (c_2[n] - z[n-1]) - a_2 d[n-1]) \,. \tag{17.40}$$

Taken together, (17.38) and (17.40) constitute a state-space form of the general second-order system with state variables d and z. Further, this particular choice of b coefficients was made due the dynamics that it allows for: rather than building up energy, the conditioned response here is such that fast input control changes result in an oscillation that converges to the given value (provided a coefficient values are subject to certain boundary constraints). From a perceptual control point of view, this behavior is an interesting addition to the instrument design when used for control of the input residual gain. With such a mapping, sharp control actions result in a high excitation noise level, having amplitude modulation. Gradual movements have little or no perceptible modulations, depending on the filter coefficients. In the context of control dynamics, *Menzies* [17.29] has referred to this as a resonant-follower.

While these two dynamical control systems can be interpreted as signal processing tools, they also possess a more intuitive physical interpretation. The leaky integrator is in fact a spring-damper system, with the response time parameter acting as a damping coefficient on the system. Similarly, the second-order resonant filter expresses a mass-spring-damper (MSD) system, which can be checked by discretizing the physical equation and setting the mass to 1. Thus we can provide a physically grounded expression by setting the coefficients to $a_1 = K_\mathrm{s}$ and $a_2 = K_\mathrm{d}$, which are spring and damping constants respectively. Further, the state variables z and d represent position and velocity, where this relationship can be seen by comparing (17.35) and (17.38). Therefore the perceptual effect of building up energy in the former case or of modulating response in the later is in fact a product of designing the physics of a real system that has a resistive (spring-damper) and resonant (MSD) feel to it. When designing this physically inspired interaction *in tandem with* the signal-focused STFT/additive sound model the result is a hybrid approach that falls between signal and physical modeling.

In order to augment the overall system to include these elements, however, we need to modify the expression a bit. If we kept (17.40) and (17.38) in their current form, the output would depend on an intermediate parameter at the same time step and an a priori estimate would need to be used. This can be avoided by combining these equations so that

$$z[n] = z[n-1] + \left(1 - \frac{K_\mathrm{d}}{k_\mathrm{r}}\right) d[n-1] + \frac{K_\mathrm{s}}{k_\mathrm{r}} (c_2[n] - z[n-1]). \tag{17.41}$$

This results in a single expression of the second-order control system in a first-order recursion.

Augmented State Space: Time–Domain Control, Time/Frequency Sound Model

With this, the mapping and control structures are fully defined, as seen in Fig. 17.2. However, we must integrate these new equations with the sound model's state space. While the essence of what we want to achieve may be expressed by

$$\boldsymbol{s}[n+1] = \hat{\mathbf{A}}\mathbf{L}[n]\boldsymbol{s}[n] + \mathbf{D}_n \boldsymbol{u}[n+1] + z[n]\boldsymbol{w}[n] \,, \tag{17.42}$$

this does not represent a full model of the dynamics, as the control structure must be fully represented in the state equation. We can achieve this by augmenting the state vector to include the three control process variables and the mapping dynamics. At this point, the system is thus modeled as an *observation of input/output values, leading to an estimate of sound/control dynamics which in turn are synthesized to produce the final audio output*.

The control-augmented dynamics model is now nonlinear due to the interaction between state variables. Because of this, we must use the EKF structure in order to take advantage of the underlying Kalman framework for estimating the dynamics. For ease of reading, the full derivation is presented in the appendix. In short, after taking into consideration the nonlinear interaction between control and sound dynamics, we have arrived

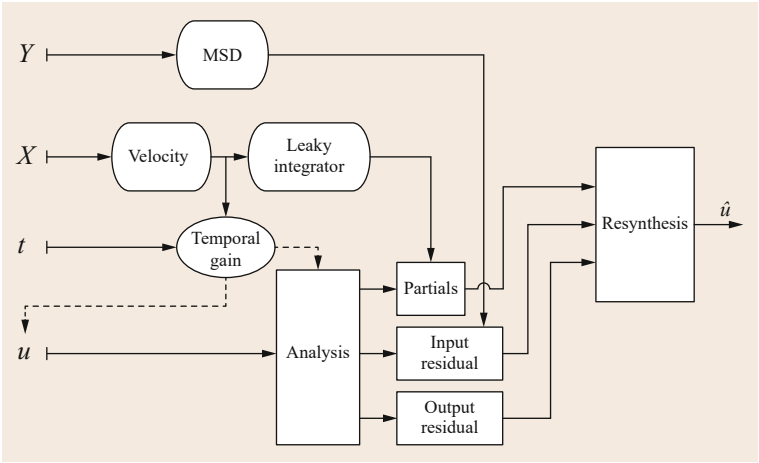

Fig. 17.2 The mapping structure for the given instrument design. *X*-*Y* tablet values feed the physically inspired dynamics of the leaky integrator and mass-spring-damper systems respectively. Time (of contact) is an implicit input that controls the *scrubbing*. This control is outside the model and so is not discussed in this chapter, but note that it may control either sound input u or the model parameters by way of some time-scaling algorithm such as a subtractive optimally localized averages technique. Finally, the analyzed sound u is an input to the analysis process, which is then affected by the control dynamics before being resynthesized into output $\hat{u}$

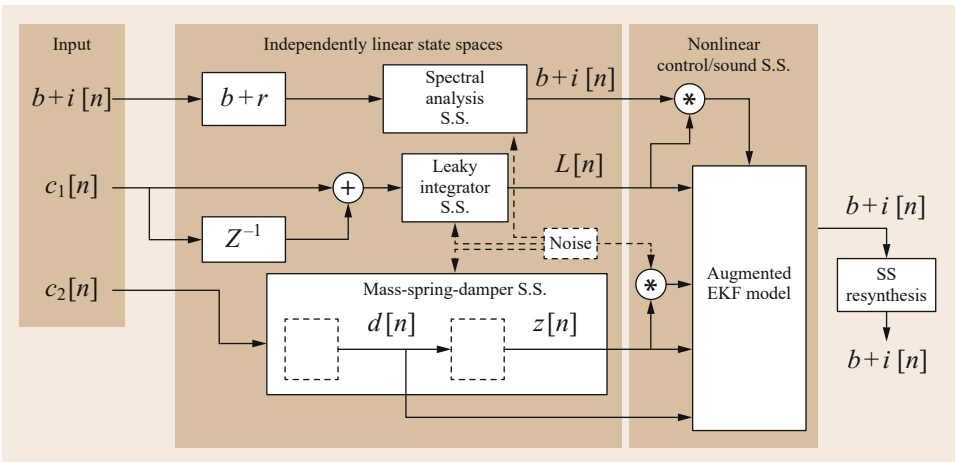

Fig. 17.3 Nonlinear state-space system for controlling time/frequency model. Analyzed input sound and control values are observed, while linear dynamical systems for control/sound are combined into a nonlinear control-sound dynamics model, augmented by an EKF. This dynamics model predicts the control/sound state value, and this is resynthesized to produce new sound output

at a complete instrument design that takes into account gestural dynamics. The layout for the entire instrumental system is depicted in Fig. 17.3. This example serves to show the process of designing an instrument that builds control and sound dynamics together in an estimation framework for control/sound analysis/synthesis. After designing the dynamics, state-space and extended Kalman filtering, the system's runtime behavior is as follows:

- Sample the control and sound input simultaneously.
- Drive the respective control/sound state equations with these values.
- Estimate the intermediate control/sound state variables using the EKF based on a nonlinear control/sound interaction model.
- Use the estimated state values to drive this nonlinear model, thereby resynthesizing new sound output $\boldsymbol{y}[n]$.

17.7 Chapter Summary

This chapter has presented a canonical way to build sound transformation instruments using a combination of ARMA and time/frequency modeling approaches, the state-space representation for dynamics, the Kalman filter for estimation and the EKF for nonlinear control. The combined use of these tools has led to both a set of novel algorithms as well as a working methodology for embedding control-sound dynamics *at the sound level* of an instrumental system, so that control structures can be built from the bottom up in a temporally focused way. The issues of sound representation and transformation were thus intersected with that of mapping and control structure design. We thus examined mapping from the point of view of a constraint on a dynamical system, expressing the co-evolution of parameters. This work shifts the focus from modeling parameter space to modeling the temporal response of action-to-sound coupling in a way that combines physically modeled dynamics with abstract time/frequency signal models. Going beyond the analysis-transformation-synthesis paradigm, the chapter introduced augmentation with nonlinear control dynamics, thus allowing for modeling of the control/sound interaction in a way that may be customized to contemporary digital musical performance contexts.

From a design point of view, in using the framework developed in this chapter the actual output may adhere closely or loosely to the control input, depending on the noise statistics among other tuning parameters. One may tune the degree of adherence to the dynamical systems model or add additional control values into the state vector. While it is beyond the scope of this chapter, some future directions include a more robust tuning by adaptively estimating the noise statistics at the same time as the state dynamics [17.27] or using the control dynamics residual itself as an interesting signal to be sonified or mapped to additional sound parameters.

17.A Appendix 1: Chandrasekhar Implementation

The computation of the state estimate in (17.12) is the essential step in which the Kalman gain – adapted by the updated state covariance – determines the amount of influence that the innovation sequence (i. e., the *novel* information) will have on the newly predicted state. This, as well as the Kalman gain of (17.12) may be factored differently, so that

$$\hat{\mathbf{K}}_n = \hat{\mathbf{A}}\mathbf{P}_n^{-}\mathbf{B}^{\mathrm{T}} , \tag{17.43}$$

$$\hat{\mathbf{R}}_n = (\mathbf{B}\mathbf{P}_n^{-}\mathbf{B}^{\mathrm{T}} + \mathbf{R}) , \tag{17.44}$$

$$\hat{s}_n = \hat{s}_n^{-} + \hat{\mathbf{K}}_n(\hat{\mathbf{R}}_n)^{-1}\boldsymbol{\epsilon}_n . \tag{17.45}$$

The quantity $\hat{\mathbf{R}}_n$ is the variance matrix of the innovations sequence $\boldsymbol{\epsilon}_n$. Using this factorization, it was shown in [17.25] that the matrices $\hat{\mathbf{K}}_n$ and $\hat{\mathbf{R}}_n$ may be computed by utilizing intermediate operations that act on matrices having a substantially smaller rank – and so possibly much less computation time. These added operations are referred to as Chandrasekhar-type recursions. The RESTFT fits this case and so was rewritten in this form. In particular, intermediate matrices $\mathbf{Y}_n$ and $\mathbf{M}_n$ arise, which are defined as

$$\mathbf{Y}_n = [\hat{\mathbf{A}} - \hat{\mathbf{K}}_n(\hat{\mathbf{R}}_n)^{-1}\mathbf{B}]\mathbf{Y}_{n-1} , \tag{17.46}$$

$$\mathbf{M}_{n+1} = \mathbf{M}_n + \mathbf{M}_n\mathbf{Y}_n^{\mathrm{T}}\mathbf{B}^{\mathrm{T}}(\hat{\mathbf{R}}_n)^{-1}\mathbf{B}\mathbf{Y}_n\mathbf{M}_n , \tag{17.47}$$

which then are used to redefine the Kalman equations as a recursion with

$$\hat{\mathbf{K}}_{n+1} = \hat{\mathbf{K}}_n + \hat{\mathbf{A}}\mathbf{Y}_n\mathbf{M}_n\mathbf{Y}_n^{\mathrm{T}}\mathbf{B}^{\mathrm{T}} , \tag{17.48}$$

$$\hat{\mathbf{R}}_{n+1} = \hat{\mathbf{R}}_n + \mathbf{B}\mathbf{Y}_n\mathbf{M}_n\mathbf{Y}_n^{\mathrm{T}}\mathbf{B}^{\mathrm{T}}t . \tag{17.49}$$

These new equations for $\mathbf{Y}_n, \mathbf{M}_n, \hat{\mathbf{K}}_n$, and $\hat{\mathbf{R}}_n$ are of size $N\times\alpha$, $\alpha\times\alpha$, $N\times p$ and $p\times p$ respectively, where p is the output dimension and α is the rank of a matrix equation defined by the initial state covariance and Kalman gain matrices [17.25]. As the system observation is of the scalar audio value in our case, the matrix $\hat{\mathbf{K}}_n$ reduces to a column vector while $\hat{\mathbf{R}}_n$ is simply a scalar. Thus the inversion of this latter value in (17.47) can be replaced by a simple multiplicative inverse, further speeding up the calculations, which is particularly time saving in the Matlab environment. Finally it can be shown – in this particular case of scalar observation – that the value $\alpha = 1$ as well, and so the overall speed for the calculation of the state estimate and related values is improved dramatically. Further, note that certain quantities such as $\mathbf{M}_n\mathbf{Y}_n^{\mathrm{T}}\mathbf{B}^{\mathrm{T}}$ are used several times, so that they can be stored in memory and only need be computed once.

17.A.1 Initial Conditions

The initial values for the matrices $\hat{\mathbf{K}}_n$ and $\hat{\mathbf{R}}_n$ are simply derived as

$$\mathbf{R}_0 = \mathbf{R} + \mathbf{B}\mathbf{P}_0\mathbf{B}^{\mathrm{T}} , \tag{17.50}$$

$$\mathbf{K}_0 = \hat{\mathbf{A}}\mathbf{P}_0\mathbf{B}^{\mathrm{T}} . \tag{17.51}$$

However those for $\mathbf{Y}_n$ and $\mathbf{M}_n$ require further derivation. It is noted in [17.25] that in particular cases the initial values $\mathbf{Y}_0$ and $\mathbf{M}_0$ assume a simple form. When the value $\hat{\mathbf{s}}_0$ is known with a high degree of certainty – and one may safely assume that $\sigma^2 = 0$ – then the values reduce to

$$\mathbf{Y}_0 = \mathbf{I}_{2N\times 2N} , \tag{17.52}$$

$$\mathbf{M}_0 = \mathbf{Q} . \tag{17.53}$$

At the same time, it is proven that if the state matrix $\hat{\mathbf{A}}$ is a stability matrix – meaning that its eigenvalues lie within the unit circle and the state sequence converges to a stationary process – then the initial conditions take another form. Our sound model is a limit case of this, and so we include this as a possible scenario in the algorithm. In this case, the initial values become

$$\mathbf{Y}_0 = \hat{\mathbf{A}}\mathbf{P}_n\mathbf{B} \tag{17.54}$$

$$\mathbf{M}_0 = (r + \mathbf{B}\mathbf{P}_n\mathbf{B}^{\mathrm{T}})^{-1} . \tag{17.55}$$

As these two scenarios are likely but not guaranteed outcomes for any given audio signal, we consider them both and leave this as an option when conducting a given analysis. That said, the latter case is generally a sufficient solution.

Now, this entire derivation has been based on the assumption that we have a stationary process, with $\hat{\mathbf{A}}$ constant over time. This is the case with our implementation based on the STFT. However, if we wish to extend this into an additive implementation then the Chandrasekhar recursions may not be used. Fortunately this is not a concern, as the need for this fast algorithm arises precisely in the case of having large state sizes brought on by the STFT. Therefore, fast implementations are used when they are needed, while the standard form still works in the additive case where state sizes are more manageable (e.g., N less than 100).

17.B Appendix 2: Example 2 EKF Derivation

The derivation of the full control structure from the example of Sect. 17.6 is calculated as follows here. It begins by augmenting the state vector to include the three control process variables. Let

$$\boldsymbol{s}_c[n] = \begin{pmatrix} \boldsymbol{s}[n] \\ L[n] \\ d[n] \\ z[n] \end{pmatrix} , \tag{17.56}$$

which results in the new state equation defined by

$$\boldsymbol{s}_c[n+1] = \mathbf{A}_{c,n} f(\boldsymbol{s}_c[n]) + \mathbf{D}_{c,n}\boldsymbol{u}_c[n] + z[n]\boldsymbol{w}[n] , \tag{17.57}$$

where

$$f(\boldsymbol{s}_c[n]) = \begin{pmatrix} L[n-1]\boldsymbol{s}[n-1] \\ L[n-1]\, 2^{\frac{-1}{k_r\lambda}} \\ d[n-1] - \dfrac{1}{k_r}(K_s z[n-1] + K_d d[n-1]) \\ z[n-1] + \left(1 - \dfrac{K_d}{k_r}\right) d[n-1] - \dfrac{K_s}{k_r} z[n-1] \end{pmatrix} . \tag{17.58}$$

Note that the scalar $L[n-1]$ is multiplied across all values of the state $\boldsymbol{s}[n-1]$, so that the augmented state vector that results from this function is of size $N+3$ for state size N. Further $\mathbf{A}_{c,n}$ is the block-diagonal matrix $\hat{\mathbf{A}}_n$ with a 3×3 identity matrix added to the diagonal, with proper zero padding of the first columns and rows of this new state matrix in order to make it well defined.

Meanwhile, input vector $\boldsymbol{u}_c[n]$ accounts for the current sound input value $\boldsymbol{u}[n]$ as well as the control inputs, so that

$$\boldsymbol{u}_c[n] = \begin{pmatrix} \boldsymbol{u}[n] \\ c_1[n] \\ c_1[n-1] \\ c_2[n] \end{pmatrix} . \tag{17.59}$$

Likewise $\mathbf{D}_{c,n}$ extends the matrix $\mathbf{D}_n$ in order to account for the input value's contribution to the control dynamics. Thus the control matrix $\mathbf{C}$ is added to the block diagonal of $\mathbf{D}_{c,n}$, where

$$\mathbf{C} = \begin{pmatrix} 1 & -1 & 0 \\ 0 & 0 & K_s/k_r \\ 0 & 0 & K_d/k_r \end{pmatrix} , \tag{17.60}$$

with zero padding of the first columns and rows of $\mathbf{D}_{c,n}$ in the same manner as applied to $\mathbf{A}_{c,n}$. Similarly $\boldsymbol{u}_c[n]$ is the input value $\boldsymbol{u}[n]$ padded with zeros, thereby finalizing this new form of the process equation. The observation $\mathbf{B}_c$ is essentially the same as in (17.1) except that it acts on the augmented state vector $\boldsymbol{s}_c$, and thus has necessary zero padding and identity elements prepended to the added rows. This new matrix is needed to account for the two control values, which are added to the observation that still includes audio output $\boldsymbol{y}[n]$.

17.B.1 EKF for Control/Sound Integration

We must linearize about a nominal state trajectory

$$\bar{\boldsymbol{s}}_c[n] = \mathbf{A}_{c,n-1} f(\hat{\boldsymbol{s}}_c[n-1]) + \mathbf{D}_{c,n-1}\boldsymbol{u}_c[n-1] \quad (17.61)$$

and calculate the nominal state based on the a posteriori estimate of the last time step; we also have control dynamics that are taken into account in making the state prediction. Given this estimate we can linearize the state trajectory in a similar fashion to the expression of (17.21). The primary difference is that we must take the control into account for the state noise process, and thus we arrive at

$$\boldsymbol{s}_c[n] \approx \bar{\boldsymbol{s}}_c[n] + \bar{\mathbf{A}}_n(\boldsymbol{s}_{n-1} - \hat{\boldsymbol{s}}_{n-1}) + \bar{\mathbf{W}}_n \boldsymbol{w}[n]\,, \quad (17.62)$$

where the two Jacobians are found to be

$$\bar{\mathbf{A}}_n = \begin{pmatrix} \hat{\mathbf{L}}[n-1] & \hat{\boldsymbol{s}}[n-1] & 0 & 0 \\ 0 & 2^{\frac{-1}{\lambda k_r}} & 0 & 0 \\ 0 & 0 & 1+K_\mathrm{d} & 0 \\ 0 & 0 & 1-\dfrac{K_\mathrm{d}}{k_\mathrm{r}} & 1-\dfrac{K_\mathrm{s}}{k_\mathrm{r}} \end{pmatrix} \quad (17.63)$$

for the process linearization and

$$\bar{\mathbf{W}}_n = \begin{pmatrix} \hat{z}[n-1] & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \quad (17.64)$$

for the linearization of the input residual control matrix. (In practice, the value $\hat{\boldsymbol{L}}[n]$ from $\bar{\mathbf{A}}_n$ is actually an $N\times N$ matrix comprised of copies of $\hat{\boldsymbol{L}}[n]$ where N is the number of partials, and the same for the $\hat{z}$ entry of the latter matrix. We express it in this simplified form for clarity of notation, without any loss of generality.) Using the newly linearized approximation from (17.62) and the already-linear observation equation, we can use the standard Kalman loop – in this case as it was defined for analysis of the additive sound model.

18. Wave Field Synthesis

Tim Ziemer

Wave field synthesis enables acoustic control in a listening area by systematic regulation of loudspeaker signals on its boundary. This chapter starts with an overview including the history of wave field synthesis and some exemplary installations. Next, the theoretic fundamentals of wave field synthesis are detailed. Technical implementations demand drastic simplifications of the theoretical core, which come along with restrictions of the acoustic control as well as with synthesis errors. Simplifications, resulting synthesis errors as well as the working principles of compensation methods and their effects on the wave field are extensively discussed. Finally, the current state of research and development is addressed.

18.1 Overview

Wave field synthesis is the concept of creating a desired sound field within an extended listening area. The objective is to control the sound field in space rather than discrete audio channels. This way of thinking has the objective to overcome the shortcoming of conventional audio systems, which give minor control over source width, distance and lateral sources as well as have the limitation of one single listening position, the *sweet spot*. Early wave field synthesis attempts arose in the 1930s [18.1], the time in which also the first stereo concepts came up. The first explicit formulations of a *wave front synthesis* concept come from the Delft University of Technology i. e., *Berkhout* et al. entitled *acoustic control* [18.2–4]. The idea of full acoustic control has nearly unlimited possibilities: a virtual singing bird could be placed on the shoulder of one listener. And this effect is not only audible for this very listener; everybody would localize the birdsong as coming from her shoulder. A virtual helicopter could circle above their heads and a virtual car could dash towards a listener. But as the sound field of the actual physical happening is recreated, the sound is *virtual* in terms of artificial creation, but absolutely real in terms of physical acoustics. Thus, a wave field synthesis system could make an electric piano sound as broad as a concert grand piano, a car like the Boston Symphony Hall, the cinema like a solutional cave or a living room like a soccer stadium.

Of course, wave field synthesis can also be used as the acoustic counterpart to stereoscopic video in movies and virtual reality applications. Acoustic control also delivers pragmatic solutions: speech intelligibility of public announcements in stadiums could be improved by creating one plane wave instead of using delay lines. The room acoustics of multipurpose halls could be artificially adjusted to the specific performance. Noise disturbance and unwanted echoes could be eliminated by either creating sound waves directed only towards the target receiver or by creating cancellation signals for quiet zones. These objectives sound almost too good to be true and of course comprehensive acoustic

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_18

control is a challenging goal. At the moment concessions have to be made. Several wave field synthesis approaches enable acoustic control to a certain degree. The terms *wave field synthesis* (WFS) and *sound field synthesis* (SFS) comprise concepts of wave front synthesis, *higher-order ambisonics* (HOA) [18.5–11], sound radiation synthesis [18.12–15] and other methods [18.16–20].

The research project CARROUSO, funded by the European Community from 2001 to 2003, brought universities and industry partners together to achieve huge steps in the development and applicability of wave front synthesis [18.21–23] paving the way for market-ready audio systems. Today, application areas of wave field synthesis systems are especially music playback and concert hall auralization [18.19, 23–25], network music performance and virtual conference rooms [18.26, 27], listening room compensation [18.28] and research [18.8, 9, 29]. Although wave field synthesis is still at a stage of research and development, several systems are already in use e.g., in cinemas, theaters, clubs, themed environments and universities. In the auditorium of the Technical University in Berlin a wave field synthesis system amplifies the lecturer without being too loud in the frontal region and without creating the annoying echo, typical for delay lines in PA systems. Additionally, a number of music compositions has been created for this system. It includes almost 1000 loudspeakers, individually controlled by a cluster of computers, just to synthesize the sound field in the horizontal plane [18.25]. This is a typical order of magnitude for large rooms. In cooperation with Fraunhofer IDMT the Audi Q7 was equipped with a 62-channel wave field synthesis system to auralize the room acoustics of concert halls or churches for driver and passengers [18.30]. Systems for entertainment are installed in TV sound boards, clubs, cinemas and at festivals to create both natural and surreal immersive, spatial sound experiences for every single listener [18.25, 31].

Implementations come together with problems that need to be compensated, resulting in limitations concerning the synthesis precision, extent of the listening area, number and potential positions of virtual sources, complexity of sound radiation patterns, auralization of virtual room acoustics or alike. The name already implies that the theoretical fundamentals of wave field synthesis are the wave equation and its solutions with appropriate boundary conditions. These are discussed next, followed by an extensive examination of wave front synthesis, the most common sound field synthesis approach. Finally, alternative approaches as well as the current state of research and development are addressed.

18.2 Wave Equation and Solutions

18.2.1 Homogeneous Wave Equation

The first base equation of the wave field is Euler's equation of motion

$$\rho_0 \frac{\partial \boldsymbol{v}(\boldsymbol{x},t)}{\partial t} = -\nabla p(\boldsymbol{x},t)\,, \tag{18.1}$$

describing the flow of frictionless fluids by means of time t, position vector $\boldsymbol{x}$, particle velocity vector $\boldsymbol{v}$, pressure p, ambient density ρ_0 and the nabla operator ∇. In Cartesian coordinates the following is valid

$$\boldsymbol{x} = \begin{bmatrix} x \\ y \\ z \end{bmatrix}$$

$$\boldsymbol{v} = \begin{bmatrix} u(x) \\ v(y) \\ w(z) \end{bmatrix}$$

$$\nabla \equiv \frac{\partial}{\partial \boldsymbol{x}} = \frac{\partial}{\partial x} + \frac{\partial}{\partial y} + \frac{\partial}{\partial z}\,. \tag{18.2}$$

The second base equation of the wave field is a form of the continuity equation

$$c^2 \rho_0 \nabla \boldsymbol{v}(\boldsymbol{x},t) + \frac{\partial p(\boldsymbol{x},t)}{\partial t} = 0 \tag{18.3}$$

with the propagation velocity c. Differentiating (18.3) with respect to time and replacing the velocity term by the right side of the equation of motion, (18.1), yields the homogeneous wave equation for pressure

$$\nabla^2 p(\boldsymbol{x},t) - \frac{1}{c^2}\frac{\partial^2 p(\boldsymbol{x},t)}{\partial t^2} = 0\,, \tag{18.4}$$

where ∇^2 is the Laplace operator

$$\nabla^2 \equiv \frac{\partial^2}{\partial \boldsymbol{x}^2} = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\,. \tag{18.5}$$

By differentiating the continuity equation with respect to $\boldsymbol{x}$ and the equation of motion with respect to t yields the homogeneous wave equation for velocity

$$\nabla^2 \boldsymbol{v}(\boldsymbol{x},t) - \frac{1}{c^2}\frac{\partial^2 \boldsymbol{v}(\boldsymbol{x},t)}{\partial t^2} = 0\,. \tag{18.6}$$

Equations (18.4) and (18.6) look very similar and can have the same solution. But sound pressure and particle velocity are not the same. Their relationship is described in (18.1). The sound pressure gradient is proportional to the temporal derivative of the particle velocity i. e., the particle acceleration. Sound pressure p and sound velocity $\boldsymbol{v}$ are perturbations of the state of equilibrium that propagate as sound waves. Solutions of the wave equation are called *sound field* or *wave field*. The equations assume the conditions listed in Table 18.1 [18.32–34].

Table 18.1 Preconditions for the wave equations

1.	The propagation medium is homogeneous
2.	The medium is quiescent and vortex free
3.	State changes are adiabatic i. e., no heat interchange between areas of low pressure and areas of high pressure due to the rapid movement of the particles
4.	Pressure and density perturbations are small compared to static pressure and density
5.	Relationships in the medium are subject to linear differential equations
6.	The medium exhibits no viscosity
7.	The medium is source-free

18.2.2 Homogeneous Helmholtz Equation

By means of a Fourier transform

$$P(\boldsymbol{x},\omega) = \int_{t=-\infty}^{\infty} p(\boldsymbol{x},t)\mathrm{e}^{\mathrm{i}\omega t}\mathrm{d}t \tag{18.7}$$

sound pressure can be transformed from the time domain to the frequency domain and we speak of a *sound spectrum*. Here, e is Euler's number, $\mathrm{i} = \sqrt{-1}$ is the imaginary unit, $\omega = 2\pi f$ is the angular frequency and f the frequency. By inverse Fourier transform

$$p(\boldsymbol{x},t) = \frac{1}{2\pi}\int_{\omega=-\infty}^{\infty} P(\boldsymbol{x},\omega)\mathrm{e}^{-\mathrm{i}\omega t}\mathrm{d}\omega\,. \tag{18.8}$$

the spectrum can be transposed back to the time domain. The wave equation in the frequency domain is known as the *homogeneous Helmholtz equation* and reads

$$\nabla^2 P(\boldsymbol{x},\omega) + k^2 P(\boldsymbol{x},\omega) = 0 \tag{18.9}$$

with *wave number* or *spatial frequency*

$$k = \frac{\omega}{c} = \frac{2\pi}{\lambda}\,,$$

where λ is the wave length. Since the Fourier transform is an integral over time, the homogeneous Helmholtz equation is only valid for stationary signals i. e., periodic vibrations, and not for transients [18.35].

18.2.3 Plane Waves

A general solution of the wave equation is d'Alembert's solution

$$p(\boldsymbol{x},t) = f(\boldsymbol{x}-ct) + f(\boldsymbol{x}+ct)\,. \tag{18.10}$$

The first term describes the propagation of a pressure state in the $\boldsymbol{x}$ direction, the second a propagation in the opposite direction. For waves the principle of superposition applies i. e., they interfere without affecting each other. Assuming the second term to be 0, only one wave in the $\boldsymbol{x}$ direction remains. Other directions can simply be added. One possible solution function $f(\boldsymbol{x}-ct)$ is the function of a plane wave in the time domain

$$p(\boldsymbol{x},t) = A(\omega)\,\mathrm{e}^{-\mathrm{i}(k\boldsymbol{x}-\omega t)} \tag{18.11}$$

and in the frequency domain

$$P(\boldsymbol{x},\omega) = A(\omega)\,\mathrm{e}^{\mathrm{i}k\boldsymbol{x}}\,. \tag{18.12}$$

Here, A is an arbitrary complex amplitude in the form $\hat{A}\mathrm{e}^{\mathrm{i}\phi}$ whose absolute value, the amplitude $\hat{A}$ and argument, the phase ϕ, are individual for each frequency.

$$k^2 = k_x^2 + k_y^2 + k_z^2$$

is the squared wave number in direction $\boldsymbol{x}$, and

$$\lambda^2 = \lambda_x^2 + \lambda_y^2 + \lambda_z^2$$

the wave length in $\boldsymbol{x}$-direction. A plane wave propagates in direction $\boldsymbol{x}$ and phase changes with respect to location. k_x, k_y and k_z are called *trace wavenumbers* [18.7]; λ_x, λ_y and λ_z are *trace wavelengths*. They are projections to the spatial axes. The wave fronts are infinite planes of equal pressure perpendicular to vector $\boldsymbol{x}$.

For a wave with nonnegative k, two formulations for k_y

$$k_y = \begin{cases} \pm\sqrt{k^2 - k_x^2 - k_z^2}, & k^2 \geq k_x^2 + k_z^2 \\ \pm\mathrm{i}\sqrt{-k^2 + k_x^2 + k_z^2}, & k^2 \leq k_x^2 + k_z^2 \end{cases} \tag{18.13}$$

point out two different sorts of wave [18.36]. In the first case all components are real, indicating a propagating plane wave. In the second case k_y is imaginary, leading to an *evanescent wave*. Inserting the second case in (18.11) yields

$$P(\boldsymbol{x},\omega) = A(\omega)\,\mathrm{e}^{\pm\sqrt{-k^2+k_x^2+k_z^2}y}\mathrm{e}^{\mathrm{i}(k_x x + \mathrm{k}_z z)}\,. \tag{18.14}$$

In this case the first exponential term is real, indicating an exponential decay in the y-direction. The term could

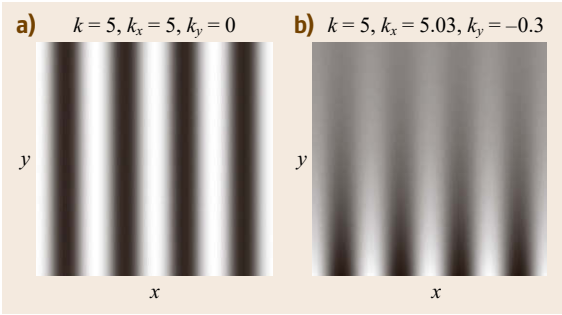

Fig. 18.1a,b Two-dimensional visualization of a propagating plane wave **(a)** and an evanescent wave **(b)**

also indicate an exponential increase, which is ignored since it is nonphysical [18.36]. Both types of waves are illustrated in Fig. 18.1. Note that in this example the propagation direction of the propagating wave and the evanescent wave are the same. Evanescent waves occur at boundaries where the sound velocity in one medium is higher than in the other.

For periodic functions, the motion equation (18.1) yields

$$\nabla p(\boldsymbol{x}, t) = -\mathrm{i}\omega\rho_0 \boldsymbol{v}(\boldsymbol{x}, t) \tag{18.15}$$

and in the frequency domain

$$\nabla P(\boldsymbol{x}, \omega) = -\mathrm{i}k\rho_0 c \boldsymbol{V}(\boldsymbol{x}, \omega)\,, \tag{18.16}$$

where $\boldsymbol{V}$ is the sound velocity in the frequency domain.

18.2.4 Inhomogeneous Wave Equation

The homogeneous wave equation assumes a source-free medium. But every sound field has at least one source that adds acoustic energy to the medium, propagating as a wave pursuant to the wave equation. To account for this, the eighth condition listed in Table 18.1 is dropped and a source term is added to the homogeneous wave equation. Then a solution $p(\boldsymbol{x}, t)$ is sought describing the temporal and spatial behavior of the source signal in the system

$$\nabla^2 p(\boldsymbol{x}, t) - \frac{1}{c^2}\frac{\partial^2 p(\boldsymbol{x}, t)}{\partial t^2} = -4\pi\delta(\boldsymbol{x} - \boldsymbol{x}_0, t - t_0)\,. \tag{18.17}$$

This wave equation is called the *inhomogeneous wave equation*. $\delta(\boldsymbol{x}, t)$ is the Dirac delta function. It is defined as being ∞ at point $\boldsymbol{x}_0$ at time t_0, otherwise it is 0. This means the source term is an impulse that occurs only at one point in time and space. A transformation of the temporal Dirac delta function into the spectral domain

$$\delta(\omega) = \int_{t=-\infty}^{\infty} \delta(t - t_0)\, \mathrm{e}^{\mathrm{i}\omega t}\mathrm{d}t = 1 \tag{18.18}$$

shows that its amplitude for every frequency is 1, i. e., all frequencies have an equal amplitude and are in phase. That means every arbitrary function $p(t)$ can be expressed by weighted and delayed Dirac delta functions $\delta(\boldsymbol{x}, t)$. The amplitude and phase of spectral components $P(\omega)$ of sound signals may be arbitrary so they can be expressed as multiplication of the spectra of the Dirac delta function by frequency-dependent complex amplitudes $A(\omega)$. That conforms to a convolution of a sound signal with the Dirac delta function in the time domain.

18.2.5 Point Sources

One solution for the inhomogeneous wave equation is the point source. A point source is a sound source with no volume. In the simplest case, its radiation is equal in each direction. This is referred to as a *monopole source*. Amplitude and phase are dependent on frequency and distance but independent of direction. Therefore, a formulation in spherical coordinates is meaningful. For spherical coordinates the following holds

$$\begin{aligned}
\boldsymbol{r} &= \begin{bmatrix} r \\ \varphi \\ \vartheta \end{bmatrix} \\
r &= \sqrt{x^2 + y^2 + z^2} \\
\varphi &= \arctan\left(\frac{y}{x}\right) \\
\vartheta &= \arccos\left(\frac{z}{r}\right) \\
\nabla_{\text{spherical}} &\equiv \frac{\partial}{\partial r} + \frac{1}{r}\frac{\partial}{\partial \vartheta} + \frac{1}{r\,\sin\vartheta}\frac{\partial}{\partial \varphi} \\
\boldsymbol{x} &= \begin{bmatrix} x \\ y \\ z \end{bmatrix} \\
x &= r\,\cos\varphi\,\cos\vartheta \\
y &= r\,\sin\varphi\,\cos\vartheta \\
z &= r\,\sin\vartheta \\
\nabla_{\text{Cartesian}} &\equiv \frac{\partial}{\partial x} + \frac{\partial}{\partial y} + \frac{\partial}{\partial z}\,.
\end{aligned} \tag{18.19}$$

Here, r is the radius, φ the azimuth angle and ϑ the polar angle. The position vector $\boldsymbol{x}$ is redefined to $\boldsymbol{r}$. The origin of the coordinate system is the source position.

Figure 18.2 illustrates the relations of Cartesian and spherical coordinate systems.

Thus, the inhomogeneous wave equation (18.17) takes the form [18.7]

$$\frac{1}{r}\frac{\partial\left(r^2\frac{\partial p}{\partial r}\right)}{\partial r}+\frac{1}{r^2\sin\vartheta}\frac{\partial\left(\sin\vartheta\frac{\partial p}{\partial\vartheta}\right)}{\partial\vartheta}+\frac{1}{r^2\sin^2\vartheta}\frac{\partial^2 p}{\partial\varphi^2}-\frac{1}{c^2}\frac{\partial^2 p}{\partial t^2}=-4\pi\delta(\boldsymbol{x}-\boldsymbol{x}_0,t-t_0)\,. \tag{18.20}$$

Since radiation of a monopole is independent of φ and ϑ the wave equation simplifies to

$$\frac{\partial^2 p(r,t)}{\partial r^2}+\frac{2}{r}\frac{\partial p(r,t)}{\partial r}-\frac{1}{c^2}\frac{\partial^2 p(r,t)}{\partial t^2}=-4\pi\delta(r-r_0,t-t_0)\,, \tag{18.21}$$

and the Helmholtz equation appropriately to

$$\frac{\partial^2 P(r,t)}{\partial r^2}+\frac{2}{r}\frac{\partial P(r,t)}{\partial r}-k^2P(r,t)=-4\pi\delta(r-r_0,\omega)\,. \tag{18.22}$$

The point source solution for this case is

$$p(r,t)=g(r,t)+\tilde{g}(r,t)=A(t)\frac{\mathrm{e}^{-\mathrm{i}(kr-\omega t)}}{r}+\tilde{g}(r,t) \tag{18.23}$$

in the time domain and

$$P(r,\omega)=G(r,\omega)+\tilde{G}(r,\omega)=A(\omega)\frac{\mathrm{e}^{-\mathrm{i}kr}}{r}+\tilde{G}(r,\omega)\,, \tag{18.24}$$

in the frequency domain. It is a *Green's function* comprised of a linear combination of a special solution – $g(r,t)$ and $G(r,\omega)$ – and a general solution – $\tilde{g}(r,t)$ and $\tilde{G}(r,\omega)$ – which are arbitrary solutions of the homogeneous wave equation (18.4) and Helmholtz equation (18.9). It is also called *impulse response* in the time domain and *complex transfer function* in the frequency domain. The impulse response describes the spatiotemporal propagation of the source signal in the medium, the second describes the spatial distribution of the source spectrum. Since the first term of the impulse response is already a complete solution of the inhomogeneous Helmholtz equation, the second term can be assumed to be zero. This case is called *free field Green's function* and describes the radiation of a monopole sound source. The exponential term describes the phase

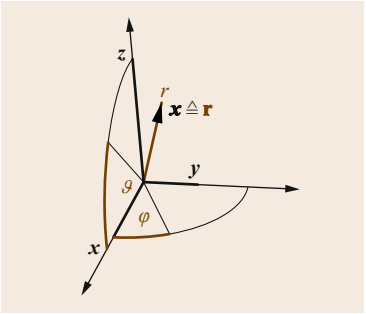

Fig. 18.2 Representation of the position vector $\boldsymbol{x}$, or respectively $\boldsymbol{r}$, via Cartesian coordinates and spherical coordinates

shift per distance of the propagating wave from the source. The fraction represents the pressure amplitude decay per distance, the so-called *inverse distance law* or $1/r$ *distance law*. It states that a local sound pressure amplitude at a receiver point is proportional to the reciprocal of its distance from the source point. This is owed to the fact that the surface of the wave front increases with an increasing sphere radius, so the pressure distributes on a growing area.

The surface of a sphere S is given as

$$S=4\pi r^2 \tag{18.25}$$

so the sound intensity I_0 in the origin of the point source at $r=0$ spreads out to the surface with

$$I(r)=I_0\frac{1}{4\pi r^2}$$

and is thus directly proportional to $1/r^2$. Since I is proportional to p^2, $p(r)$ it is directly proportional to $1/r$ [18.37]

$$I(r)\propto\frac{1}{r^2}\qquad p(r)\propto\frac{1}{r}\,. \tag{18.26}$$

The wave front of a propagating plane wave, in contrast, is assumed to be infinite and thus does not decay. In the far field – i. e., ignoring near-field effects that show a complicated behavior close to the source – any stationary sound source can be simplified by considering it as point source [18.36]. These point sources, however, do not necessarily have to be monopoles. A dependence on direction $\Psi(\omega,\varphi,\vartheta)$ can be introduced ex post by reconsidering $A(\omega)$ as $A(\varphi,\vartheta,\omega)$ or, respectively, $\Psi(\omega,\varphi,\vartheta)A(\omega)$ for the far field

$$p(\varphi,\vartheta,r,t)=g(\varphi,\vartheta,r,t)+\tilde{g}(\varphi,\vartheta,r,t)=\Psi(\omega,\varphi,\vartheta)A(\omega)\frac{\mathrm{e}^{-\mathrm{i}(kr-\omega t)}}{r}+\tilde{g}(r,t) \tag{18.27}$$

which keeps its properties in the frequency domain

$$P(\varphi,\vartheta,r,\omega) = G(\varphi,\vartheta,r,\omega) + \tilde{G}(\varphi,\vartheta,r,\omega)$$
$$= \Psi(\omega,\varphi,\vartheta)A(\omega)\frac{\mathrm{e}^{-\mathrm{i}kr}}{r} + \tilde{G}(r,\omega)\,. \tag{18.28}$$

Due to the complex factor $\Psi(\omega,\varphi,\vartheta)$, the amplitude $A(\omega)$ is modified for any direction. Note, that the Green's function with a direction-dependent radiation factor is not a solution to the inhomogeneous Helmholtz function as such [18.36]. It rather comprises the spherical harmonics, which are a solution to the angular dependencies of the Helmholtz equation in spherical coordinates over a sphere rather than a point. The radiation characteristic of point sources can be any arbitrary function of angles φ and ϑ, which can be composed by a linear combination of mono- and multipoles. In the literature, point sources with a direction-dependent radiation factor are called *complex point sources*, *multipole point sources*, *higher mode radiators* or *point multipoles*; the directivity is called *far-field signature function* [18.36, 38–40].

18.2.6 Huygens' Principle

Every arbitrary radiation from a sound source can be described as integral of elementary sources on its surface. Together, the wave fronts of these elementary sources form the advanced wave front via superposition. This finding is called *Huygens' principle* and is the foundation on which wave field synthesis is based. Figure 18.3 illustrates Huygens' principle. A wave front propagating outwards from a point source is a sphere whose radius increases proportional to the sound velocity c. As stated earlier, such a point source can have individual amplitudes and phases in each direction, indicated here by brightness. At an arbitrary point in time t_1, the wave front can be sampled by a number of points, illustrated as a finite number of dots. These points can be considered as sources of *elementary waves*. The superimposed wave fronts of these elementary sources create the new wave front at a later point in time t_2; an increased sphere. Obviously, the radiation of the elementary waves is not monopole-like. They propagate outwards and set all particles on the increased spherical surface in motion. Inwards, their superposition must yield exactly 0, so no wave front is traveling back to the origin. This radiation characteristic is described by the Kirchhoff–Helmholtz (K–H) integral, discussed in the subsequent subsection.

This principle constitutes the idea of an *acoustic curtain* [18.1, 36]: If an array of microphones records elementary waves, the playback of these recordings via loudspeakers, which are arranged in the exact same way as the microphones, should recreate the original wave field to a certain degree. This idea is a basic concept of wave field synthesis. It is illustrated in Fig. 18.4. The black dots represent pressure microphones that are directly connected to loudspeakers. However, this setup does not provide a thorough sound field capture and synthesis. Errors occur due to the discrete and finite microphone and loudspeaker array as well as due to deficient knowledge of the pressure gradient. How to overcome these issues to increase acoustic control is described in the following section.

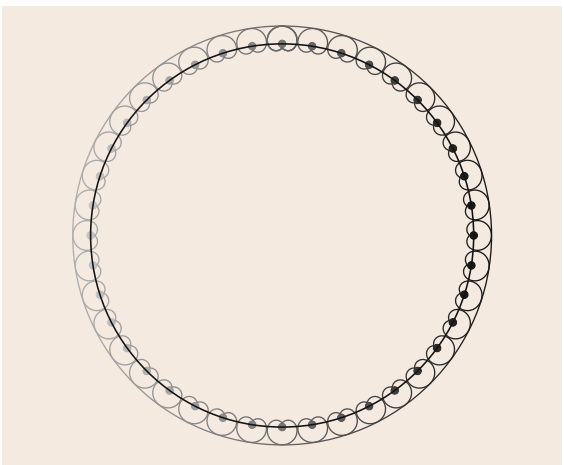

Fig. 18.3 Illustration of Huygens' principle

18.2.7 Kirchhoff–Helmholtz Integral

Gauss' theorem or the *divergence theorem* states that spatial area integrals of a function over a volume V are equal to surface integrals of the normal components $\boldsymbol{n}$ of a function over the volume's surface S

$$\int_V \nabla \boldsymbol{f}\,\mathrm{d}V = \int_S \boldsymbol{f}\boldsymbol{n}\,\mathrm{d}S \tag{18.29}$$

if it has a piecewise smooth boundary and the function $\boldsymbol{f}$ is a steady, differentiable vector function [18.41].

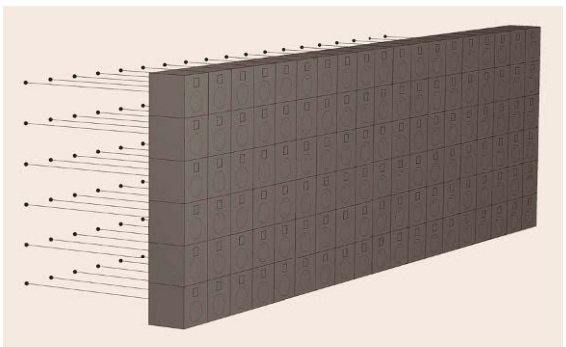

Fig. 18.4 Illustration of an acoustic curtain (after [18.40])

A special case of Gauss' theorem is described by Green's second theorem [18.41]

$$\int_V f\nabla^2 g - g\nabla^2 f \,\mathrm{d}V = \int_S f\nabla g\boldsymbol{n} - g\nabla f\boldsymbol{n} \,\mathrm{d}S\,. \tag{18.30}$$

From Green's second theorem and the Helmholtz equations, (18.9) and (18.22), the Kirchhoff–Helmholtz integral can be derived, which describes the relation between the wave field in a source-free volume V and sources $\boldsymbol{Y}$ on its surface S

$$-\frac{1}{4\pi}\oint_S \left(G(\omega, \Delta\boldsymbol{r}) \frac{\partial P(\omega, \boldsymbol{Y})}{\partial \boldsymbol{n}} - P(\omega, \boldsymbol{Y}) \frac{\partial G(\omega, \Delta\boldsymbol{r})}{\partial \boldsymbol{n}} \right) \mathrm{d}S = \begin{cases} P(\omega, \boldsymbol{X}), & \boldsymbol{r} \in V \\ \frac{1}{2} P(\omega, \boldsymbol{X}), & \boldsymbol{r} \in S \\ 0, & \boldsymbol{r} \notin V \end{cases} \tag{18.31}$$

The K–H integral is a solution to the homogeneous Helmholtz equation with inhomogeneous boundary conditions on the surface. It states that the spectrum $P(\omega, \boldsymbol{X})$ at each point $\boldsymbol{X}$ in a source-free volume V is the integral of the spectra $P(\omega, \boldsymbol{Y})$ at every point $\boldsymbol{Y}$ on the bounding surface S and their propagation function $G(\omega, \Delta\boldsymbol{r})$ in the direction of the normal vector pointing inwards. $G(\omega, \Delta\boldsymbol{r})$ is a Green's function, a solution of the inhomogeneous Helmholtz equation (18.23), and $P(\omega, \boldsymbol{Y})$ is a spectrum, a solution for the homogeneous Helmholtz equation (18.9). $\Delta\boldsymbol{r}$ is the Euclidean distance $||\boldsymbol{Y} - \boldsymbol{X}||_2$. The sources $\boldsymbol{Y}$ on the boundary surface are *secondary sources*, excited by a *primary source* $\boldsymbol{Q}$, which lies in the source volume U. The first term of the closed double contour integral describes a wave that propagates as a monopole since the propagation term

$$G(\omega, \Delta\boldsymbol{r}) = \frac{\mathrm{e}^{-\mathrm{i}k\Delta\boldsymbol{r}}}{\Delta\boldsymbol{r}}$$

is a monopole. From the periodic motion equation (18.15) it emerges that $\partial P/\partial\boldsymbol{n}$ is proportional to sound particle velocity in normal direction $\boldsymbol{V}_\mathrm{n}$. The second term of the integral is a wave that radiates as a dipole, since

$$\frac{\partial G(\omega, \Delta\boldsymbol{r})}{\partial \boldsymbol{n}} = \frac{1 + \mathrm{i}k\Delta\boldsymbol{r}}{\Delta\boldsymbol{r}^2} \cos(\varphi) \mathrm{e}^{-\mathrm{i}k\Delta\boldsymbol{r}} \tag{18.32}$$

is a dipole term. Sound field quantities P and $\boldsymbol{V}$ are convertible into each other after Euler's equation of motion (18.1), so (18.31) is overdetermined and several approaches to a solution exist.

As already stated, the secondary sources on the surface of the source-free medium are monopole and dipole sources. Inwards they radiate in phase and outwards inversely phased. So the radiation doubles inwardly by constructive interference and outwardly becomes 0 by destructive interference. Combined, they create a *cardioid*, also referred to as *kidney* or *heart*. It is illustrated in Fig. 18.5.

The boundary surface could be the wave front around a source and the source-free volume could be the room beyond this wave front. Then, the K–H integral is a quantified formulation of Huygens' principle. But the volume could also be any other arbitrary geometry and the surface a physically existing or nonexisting boundary. This boundary is the separation surface between a source volume, which contains one or more sources, and a source-free volume, which contains the listening area. Any arbitrary closed boundary is conceivable as long as the premises of Gauss' theorem are observed. Figure 18.6 illustrates three examples for a volume boundary that will be considered later in this chapter. Two setup concepts exist: surrounding the listener with secondary sources – as in Fig. 18.6a,b – or surrounding the primary source(s), as illustrated in Fig. 18.6c.

The Kirchhoff–Helmholtz integral describes analytically how spectrum and radiation on a volume surface are related to any arbitrary wave field inside a source-free volume. Therefore, this integral is the core of wave field synthesis [18.3].

18.3 Wave Front Synthesis

The Kirchhoff–Helmholtz integral is a theoretical construct that cannot simply be put into practice by technical means. It demands a continuous distribution of an infinite number of secondary sources with infinitesimal distance, surrounding a volume entirely. That means sound pressure and velocity need to be controllable everywhere on the volume surface, which is hardly possible. However, what we can control is the sound pressure of loudspeakers. But an infinite number of infinitesimally distanced loudspeakers would be required, completely separating a listening area from a source volume and radiating inwards to the listening area but not outwards. This is still not implementable. For a practical realization the reduction of secondary sources to a real number of loudspeakers with discrete distances radiating approximately as monopoles or dipoles is feasible. These have to be fed with the correct *driving functions* [18.5]. Surrounding an entire room with speakers is impracticable as it requires overcoming enormous technical challenges, large computational power and large acquisition and operating costs. Therefore, concepts with plane loudspeaker arrays [18.42] and line arrays [18.25, 43, 44], circular arrays [18.44, 45] and three to four lines surrounding the listening area [18.28, 45] are proposed and in use.

For implementing a wave field synthesis system the K–H integral has to be adjusted to the restrictive circumstances, which leads to errors in the synthesis. Adjustment steps, resulting synthesis errors and their effects as well as compensation methods are discussed in the following.

18.3.1 Adjustments for Implementations

A number of adjustments simplify the K–H integral in a way that allows for a technical implementation of the theory by means of loudspeaker arrays [18.45]. These are listed in Table 18.2. The particular steps will be successively accomplished in the following subsections.

Table 18.2 Adjustments to simplify the Kirchhoff–Helmholtz integral

1.	Enable sources inside the source-free volume
2.	Reduction of the boundary surface to one separation plane between source-free volume and source volume
3.	Restriction to one type of radiator (monopole or dipole)
4.	Reduction of three-dimensional synthesis to two dimensions
5.	Discretization of the surface
6.	Finitization of the surface

18.3.2 Focused Sources

Although the listening volume is required to be source-free, the K–H integral provides us with a tool to create a virtual source located in the inside. This is achieved by creating a concave wave front on the surface, which focuses in one point inside. From this focus point the wave front appears to be convex and cannot be distinguished from a point source located at the focus position. Such sources are called *focused sources*. In the half space behind the focus point the wave front propagation is synthesized correctly. Between the secondary sources and the focus point, however, this is not the case. Here, the wave front does not propagate away from the virtual source position but towards it. Due to this synthesis error, listeners in this region will not localize the sound as coming from the focus point. For focused sources, not the secondary source distribution but the focus point defines the new separation plane between source volume and listening area. So focused sources reduce the listening area to positions behind the focus point. For an implementation a decision has to be made: either the subset of loudspeakers closest to the virtual focused source is used, resulting in the largest possible listening area; or a preferred listening area is defined and those loudspeakers are chosen that create the least erroneous wave fronts inside this area. The derivation of the secondary source signals and further information on these sources can be found, e.g., in [18.29, 46]. Illustrations, Figs. 18.13 and 18.14, are given later in the context of artifacts and compensation methods.

18.3.3 Rayleigh Integrals

Imagine a volume V consisting of a circular plane $S1$ closing a hemisphere $S2$, as illustrated in Fig. 18.6b, whose radius converges to ∞. The influence of the radiation from the secondary sources on $S2$ becomes 0 for the area right in front of $S1$. This coherence satisfies the so-called *Sommerfeld condition*. A separating plane between two half spaces, the source-free volume and source volume, remains. The K–H integral then consists of an integral over the plane $S1$ and thus fulfills the second simplification criterion from Table 18.2.

$$-\frac{1}{4\pi}\iint_{S1}\left(G(\omega,\Delta\boldsymbol{r})\frac{\partial P(\omega,\boldsymbol{Y})}{\partial \boldsymbol{n}} - P(\omega,\boldsymbol{Y})\frac{G(\omega,\Delta\boldsymbol{r})}{\partial \boldsymbol{n}}\right)\mathrm{d}S = \begin{cases} P(\omega,\boldsymbol{x}), & \boldsymbol{x}\in V \\ 0, & \boldsymbol{x}\notin V\,. \end{cases} \tag{18.33}$$

This step reduces the area of secondary sources from a three-dimensional surrounding of a source-free volume to a separation plane.

Since the Green's function that was given in (18.23) is a linear combination of a special solution and a general solution, one term of the integral can be eliminated by adding a carefully chosen general solution to the free-field Green's function. This way the radiation can be restricted to one type of radiator. If the Green's function is chosen to be

$$G_{\mathrm{D}}(\omega, \Delta\boldsymbol{r}) = \frac{\mathrm{e}^{-\mathrm{i}k\Delta r}}{\Delta r} + \frac{\mathrm{e}^{-\mathrm{i}k\Delta r'}}{\Delta r'} \,, \tag{18.34}$$

where $\Delta\boldsymbol{r}'$ is the mirrored position of $\boldsymbol{X}$, mirrored at the tangent of point $\boldsymbol{Y}$ on $S1$. Then $G_{\mathrm{D}}(\omega, \Delta\boldsymbol{r})$ is 0 on the surface $S1$ – which satisfies the *homogeneous Dirichlet boundary condition* [18.47] – and the second term vanishes. This implicitly models the boundary as a rigid surface [18.5], leading to the *Rayleigh I integral* for secondary monopole sources, which is not only applied for wave front synthesis but also for other wave field synthesis approaches as well as near-field acoustic holography and other applications

$$P(\omega, \boldsymbol{X}) = -\frac{1}{2\pi} \iint\limits_{S1} \left(G_{\mathrm{D}}(\omega, \Delta\boldsymbol{r}) \frac{\partial P(\omega, \boldsymbol{Y})}{\partial \boldsymbol{n}} \right) \mathrm{d}S \,. \tag{18.35}$$

Now, considering

$$\frac{\partial P(\omega, \boldsymbol{Y})}{\partial \boldsymbol{n}}$$

the desired driving functions of the secondary sources, an explicit solution can be found, e.g., by means of wave field expansion. This approach is called the *simple source approach* and is the basis of some sound field synthesis methods such as higher-order ambisonics. Here, the sound pressure and pressure gradients are measured (data-based) or calculated (model-based) at a listening position. After decomposing these to a series of *spherical harmonics* – which are orthonormal eigensolutions of the wave equation – an analytical solution for a spherical distribution of secondary sources can be found. The higher the number of measured or calculated pressure gradients, the more the listening point expands to a listening area in which the sound field is synthesized correctly, if enough secondary sources are available. Further information on higher-order ambisonics can be found, e.g., in [18.5–11].

Since the distance $|\Delta\boldsymbol{r}|$ between secondary source position $\boldsymbol{Y}$ and considered position in the source-free volume $\boldsymbol{X}$ equals the distance between the secondary source position and the mirror position $|\Delta\boldsymbol{r}'|$, $G_{\mathrm{D}}(\omega, \Delta\boldsymbol{r})$ is nothing but a doubling of the free-field Green's function $G(\omega, \Delta\boldsymbol{r})$

$$G_{\mathrm{D}}(\omega, \Delta\boldsymbol{r}) = 2G(\omega, \Delta\boldsymbol{r}) \,. \tag{18.36}$$

Assuming

$$\frac{G_{\mathrm{N}}(\omega, \Delta\boldsymbol{r})}{\partial n}$$

to be 0 satisfies the *homogeneous Neumann boundary condition* [18.47] and the first term of (18.33) vanishes. This is accomplished by choosing

$$G_{\mathrm{N}}(\omega, \Delta\boldsymbol{r}) = \frac{\mathrm{e}^{-\mathrm{i}k\Delta r}}{\Delta r} - \frac{\mathrm{e}^{-\mathrm{i}k\Delta r'}}{\Delta r'} \,, \tag{18.37}$$

yielding the *Rayleigh II integral* for secondary dipole sources

$$P(\omega, \boldsymbol{X}) = -\frac{1}{2\pi} \iint\limits_{S1} \left(P(\omega, \boldsymbol{Y}) \frac{\partial G(\omega, \Delta\boldsymbol{r})}{\partial \boldsymbol{n}} \right) \mathrm{d}S \,. \tag{18.38}$$

In both cases the third simplification criterion from Table 18.2 is satisfied. But since the destructive interference outside the source-free volume is missing, $P(\omega, \boldsymbol{X})$ for $\boldsymbol{X} \notin V$ is not 0. A mirrored sound field in the source volume is the consequence. In the case of monopoles, the sound field created by the secondary sources is identical with the one inside the source-free volume. This is illustrated in Fig. 18.7. In the case of dipole sources, the phase in the source volume is the inverse of the phase inside the source-free volume as illustrated in Fig. 18.8. Additionally, the sound pressure, or respectively the particle velocity, duplicate by adding the general solution of the Green's function.

Both formulations do not apply for arbitrary volume surfaces but for separation planes only [18.5]. To ensure that any position around the listening area can be a source position, the listening area has to be surrounded by several separation planes. If (18.35) and

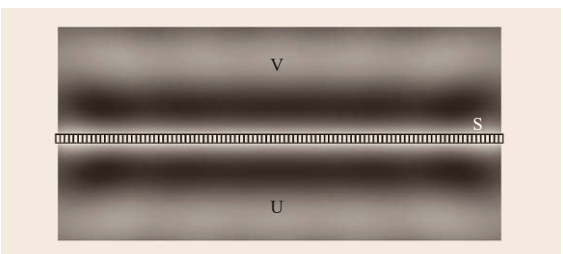

Fig. 18.7 Mirrored sound field due to the exclusive use of secondary monopole sources

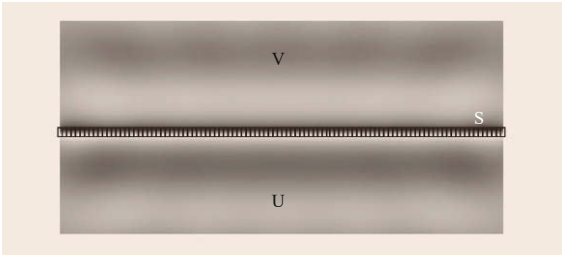

Fig. 18.8 Inversely phased mirrored sound field due to the exclusive use of secondary dipole sources

(18.38) are applied to other geometries, they still deliver approximate results [18.5]. In any case, the source-free volume has to be convex so that no mirrored sound field lies inside the source-free volume, i. e., volume in Fig. 18.6a is inappropriate [18.8]. Since $S1$ is modeled as a rigid surface, reflections occur when a listening area is surrounded by several separation planes. This problem is illustrated in Fig. 18.9. The squares represent loudspeakers that surround the source-free area. Loudspeaker signals from three directions propagate towards the inside. Loudspeakers contribute to the synthesis of the wave front in the half space behind the connection line between them and the virtual source. This half space needs to cover a large portion of the listening area. Otherwise, its mirrored version arrives at the listening area, creating an undesired echo wavefront.

These artifacts can be reduced by a *spatial windowing* [18.5, 43] technique applied to the Rayleigh I integral

$$P(\omega, \boldsymbol{X}) = d(\boldsymbol{Y}) \frac{P(\omega, \boldsymbol{Y})}{\partial \boldsymbol{n}} 2G(\omega, \boldsymbol{Y}) \,,$$
$$d(\boldsymbol{Y}) = \begin{cases} 1, & \text{if } \langle \boldsymbol{Y} - \boldsymbol{Q}, n(\boldsymbol{Y}) \rangle > 0 \\ 0, & \text{otherwise} \end{cases} \qquad (18.39)$$

The variable $d(\boldsymbol{Y})$ is the windowing function for spherical waves, which is 1 if the local propagation direction of the sound of the virtual source at the position of the secondary source has a positive component in normal direction of the secondary source. If the deviation is $\pi/2$ or more, $d(\boldsymbol{Y})$ becomes 0 and the speaker is muted. That means only those loudspeakers whose normal component resembles the tangent of the wave front of the virtual source are active. $G(\omega, \Delta \boldsymbol{r})$ describes the directivity function of the secondary source, i. e., of each loudspeaker. The other terms are the sought-after driving functions D of the loudspeakers [18.5]

$$D(\omega, \boldsymbol{Y}) = 2d(\boldsymbol{Y}) \frac{P(\omega, \boldsymbol{Y})}{\partial \boldsymbol{n}} \,. \qquad (18.40)$$

Figure 18.10 illustrates the same virtual source as Fig. 18.9 but with the applied windowing function, (18.39). The dashed squares represent muted loudspeakers. Here the desired wave front is clearly visible. It is the wave front of a virtual point source located below the loudspeaker array, propagating upwards. Still, strong artifacts occur. The reasons and solutions for these artifacts are discussed next.

Two Dimensions

For applications in which the audience is organized more or less in plane, it is sufficient to recreate the wave field correctly for that listening plane only, rather than in the whole listening volume. Typically, listeners are organized roughly in plane, e.g., in conference rooms, concert halls, cinemas, theaters, in the car, on the couch etc. Furthermore, one or several one-dimensional distributions of loudspeakers are easier implementable than covering a complete room surface with loudspeakers. Reducing the three-dimensional wave field synthesis to two dimensions reduces the separation plane $S1$ to a separation line $L1$. In theory, one could simply reduce the surface integral to a simple integral and the Rayleigh integrals would take the forms

$$P(\omega, \boldsymbol{X}) = \frac{1}{2\pi} \int_{L1} \left(G(\omega, \Delta \boldsymbol{r}) \frac{\partial P(\omega, \boldsymbol{Y})}{\partial \boldsymbol{n}} \right) \mathrm{d}S1 \,, \qquad (18.41)$$

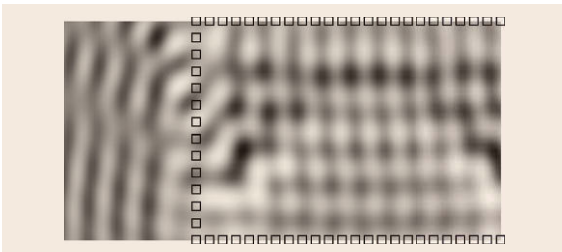

Fig. 18.9 Calculating a surrounding loudspeaker array with Rayleigh I integral implicitly models $S1$ as rigid surfaces creating reflections

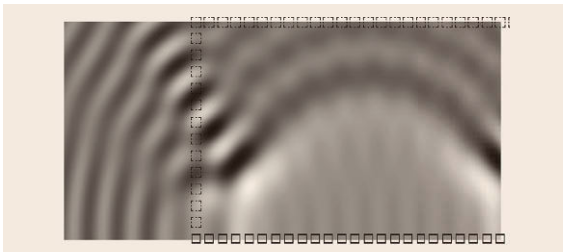

Fig. 18.10 Muting loudspeakers whose normal component deviates strongly from the local propagation direction of the virtual wave front suppresses virtual reflections

and

$$P(\omega, \boldsymbol{X}) = \frac{1}{2\pi} \int_{L1} \left(P(\omega, \boldsymbol{Y}) \frac{\partial G(\omega, \Delta \boldsymbol{r})}{\partial \boldsymbol{n}} \right) \mathrm{d}S1 \,. \tag{18.42}$$

In these cases $\boldsymbol{X}$ is two-dimensional

$$\boldsymbol{X} = \begin{bmatrix} x \\ y \end{bmatrix} . \tag{18.43}$$

This solution was satisfying if no third dimension existed, e.g., if wave fronts of the secondary sources had no spherical but a circular or cylindrical propagation [18.5, 45]. Then, the propagation function $G(\omega, \Delta \boldsymbol{r})$ was different, having an amplitude decay of $1/\sqrt{r}$ instead of $1/r$. This is owed to the fact that the surface S of a circle or cylinder doubles with a doubled circle radius r_{circle}

$$S = 2\pi r_{\mathrm{circle}} \tag{18.44}$$

in contrast to the spherical case in which it squares with the doubled radius as already indicated in (18.26). In this case

$$I \propto \frac{1}{r} \tag{18.45}$$

and thus

$$p \propto \frac{1}{\sqrt{r}} \,. \tag{18.46}$$

So the practical benefit of (18.41) and (18.42) is minor since transducers with a cylindrical radiation in the far field are hardly available. An approximately cylindrical radiation could be achieved with line arrays of loudspeakers, as often applied in PA systems for concerts. But replacing each individual loudspeaker by a line array of speakers contradicts the goal of reducing the number of loudspeakers. Simply replacing cylindrically radiating speakers by conventional loudspeakers that have a spherical radiation function leads to errors in this wave field synthesis formulation due to the deviant amplitude decay.

Huygens' principle states that a wave front can be considered as consisting of infinitesimally distanced elementary sources. An infinite planar arrangement of elementary point sources with a spherical radiation could (re-) construct a plane wave, since the amplitude decay, which is owed to the $1/r$-distance law, is compensated by the contribution of the other sources. Imagining secondary line sources with a cylindrical radiation, a linear arrangement of sources would be sufficient to create a planar wave front. In a linear arrangement of elementary point sources, the contribution of the sources from the second dimension is missing, resulting in an amplitude decay. Therefore, a *2.5-dimensional operator* including a *far-field approximation* that modifies the free-field Green's function to approximate a cylindrical propagation is used [18.5, 48]. This changes the driving function to

$$D_{2.5\mathrm{D}}(\omega, \boldsymbol{Y}) = \sqrt{\frac{2\pi \, |\boldsymbol{Y} - \boldsymbol{X}_{\mathrm{ref}}|}{\mathrm{i}k}} D(\omega, \boldsymbol{Y}) \tag{18.47}$$

with $\boldsymbol{X}_{\mathrm{ref}}$ being a reference point in the source-free volume. This yields the *2.5-dimensional* Rayleigh integral [18.5, 25, 49]

$$P(\omega, \boldsymbol{X}) = -\oint_S D_{2.5\mathrm{D}}(\omega, \boldsymbol{Y}) G(\omega, \Delta \boldsymbol{r}) \,. \tag{18.48}$$

Taking reference points $\boldsymbol{X}_{\mathrm{ref}}$ parallel to the loudspeaker array, the wave field can be synthesized correctly along a reference line. Between the speakers and the reference line, the sound pressures are too high, behind the reference line they are too low.

Until now, free-field conditions are assumed. However, if not installed in the free field, reflections may occur and superimpose with the intended wave field created by the loudspeaker system. Under the term *listening room compensation* a variety of methods are proposed to reduce the influence of reflections. The simplest form is passive listening room compensation, which means that the room is heavily damped. This is an approved method, applied, e.g., in cinemas. However, for some listening rooms, for example living rooms, damping is impractical. Therefore, active solutions are proposed, like adding a filtering function that eliminates the first reflections of the room to the calculated loudspeaker signals [18.50, 51]. *Adaptive wave field synthesis* uses error sensors that measure errors occurring during WFS of a test stimulus emerging, e.g., from reflections or the loudspeaker radiation characteristics [18.43]. Then any WFS solution is modified by a regularization factor that minimizes the squared error. This is of course a vicious circle since compensation signals corrupt the synthesized wave field and are reflected too, adding further errors. Due to an exponentially increasing reflection density it is hardly possible to account for all higher-order reflections. Thus, the approach is limited to first-order reflections.

Discretization

A discretization of the Rayleigh integrals adopts the continuous formulation to discrete secondary source

positions

$$P(\omega, \boldsymbol{X}) = \frac{1}{2\pi} \sum_{\boldsymbol{r}_\mathrm{Y}=-\infty}^{\infty} \left(G(\omega, \Delta\boldsymbol{r}) \frac{\partial P(\omega, \boldsymbol{Y})}{\partial \boldsymbol{n}} \right) \Delta \boldsymbol{r}_\mathrm{Y} \tag{18.49}$$

and

$$P(\omega, \boldsymbol{X}) = \frac{1}{2\pi} \sum_{\boldsymbol{r}_\mathrm{Y}=-\infty}^{\infty} \left(P(\omega, \boldsymbol{Y}) \frac{\partial G(\omega, \Delta\boldsymbol{r})}{\partial \boldsymbol{n}} \right) \Delta \boldsymbol{r}_\mathrm{Y} \,. \tag{18.50}$$

Thereby the Nyquist–Shannon sampling theorem has to be regarded: the sampling frequency has to be at least twice the highest frequency of the signal to be presented for no aliasing to occur. The highest frequency to be represented error-free is the *critical frequency* or *aliasing frequency*. In this case the sampling frequency is spatial; the speaker distance $\Delta \boldsymbol{Y}$ needs to be smaller than half the distance of the largest trace wavelength between the speakers

$$f_\mathrm{max} = \frac{c}{2\Delta \boldsymbol{Y}} \,. \tag{18.51}$$

Typically, secondary sources are equally spaced. The spatial sampling of the secondary source distribution is a process of sampling and interpolation; the interpolator is given by the radiation characteristics of the loudspeakers [18.52]. An adaption of WFS to the radiation characteristic of the loudspeakers is derived in [18.53]. For the trace wavelength between the speakers

$$\lambda_{\Delta \boldsymbol{Y}} = \lambda \, |\sin\alpha| \tag{18.52}$$

is valid, where α is the angle between the normal direction of a loudspeaker and the propagation direction of the virtual source at this loudspeaker position. Respectively, it can be considered as angle between separation line $L1$ and the tangent of the wave front when striking the speaker position. This leads to an adjustment of (18.51) to

$$f_\mathrm{max} = \frac{c}{2\Delta \boldsymbol{Y} \sin\alpha} \,. \tag{18.53}$$

The angle α may vary dependent on position and radiation of the source in a range between $\pi/2$ and $3\pi/2$. Two examples for α are illustrated in Fig. 18.11 to clarify the coherency. The black disk represents the source, the dark and light gray disks the wave front at two different points in time.

Undersampling creates regular erroneous wave fronts above f_max. These erroneous wave fronts, *artifacts*, contain the frequencies above the critical frequency and cause perceivable changes in sound color and disturb the location of the auditory event [18.5, 9]. They can be heard as echoes following and partly superimposing with the synthesized wave fronts. Aliasing artifacts are illustrated in Fig. 18.12. Four periods of a sinusoidal sound are synthesized as a plane wave. Due to undersampling, wave fronts with an unwanted propagation direction superimpose with the synthesized wave front. As a result the synthesized wave fronts are partly overlain and partly followed by unwanted wave fronts. A comb filter effect, well known from stereophonic loudspeaker setups, occurs. Furthermore, the amplitude of the wave front decays with increasing distance to the loudspeaker array, which is not the case for actual plane waves, (18.11) and (18.12). As mentioned earlier, this error occurs due to the missing third dimension.

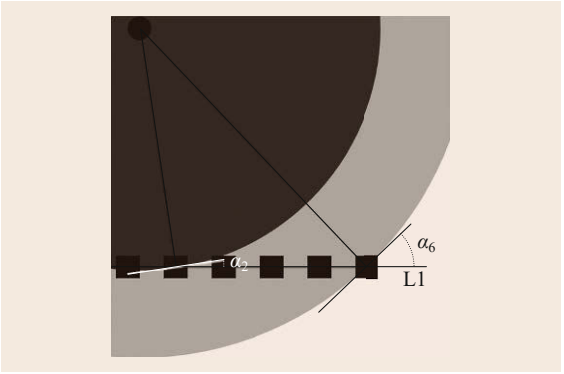

Fig. 18.11 Several incidence angles for one source position (after [18.40])

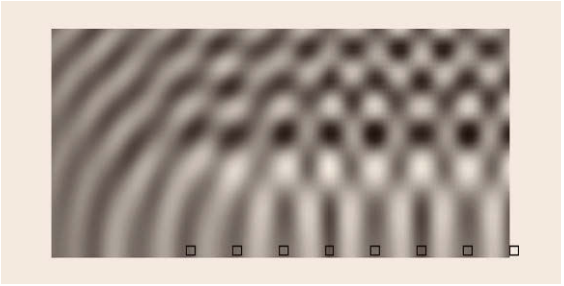

Fig. 18.12 Spatial aliasing due to undersampling with discrete loudspeaker positions (after [18.40])

As long as the condition

$$|\sin\alpha(\omega)| < \frac{c}{2\Delta \boldsymbol{Y} f_\mathrm{max}} = \frac{\pi c}{\Delta \boldsymbol{Y} \omega_\mathrm{max}} \tag{18.54}$$

is satisfied, no aliasing wave fronts will occur.

A focused source with and without aliasing artifacts is illustrated in Figs. 18.13 and 18.14. The virtual source is located the center of the white region.

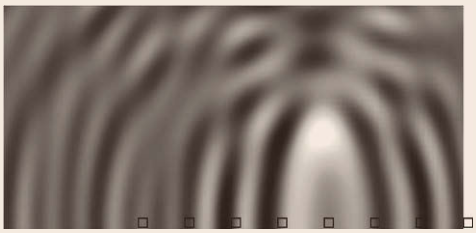

Fig. 18.13 Focused source corrupted by spatial aliasing and truncation errors (after [18.40])

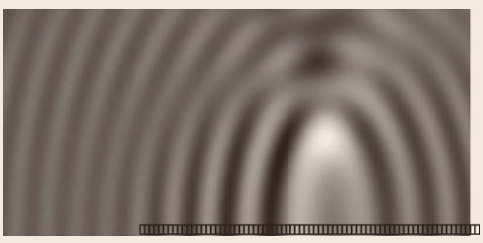

Fig. 18.14 Focused source without spatial aliasing corrupted by truncation errors (after [18.40])

Both have truncation errors due to the finite extent of the loudspeaker array, which will be addressed subsequently. For focused sources, aliasing artifacts occur as pre-echoes preceding the synthesized wave front. Note that the illustrated snapshot shows a point in time at which the loudspeakers are already silent for a while, so there are no wave fronts traveling towards the focus point anymore.

One suggestion to reduce artifacts is to process frequencies above the critical frequency not by means of wave front synthesis but by conventional stereophonic sound between two to three loudspeakers. This method is called *optimized phantom source imaging* (OPSI) [18.5, 48] and combines WFS with conventional intensity panning. Thus, OPSI reintroduces psychoacoustic considerations to WFS. In that manner no aliasing echoes as such occur but the common disadvantages of stereophonic sound become effective: a comb filter effect arises, the display of depth becomes worse and high frequencies are only located correctly in the sweet spot. At other positions two to three wave fronts arrive slightly shifted in time. *J.J. Lopez* et al. [18.54] suggest a related approach, called the *subband approach*, which involves playing frequencies above the aliasing frequency through the one loudspeaker with the most similar direction to the virtual source only. This approach does not bring along the disadvantages of stereo but still a more or less correct localization of virtual sources is only possible in a small part of the listening area. By randomizing the phase of the high frequencies of the loudspeakers artifacts can be smeared [18.5]. The result in illustrated in Fig. 18.15. This minimizes the sound coloration but localization accuracy is reduced [18.48], since amplitude and phase have to be correct for a proper localization via WFS. Also, the resulting wave field does not correspond to the desired one.

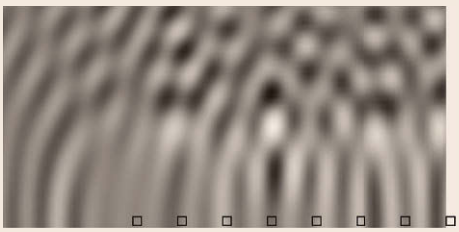

Fig. 18.15 By randomizing the phase of signal components above the aliasing frequency synthesis errors become irregular

In all three cases the signal is divided by the critical frequency into two frequency regions. For the lower frequency region the theory of WFS is applied. For the high frequencies the goal is to retain the natural temporal and spectral properties of the sound wave as well as an approximately correct source position rather than physically correct replicas. The methods are based on the same psychoacoustic considerations:

- Partials of a sound tend to fuse
- Higher frequencies tend to be masked by lower frequencies
- Altogether the audible portion of sound will be integrated into one auditory stream with one group source position.

Then, the lower frequency region – which offers very precise localization cues due to the correct reconstruction of the wave front – is crucial for a distinct and correct localization, and the ambiguous localization cues of higher frequencies are neglected by the auditory system.

Another approach is to increase the aliasing frequency at the expense of the size of the listening area. *Local wave field synthesis* creates several proximate focused sources that act as secondary sources synthesizing high frequency wave fronts correctly for a subspace of the listening area [18.55]. The result is illustrated in Fig. 18.16. The virtual focused sources are marked by an $\times$. Compared to the aliasing case, Fig. 18.12, errors are reduced. This is, however, only true for the area above the line of focused sources. An unintended wave front occurs on the left of the virtual source array. Just as with actual loudspeakers, the finite array of focused point sources introduces truncation errors,

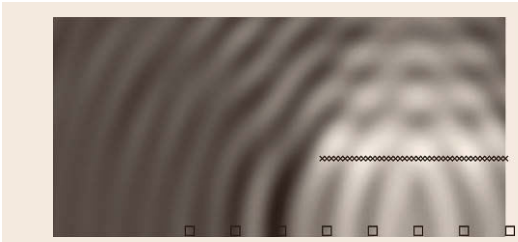

Fig. 18.16 Local wave field synthesis creates plane waves above the aliasing frequency in a subspace of the listening area. Here, the aliasing frequency is increased but truncation errors persist

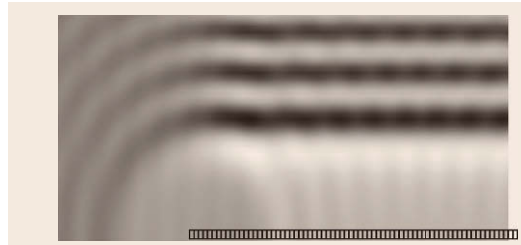

Fig. 18.17 No aliasing but a truncation error due to the finite loudspeaker array length (after [18.40])

which can again be compensated by methods discussed in the following subsection. The computational costs for rendering a high number of virtual sources for each wave front are rather high. Quite a different method is to recreate the wave field not for the discrete loudspeaker positions but for discrete listening positions sampling the listening area. The approach is called *sound field reconstruction* [18.17]. Sampling positions are chosen under the assumption that if a wave field is reproduced correctly on a grid satisfying the Nyquist–Shannon sampling theorem, the wave field is correct everywhere inside the grid. For stationary signals this approach is straightforward. For transient signals psychoacoustic considerations are necessary to achieve a natural sound and a proper source localization [18.19]. The approach can be combined with crosstalk cancellation to create a realistic binaural signal at discrete listening positions [18.18].

Of course, these methods work best if the chosen distance between adjacent speakers is so small that the aliasing frequency is as high as possible. At loudspeaker spacing of 0.1–0.3 m it can be speculated that the influence of the frequencies above the critical frequency is weak concerning sound coloration and localization as perceived by human listeners [18.5].

18.3.4 Finite Extent

Limiting the sum in the discrete Rayleigh integrals (18.49) and (18.50) to a finite number of loudspeaker positions corresponds to the sixth simplification of Table 18.2. This truncates the loudspeaker array. Figure 18.17 shows this scenario. On the left-hand side of the loudspeaker array the synthesized wave front fades to the curved wave front of the outermost speaker. This effect is called *truncation* [18.49]. It appears like diffraction through a gap and has the effect that the wave field cannot be synthesized in the area beyond this border. Furthermore, a spherical wave propagates from the end loudspeaker since the compensatory effect of adjacent speakers is missing. Even behind the synthesized plane wave front this spherical wave front is propagating towards the right. The truncation effect can be compensated by gradually reducing the amplitudes of the outermost loudspeakers, e.g., in terms of a half-Hann function [18.49]

$$\hat{A}(\boldsymbol{Y}_n) = 0.5\left(1-\cos\left(\frac{\pi n}{N}\right)\right),\ n = 0,\ldots,N \tag{18.55}$$

for the nth speaker. The procedure is called *tapering* and the result is illustrated in Fig. 18.18. The amplitude of the loudspeaker signals is indicated by the size of the square. Here, the only errors left are the truncation error arising from the untapered right end of the loudspeaker array. Compensation sources as used in listening room compensation minimize truncation by using speakers with inversely phased signals. However, when surrounding the listening area with three to four speaker line arrays the border effect is inferior [18.49] as the truncation error in corners is weak. This is illustrated in Fig. 18.19. This figure also points out the necessity of heavy damping or listening room compensation: due to constructive interference the signal amplitude outside the source-free volume is higher than the synthesized wave front inside. A reflecting wall would heavily corrupt the sound field inside the source-free volume. This is demonstrated in Fig. 18.20. It shows the same loudspeaker signals as in Fig. 18.19.

Fig. 18.18 A tapering window eliminates the truncation error but reduces the extent of the listening region (after [18.40])

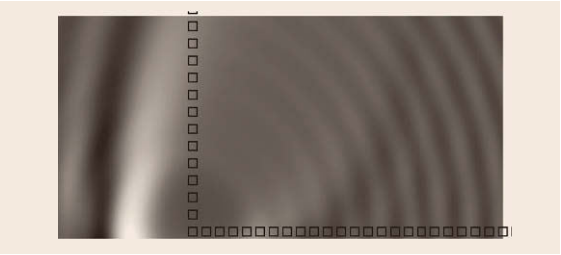

Fig. 18.19 When two loudspeaker line arrays meet, the truncation error is weak

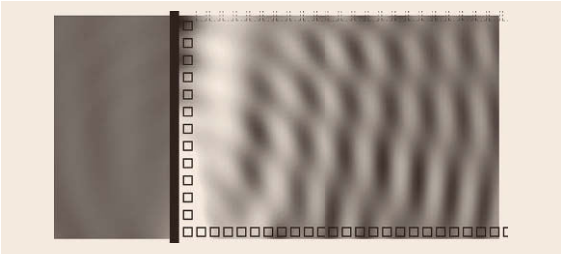

Fig. 18.20 Reflections of the listening room heavily corrupt the synthesized wave field

The black line represents a wall with minor absorption and transmission and without scattering. The reflection corrupts the wave front curvature and propagation direction, and creates a spatial comb filter effect and high amplitudes in the listening area, right in front of the speakers.

18.4 Current Research and Development

Wave field synthesis has reached a state in which the direct sound of virtual monopole sources and plane waves can be synthesized with a high precision in a listening area, which is only limited by the extent of the loudspeaker array and sometimes restricted to a subspace when creating focused sources. Some wave field synthesis systems are already available on the market.

Current research and development projects mainly address two issues. First, the expensive installation and operation of wave field synthesis. Here, one aim is to develop easy accessible software and formats to simulate, create, control, store and play WFS content. The other aim is to make installations more accessible and compatible to interior design by applying flat panel loudspeakers, reducing the number of necessary secondary sources as well as the computational demands. Second, expansions of functionality and the implementation of more acoustical parameters, like sound radiation characteristics and room modes, is still of great interest. Here, the rise of psychoacoustic considerations help to increase control over the perceived sound experience. These two topics are discussed individually in the last subsections.

18.4.1 Applicability

To make wave field synthesis systems more applicable, user interfaces [18.25] and plugins for digital audio workstations [18.31, 56, 57] have been programmed. Here, source signals can be associated with positions and paths in relation to the loudspeaker setup. Also, implementations for mobile devices are being developed [18.26]. Matlab toolboxes help for numerical simulations and visualizations for an easier access to sound field synthesis research and development [18.58, 59]. Because loudspeaker configurations are not standardized, object-based source material is necessary, combining audio tracks with dynamic metadata describing source position and trajectories, source orientation and sound radiation characteristics and information on early reflections and reverberation. Although several formats have been proposed, no standardized wave field synthesis format has established yet [18.25, 36]. The need for object-based source material implies incompatibility with current channel-based audio formats for stereo and 5.1 setups. *M. Cobos* and *J.J. López* evaluated blind audio source separation techniques to use stereo source material for wave front synthesis applications [18.60]. The ISO/MPEG-H 3-D audio standard, which is under development, is supposed to deliver spatial audio object coding that is compatible with stereo, 5.1, 22.2 and higher-order ambisonics [18.61].

Of course, covering a complete living room, concert hall, theater or cinema with a surrounding loudspeaker array is a drastic impairment of the interior decoration. To solve this problem, research currently goes in two directions. The first concept is to apply multiactuator panels (MAPs) [18.24, 27, 62]. Due to their flat, inconspicuous nature, they do not harm interior decoration as much as conventional loudspeakers. MAPs have the additional advantage that they can be arranged continuously, preventing aliasing when sufficient control is reached. However, elaborate filtering is necessary to compensate effects of modes and reverberation within the panels. The second concept is to decrease the number of loudspeakers [18.40, 63, 64]. With psychoacoustic considerations concerning source localization mechanisms and the perception of source width and

spaciousness, the necessary number of loudspeakers can be reduced drastically while maintaining spatial listening experience. Here, all loudspeakers contribute to synthesize the sound field within a defined listening area. Instead of the emanating wave front, a succession of quasistationary sound fields is synthesized in the listening area by solving the discretized Rayleigh I integral, (18.49). This sound field resembles an original sound field as created by a musical instrument including its angle- and frequency-dependent radiation characteristics. In this way, the natural interaural level and phase differences are recreated, giving clues about source direction and extent. However, the spectral cues are not sufficient for a proper localization. As all loudspeaker wavefronts arrive from different angles and at different points in time, source localization is affected by the *precedence effect* [18.65], i. e., the nearest loudspeaker is heard as source position. The result of the precedence effect is unwanted but its initiator can be used. When only one loudspeaker actively plays all note onsets, the perceived source position will coincide with the position of this *precedence loudspeaker*. The signal amplitudes of the other loudspeakers are faded in within several milliseconds. As long as the fading duration is longer than the arrival time difference of the speaker wavefronts and shorter than the *overshoot* phenomenon [18.66] at note onsets, the fading is masked and stays inaudible. This psychoacoustic approach is also applicable with more common loudspeaker setups, such as 5.1 or 22.2, which largely increases compatibility and applicability. The reduced number of loudspeakers also comes along with a reduction of computational demands, which is another topic of current research. *Beckinger* and *Brix* calculated that synthesizing 21 000 rain particles falling in 20 sec with a 64-channel wave front synthesis system would require 26 900% of a typical single-core processor in modern personal computers and suggested an approach that reduces the computational demands to 36% [18.67]. Additionally, ways are investigated to include height with a small number of additional channels [18.68]. This approach is very promising because localization accuracy of human listeners in the median plane is rather poor.

18.4.2 Feature Expansion

So far research has mostly concentrated on synthesizing wave fronts of virtual monopole sources and plane waves. The sound field is synthesized in the spatiotemporal domain. The synthesized wave fronts propagate in a natural manner and deflect around the listeners' heads. Thus, they provide natural localization cues, like interaural time and level differences, wave front curvature and the individual head-related transfer function. Monopoles create a discrete source position localizable by every listener, i. e., they include the source distance. Focused sources are localized within the listening room but not for listeners who are located between the active speakers and the focus point. Plane waves create a common source angle that all listeners agree on. Additional control over virtual sources is gained by motion capture technology [18.26]. By tracking an individual, a singing bird could be placed on both of his shoulders and even stay there while he walks around. However, the left bird is only localized correctly by him and listeners on his right and vice versa. This approach enables 3-D sound for one listener but reintroduces the sweet-spot limitation. For rapidly moving sources, implementing the Doppler effect is important for an authentic sound experience [18.69, 70]. Additionally, several methods have been proposed and implemented to synthesize higher-order radiation patterns, especially the radiation characteristics of musical instruments [18.19, 24, 25, 64, 71]. Effects on perceived timbre, localization, source extent and orientation of the instrument have been reported. As an example, the radiation pattern of a single violin frequency is illustrated in Fig. 18.21. Amplitudes and phases are dependent on direction, therefore wave fronts are no isobars but show certain inhomogeneities. There are also several attempts to include room modes, early reflections and late reverberations, both data-based and model-based [18.23, 72, 73]. It has been found that listeners are very sensitive to diffuseness and overall level of reverberation. An example of virtual room modes is illustrated in Fig. 18.22. The two loudspeaker line arrays synthesize perpendicular plane waves, creating a typical interference pattern. In contrast to a real room, the amplitudes of the the virtual standing waves decrease with increasing distance to the line arrays. This can only partly be compensated by two additional lines.

Many researchers emphasize the potential of psychoacoustics in auralization and wave field synthesis applications [18.22, 64, 74, 75]. The precision of the physical replication of sound fields and thus the amount of data to be processed can be reduced without audible effects. In a psychoacoustic sound field synthesis approach loudspeakers create the desired sound field in a listening area by calculations in the frequency domain [18.19, 64]. Although only valid for stationary signals, calculations are applied for transient sounds. By considering the integration time, precedence effect, critical bands and auditory scene analysis principles physical synthesis errors become inaudible. Another approach based on psychoacoustic considerations is directional audio coding (DirAC) [18.76]. Signals are separated into directional and diffuse components and

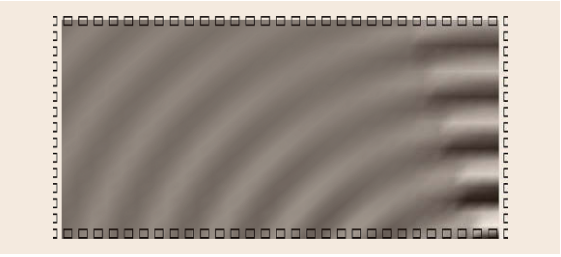

Fig. 18.21 Synthesis of a source with nonuniform radiation pattern

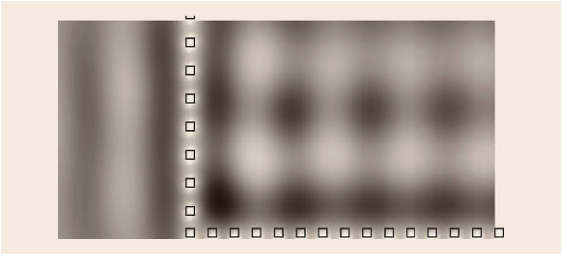

Fig. 18.22 Room modes modeled by orthogonal plane waves

can be treated differently according to those aspects of sound the auditory system is sensitive for. Direct sound and very early reflections affect the perceived source location, orientation and extent, whereas reverberation is characterized by the duration, timbre and degree of diffusion and has an effect on perceived reverberance, spatial impression, listener envelopment and liveness and may modify the perceived loudness, warmth and brilliance of the sound [18.77–79]. Combining limited acoustic control with psychoacoustic control might have the potential to overcome all current issues and restrictions.

19. Finite-Difference Schemes in Musical Acoustics: A Tutorial

Stefan Bilbao, Brian Hamilton, Reginald Harrison, Alberto Torin

The functioning of musical instruments is well described by systems of partial differential equations. Whether one's interest is in pure musical acoustics or physical modeling of sound synthesis, numerical simulation is a necessary tool, and may be carried out by a variety of means. One approach is to make use of so-called finite-difference or finite-difference time-domain methods, whereby the numerical solution is computed as a recursion operating over a grid. This chapter is intended as a basic tutorial on the design and implementation of such methods, for a variety of simple systems. The 1-D wave equation and simple difference schemes are covered in Sect. 19.1, accompanied by an analysis of numerical dispersion and stability, as well as implementation details via vector-matrix representations. Similar treatments follow for the case of the ideal stiff bar in Sect. 19.2, the acoustic tube in Sect. 19.3, the 2-D and 3-D wave equations in Sect. 19.4, and finally the stiff plate in Sect. 19.5. Some more general nontechnical comments on more complex extensions to nonlinear systems appear in Sect. 19.6.

Systems in musical acoustics, whether they are musical instruments, electromechanical effects, or the 3-D spaces in which they are immersed, can all be described by systems of partial differential equations (PDEs). These equations are accompanied by the regions over which they are defined, coupling and boundary conditions, and forcing terms, which ultimately lead back to the player – whose behavior, as yet, is not well modeled by an equation. Sometimes, as in the case of wave propagation in a room, the equation itself is simple, but the geometry is complex; in other cases, one may have a very complex system of PDEs to solve, as in the case of a gong or a spring reverberation device, but the problem is defined over a relatively simple geometry. In either case, it is almost never possible to obtain an exact analytical solution, and thus simulation is a necessary tool. The ultimate application may be the validation of a particular musical instrument model in a scientific musical acoustics setting, or, perhaps, synthesis: the generation of sound from a numerical model.

There are many approaches to the design of a simulation for a musical instrument. Particularly in musical acoustics, a common approach involves an eigenvalue-eigenmode decomposition, leading to a representation in terms of modes of vibration. Such approaches are appropriate when the system under study is linear and time invariant. Once the modal shapes and their frequencies have been determined, a simulation can be

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_19

very easily implemented – essentially, the system is reduced to a set of uncoupled oscillators. In some cases, such as a stiff string under simply supported boundary conditions, or a rectangular or circular membrane under simply supported conditions, such shapes and frequencies are available in closed form, and the system may be simulated to a very high degree of accuracy. For more complex systems involving, say, irregular geometries, more complex boundary conditions, or perhaps coupling among various linear components, the shapes and frequencies must be determined numerically, through the solution of a (potentially large) eigenvalue problem. When nonlinearity is present, the modal shapes (if they can be thought of as such) are coupled, and the possibility of an efficient solution rapidly becomes remote.

For these reasons, it can be useful to make use of direct grid-based time-domain methods. Such methods are much more generally applicable, but one usually loses from the outset the possibility of an exact solution. Furthermore, new difficulties are introduced, many of which will be described in this chapter. Finite-difference methods are the oldest and perhaps the simplest and most straightforward means of performing a time-domain simulation – they are particularly well suited to problems without enormous geometric complexity, and some key components of musical instruments do fit this requirement nicely. These methods date back at least to the work of *Courant* et al. in the 1920s [19.1], but they were only applied to physical problems with the emergence of computers in the 1940s, and they saw major developments when applied to problems in fluid dynamics in the 1940s and 1950s (see [19.2, 3] and the references therein). Finite difference methods have also seen extensive use in electromagnetics, starting with [19.4] and increasing in popularity in the 1980s [19.5] (in this setting, such methods are often referred to as the finite-difference time-domain method, or FDTD). Finite-difference methods were first employed in musical acoustics (and indeed for sound synthesis) by *Ruiz* [19.6], and *Hiller* and *Ruiz* [19.7], in the case of strings, though earlier work by *Kelly* and *Lochbaum* on speech synthesis [19.8] led to structures that are identical to those which arise when using finite-difference methods. Such studies were followed by more research on strings [19.9], and finally, when computing power reached a level necessary for simulation in a reasonable amount of time, a large body of work emerged, first with *Boutillon* [19.10] and *Chaigne* and *Askenfelt* [19.11], in the case of the hammer string interaction, and then continuing with work on finite-difference and waveguide mesh structures (which can ultimately be viewed as finite-difference methods), for the wave equation in both 2-D [19.12, 13] and 3-D [19.14–16], for membrane vibration and room acoustics applications. See [19.17] for an overview of more recent developments.

This chapter is intended as a basic tutorial on the design and implementation of such methods, for a variety of simple systems. The 1-D wave equation and simple FD schemes are covered in Sect. 19.1, accompanied by an analysis of numerical dispersion and stability, as well as implementation details via vector-matrix representations. Similar treatments follow for the case of the ideal stiff bar, in Sect. 19.2, the acoustic tube in Sect. 19.3, the 2-D and 3-D wave equations in Sect. 19.4, and finally the stiff plate in Sect. 19.5. Some more general nontechnical comments on more complex extensions to nonlinear systems appear in Sect. 19.6.

19.1 The 1-D Wave Equation

The natural starting point for any discussion of numerical methods in musical acoustics has to be the 1-D wave equation [19.18], which may be written as

$$\partial_t^2 u = c^2 \partial_x^2 u \,. \tag{19.1}$$

This is a second-order partial differential equation, in both time t and a spatial coordinate x; $u(x,t)$ is the solution and c is the wave speed, in m/s. Here, ∂_t and ∂_x represent partial differentiation with respect to t and x respectively. Normally, t is defined for $t \in \mathbb{R}^+$, and x is defined over an interval $x \in \mathcal{D} \subset \mathbb{R}$. For practical purposes, it is the interval $\mathcal{D} = \mathcal{D}_L = [0\,, L]$, for some length $L > 0$. For some analysis purposes, it is also useful to examine the solution over an unbounded domain, i. e., $\mathcal{D} = \mathbb{R}$.

The equation above needs to be complemented by initial and boundary conditions. For initial conditions, it is usual to specify the values of u and $\partial_t u$ at time $t = 0$, i. e.,

$$u(x,0) = u_0(x) \quad \partial_t u(x,0) = v_0(x) \,. \tag{19.2}$$

If the domain is a finite interval such as $\mathcal{D}_L$, one boundary condition must be specified at either end of the domain (i. e., at $x = 0$ and $x = L$). Taking just the left end of the domain at $x = 0$ as an example, here are two of the most commonly encountered boundary

conditions

$$u(0,t) = 0 \quad \text{(Dirichlet)}$$
$$\partial_x u(0,t) = 0 \quad \text{(Neumann)} \,. \tag{19.3}$$

There are, of course, many other conditions that one may apply.

The second-order form above arises in different settings, and is normally derived from a more fundamental first-order system. For example, in the case of linear string vibration, the system is

$$\rho \partial_t v = \partial_x f \quad \partial_t f = T \partial_x v \,, \tag{19.4}$$

where here, $v(x,t)$ is transverse string velocity, $f(x,t)$ is vertical force, ρ is the linear mass density of the string in kg/m, and T is the nominal tension. In this case, one has $c = \sqrt{T/\rho}$. As another example, in the case of linear and lossless acoustic field equations in a uniform cylindrical tube, the system is

$$\rho_0 \partial_t v = -\partial_x p \quad \partial_t p = -\rho_0 c^2 \partial_x v \,, \tag{19.5}$$

where here, $v(x,t)$ is particle velocity, $p(x,t)$ is pressure deviation from atmospheric, and ρ_0 is air density in kg/m^3.

First-order systems such as (19.4) and (19.5) are one point of departure for numerical methods, leading to a formulation with staggered grids in time and space [19.2, 4]. In the mechanical setting, second-order forms such as (19.1) are more commonly encountered, and will be the main focus here. In either case, the substitution of one member of the first-order system into the other leads to the 1-D wave equation, in any of the constituent variables.

19.1.1 Behaviour of Solutions

Before moving directly to a simulation setting though, it is always useful to have some insights into the behavior of the solution.

Solution Characteristics: Traveling Waves

It is well known that the 1-D wave equation possesses a solution in terms of traveling waves. Considering the case of an unbounded domain $\mathcal{D} = \mathbb{R}$, the solution may be written directly as

$$u = u_+(x - ct) + u_-(x + ct) \tag{19.6}$$

in terms of two arbitrary functions u_+ and u_-, which represent waves traveling with constant speed c to the right and left respectively. Such a decomposition, which is peculiar to the 1-D wave equation, and not easily extended to more complex systems, has served as the starting point for efficient digital waveguide techniques in sound synthesis applications [19.19]; see Fig. 19.1.

Solution Characteristics: Dispersion Relation

A very useful analysis tool for PDE systems that are linear, and for which there is no variation in the coefficients in either space or time, is dispersion analysis. This is true in the present case of the 1-D wave equation (19.1). The idea is to examine the problem over an unbounded spatial domain, and in particular complex exponential solutions of the form

$$u = \mathrm{e}^{j(\omega t + \beta x)} \,, \tag{19.7}$$

where here, ω is an angular frequency of oscillation in radian/s, and β is a spatial wavenumber (where $2\pi/\beta$ is wavelength, in m). ω and β can be related by the insertion of (19.7) into the wave equation (19.1), to give

$$\omega = \pm c\beta \,. \tag{19.8}$$

This relation (or rather, pair of relations) is referred to as the dispersion relation for the 1-D wave equation – the sign indicates the direction of wave propagation (i. e., to the left or right). From the dispersion relation, one may

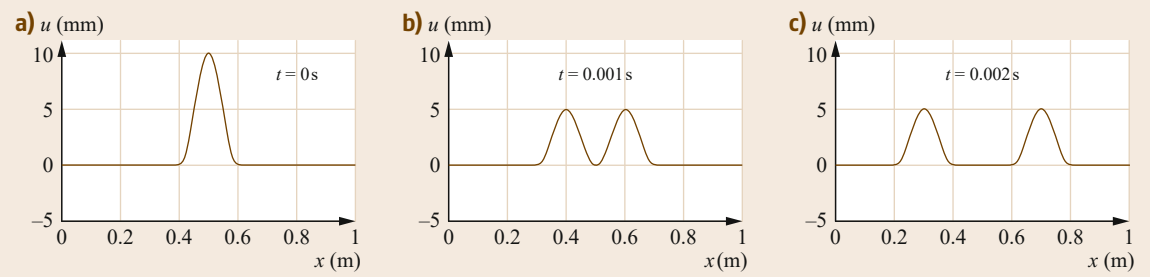

Fig. 19.1a–c Time evolution of a string profile with zero velocity, under an initial condition of a raised cosine distribution, at time instants as indicated. This illustrates the decomposition of the solution into traveling wave components. Here, the string is of length $L = 1$ m, and $c = 100$ m/s

arrive at an expression for the phase velocity, $v_{\text{phase}} = \omega/\beta$, leading to

$$v_{\text{phase}} = \pm c\,. \tag{19.9}$$

All waves thus travel at the same speed, c – this is another way of understanding the lack of distortion of traveling waves.

Solution Characteristics: Modes

For bounded domains, such as, in the present case, $\mathcal{D} = \mathcal{D}_L$, yet another means of analyzing behavior is in terms of natural frequencies or modes. The choice of boundary conditions is of major significance in this case. If the system, including boundary conditions, is lossless, then the solution may be written as

$$u(x,t) = \sum_{p=0}^{\infty} U_p(x)(a_p \sin(2\pi f_p t) + b_p \cos(2\pi f_p t)) \tag{19.10}$$

for some functions $U_p(x)$, and a set of modal frequencies f_p as well as constants a_p and b_p, which depend on initial conditions. (In fact, this is not quite true: for such a representation to hold, it is required, furthermore, that there is no degeneracy of the modal frequencies.)

For example, under Dirichlet conditions (19.3) at both ends of the domain, the series of modal functions and frequencies is given by

$$U_p(x) = \sin\left(\frac{\pi p x}{L}\right), \quad f_p = \frac{cp}{2L}, \quad p = 1, \ldots \tag{19.11}$$

and for Neumann conditions at both ends,

$$U_p(x) = \cos\left(\frac{\pi p x}{L}\right), \quad f_p = \frac{cp}{2L}, \quad p = 0, \ldots\,. \tag{19.12}$$

For Neumann conditions, note that there is an *extra* modal shape when $p = 0$, corresponding to zero-frequency or DC rigid body motion – in terms of a string, for example, when both boundaries are free to move, the string may drift away. This is clearly ruled out under fixed or Dirichlet conditions.

Figure 19.2 shows the frequency response of a string under Dirichlet conditions, and illustrates the equally spaced set of frequency components.

19.1.2 A Grid and Difference Operators

The first step in the construction of a numerical scheme simulating (19.1) is the definition of a grid function u_l^n, representing an approximation to $u(x,t)$ at time instants $t = nk$, for integer $n = 0, \ldots$, and $x = lh$ for integer $l \in d$, for some subset of the integers $d \subset \mathbb{Z}$. Here, k is the time step (and $F_s = 1/k$ is the sample rate in acoustics and audio applications, usually set a priori), and h is the grid spacing. For a grid corresponding to the interval $\mathcal{D}_L$, of length L, the finite discrete domain $d = d_N$ may be defined as $d_N = \{0, \ldots, N\}$, for an integer N such that $h = L/N$. For analysis purposes, the infinite set of grid points $d = \mathbb{Z}$ is also useful. See Fig. 19.3 for a representation of this particular 1-D grid. As will be seen shortly, once a finite-difference scheme is introduced, the grid spacing h and time step k cannot in general be chosen independently!

A useful device in the construction and analysis of finite-difference schemes is the difference operator; such operators can be used in order to represent even relatively complex schemes in a compact manner. Time difference operators can be defined as

$$\begin{aligned}
\delta_{t+} u_l^n &= \frac{1}{k}\left(u_l^{n+1} - u_l^n\right) \\
\delta_{t-} u_l^n &= \frac{1}{k}\left(u_l^n - u_l^{n-1}\right) \\
\delta_{t\cdot} u_l^n &= \frac{1}{2k}\left(u_l^{n+1} - u_l^{n-1}\right).
\end{aligned} \tag{19.13}$$

All are approximations to a first time derivative at time $t = nk$; they are often referred to as forward, backward and centered first difference operators respectively. A second difference operator, approximating a second time derivative, is defined as

$$\begin{aligned}
\delta_{tt} &= \delta_{t+}\delta_{t-} \\
\Rightarrow \delta_{tt} u_l^n &= \frac{1}{k^2}\left(u_l^{n+1} - 2u_l^n + u_l^{n-1}\right).
\end{aligned} \tag{19.14}$$

Similarly, spatial operators may be defined as

$$\begin{aligned}
\delta_{x+} u_l^n &= \frac{1}{h}\left(u_{l+1}^n - u_l^n\right) \\
\delta_{x-} u_l^n &= \frac{1}{h}\left(u_l^n - u_{l-1}^n\right) \\
\delta_{x\cdot} u_l^n &= \frac{1}{2h}\left(u_{l+1}^n - u_{l-1}^n\right)
\end{aligned} \tag{19.15}$$

and

$$\begin{aligned}
\delta_{xx} &= \delta_{x+}\delta_{x-} \\
\Rightarrow \delta_{xx} u_l^n &= \frac{1}{h^2}\left(u_{l+1}^n - 2u_l^n + u_{l-1}^n\right),
\end{aligned} \tag{19.16}$$

which are approximations to first and second spatial derivatives. Notice here that for a grid function u_l^n

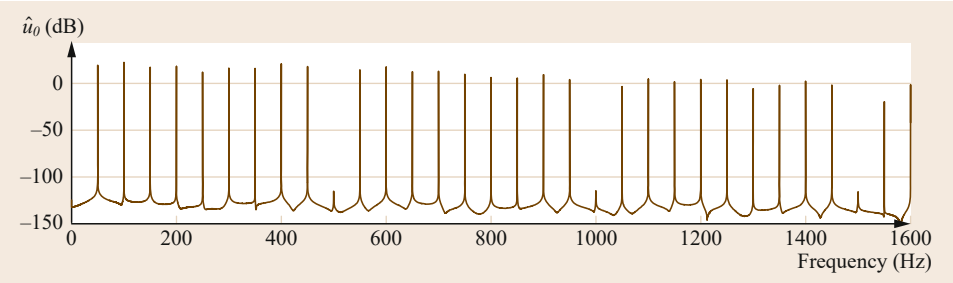

Fig. 19.2 Frequency response of the string described in the caption to Fig. 19.1, obtained by taking the Fourier transform $\hat{u}_o$ of the string displacement at a given grid location (here, approximately 1/5 of the way along the string). Here the string has been initialized with a raised cosine distribution, centered at approximately 0.3 of the length of the string. Note that the response exhibits peaks that are at integer multiples of the string fundamental, which in this case is 50 Hz

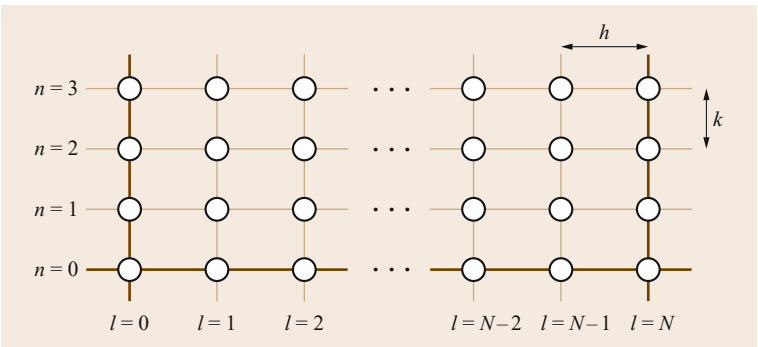

Fig. 19.3 A 1-D grid, with time step k and grid spacing h, represented for $n \geq 0$, and for $l \in d_N = \{0, \ldots, N\}$

defined for $l = 0 \ldots, N$, then at some locations these operators refer to grid points beyond the grid definition – for example, $\delta_{x-} u_0^n = \left(u_0^n - u_{-1}^n\right)/h$. In this case, one will ultimately need a means of relating the value u_{-1}^n at the *ghost* location $l = -1$ back to the domain interior – such a relation comes from an appropriate boundary condition, as will be discussed shortly.

19.1.3 A Simple Finite-Difference Scheme

Consider now the following approximation to the 1-D wave equation (19.1), obtained by approximating the second derivatives ∂_t^2 and ∂_x^2 by δ_{tt} and δ_{xx} respectively.

$$\delta_{tt} u_l^n = c^2 \delta_{xx} u_l^n \tag{19.17}$$

This is certainly the simplest possible scheme for the 1-D wave equation. When the actions of the difference operators are expanded out in full, the scheme may be written as

$$u_l^{n+1} = 2u_l^n - u_l^{n-1} + \lambda^2 \left(u_{l+1}^n - 2u_l^n + u_{l-1}^n\right) \quad \text{where } \lambda = \frac{ck}{h} . \tag{19.18}$$

This is a two-step update: the value u_l^{n+1} may be computed from previously calculated values of the grid function at time steps n and $n-1$. Furthermore, it is explicit: each unknown value of the grid function at time step $n+1$ may be calculated independently of others at the same time step. The scheme as a whole is written in terms of a single dimensionless parameter λ, which is referred to as the Courant number for the scheme.

von Neumann Analysis and Stability

A standard approach to the analysis of stability for finite-difference schemes is a frequency domain method sometimes referred to as von Neumann analysis [19.20]. In general, it yields necessary conditions for stability, and does not directly take into account boundary conditions – it may be viewed as examining the stability of a scheme over the interior of the domain, or, alternatively, when the grid is infinite.

The analysis proceeds much as in the case of dispersion analysis for the continuous problem in Sect. 19.1. Consider now the finite-difference scheme given in the previous section, defined over the infinite grid $d = \mathbb{Z}$. Now, examine the behavior of a test solution of the form

$$u_l^n = z^n \mathrm{e}^{j\beta lh} \quad \text{where} \quad z = \mathrm{e}^{sk} \tag{19.19}$$

for a real wavenumber β and a complex frequency s. Notice that when $s = j\omega$, the solution above is a sampled form of the wavelike solution given in (19.7), at $t = nk$ and $x = lh$. The complex frequency s is introduced here, as the solutions to the difference scheme (19.17) are not necessarily purely oscillatory and may exhibit exponential decay or growth – precisely when the scheme is unstable!

Inserting this solution into the definition (19.17) of the scheme leads to the following characteristic equation relating z and β

$$z + \left(-2 + 4\lambda^2 \sin^2\left(\frac{\beta h}{2}\right)\right) + z^{-1} = 0\,. \qquad (19.20)$$

In order for the scheme to be stable, the solutions must satisfy $|z| \le 1$, for all β. This will be true under the following condition on λ

$$\lambda \le 1 \;\Rightarrow\; h \ge h_{\min} = ck$$
$$\text{(Courant–Friedrichs–Lewy)}\,. \qquad (19.21)$$

If this condition is not respected, then the computed solution will be numerically unstable – this behavior is exhibited as an explosive growth in amplitude of the highest wavenumbers supported by the grid. See Fig. 19.4 for an illustration of such numerical instability, with a value of $\lambda > 1$. Such explosive growth of high frequencies or wavenumbers is typical of instability not just in the case of the wave equation, but for virtually any system in musical acoustics. The condition above, at least in this simple case of the 1-D wave equation, has a nice geometrical interpretation when rewritten as $h \ge ck$: the spacing h between adjacent grid points must be large enough to *track* waves that will have traveled a distance ck in one time step! This argument, due to Courant, is to be viewed as a heuristic in the case of explicit schemes, but is a powerful one indeed.

Numerical Dispersion and Mode Detuning

The characteristic equation (19.20), beyond yielding a stability condition, also indicates something more about the way in which waves propagate in the finite-difference scheme. Under the stability condition (19.21), it is in fact true that not only is $|z| \le 1$, but in fact $|z| = 1$. This means that solutions, when the scheme is stable, are purely oscillatory, and one may write $z = e^{j\omega k}$. The characteristic equation may then be written as

$$\sin^2\left(\frac{\omega k}{2}\right) = \lambda^2 \sin^2\left(\frac{\beta h}{2}\right)$$
$$\Longrightarrow \omega = \pm\frac{2}{k}\sin^{-1}\left(\lambda \sin\left(\frac{\beta h}{2}\right)\right)\,. \qquad (19.22)$$

Notice that this relationship is not the same as that for the continuous problem from (19.8), and consequently the phase velocity given by $v_{\text{phase}} = \omega/\beta$ is not equal to c! In short, wave speed is now frequency dependent. This characteristic is sometimes referred to as numerical dispersion, leading to progressive decoherence of traveling waves, and also to the detuning of modal frequencies; see Fig. 19.5. As illustrated in the figure, the effect becomes progressively worse as λ is decreased away from its limiting value at $\lambda = 1$, and thus it is a good idea to choose h, for a given k, as close to the bound as possible. An interesting, but pathological feature here is that when $\lambda = 1$, the scheme produces an exact solution – a great rarity for a numerical method, and one that has been exploited to great effect in the development of digital waveguide methods [19.19]. For virtually all other systems in musical acoustics, such an exact numerical solution is not available.

Another useful piece of information that the numerical dispersion relation (19.22) provides is a numerical cutoff frequency f_c, which is, in Hz,

$$f \le f_c = \frac{1}{\pi k}\sin^{-1}(\lambda)\,. \qquad (19.23)$$

Notice that the cutoff is below half the sample rate $F_s = 1/k$ – and in fact, substantially so when λ is far

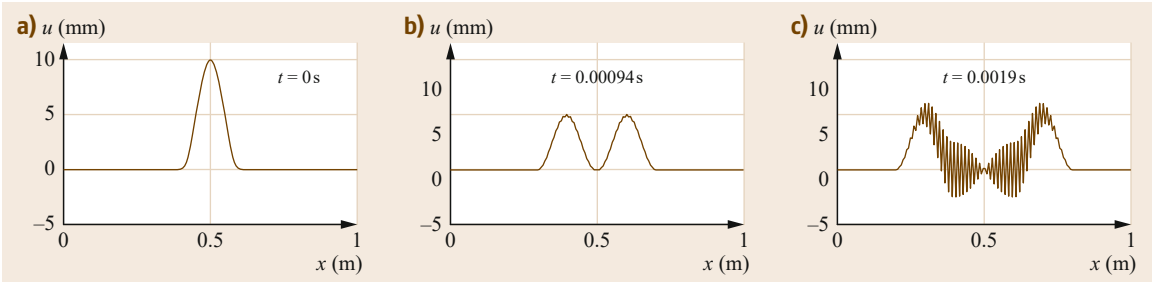

Fig. 19.4a–c Time evolution of a string profile, under conditions as given in the caption to Fig. 19.1, using the simple finite difference scheme, operating at 16 kHz, and with $\lambda = 1.00625$, leading to numerical instability

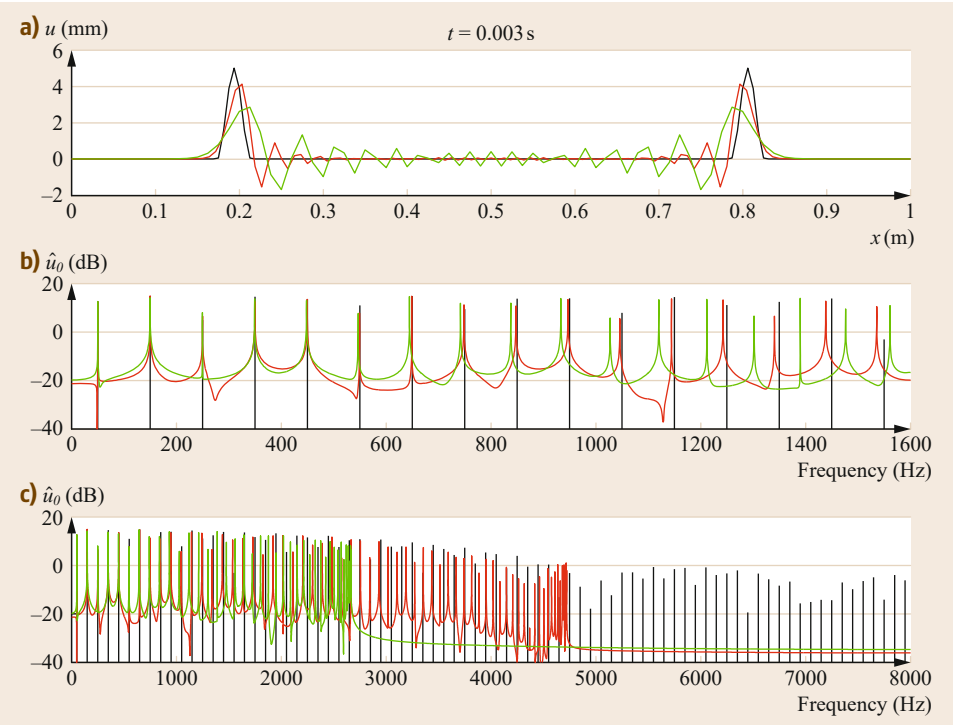

Fig. 19.5a–c Simulation results, for the string of parameters as given in the caption to Fig. 19.1, using scheme (19.17) with different values of the Courant number λ: $\lambda = 1$ (*black*), $\lambda = 0.8$ (*red*), and $\lambda = 0.5$ (*green*). **(a)** Dispersion effects in traveling waves. **(b)** Mode detuning. **(c)** Bandwidth limitation effects

from the limiting value of $\lambda = 1$. This is another good reason for choosing λ as close to the bound as possible – so as not to impose a bandwidth limitation on the scheme, as is easily observed in Fig. 19.5.

Numerical Boundary Conditions

Up to this point, only the case of the wave equation defined over an infinite domain has been treated. In practice, however, one must necessarily work with finite domains such as the $N+1$ point interval $d = d_N = \{0 \ldots, N\}$, where it is to be recalled that $h = L/N$. Now, one is faced with terminating the scheme (19.17) at the endpoints $l = 0$ and $l = N$, requiring the imposition of numerical boundary conditions.

Consider first the Dirichlet type condition for the 1-D wave equation given in (19.3), at the left end point at $x = 0$. In the scheme, this corresponds to the grid location at $l = 0$, and thus the obvious condition to set is

$$u_0^n = 0 \qquad (19.24)$$

permanently for all n, and similarly at the other endpoint at $l = N$. Thus the scheme (19.17) need only be updated at the locations $l = 1, \ldots, N-1$.

Slightly less trivial is the case of a Neumann-type condition, as given in (19.3), again, say, at the left endpoint at $l = 0$. In order to be updated at grid location $l = 0$, the scheme (19.17) requires a value at $l = -1$, which is not part of the grid interior! There are various ways of discretizing the Neumann condition. Two examples are

$$\begin{aligned} u_{-1}^n &= u_0^n \quad \text{(non-centered)} \\ u_{-1}^n &= u_1^n \quad \text{(centered)} \,. \end{aligned} \qquad (19.25)$$

The scheme update (19.17) becomes, at the grid location $l = 0$

$$u_0^{n+1} = 2u_0^n - u_0^{n-1} + \lambda^2 \left(u_1^n - u_0^n\right) \quad \text{(non-centered)} \qquad (19.26)$$

$$u_0^{n+1} = 2u_0^n - u_0^{n-1} + 2\lambda^2 \left(u_1^n - u_0^n\right) \quad \text{(centered)} \,. \qquad (19.27)$$

Both are viable numerical boundary conditions approximating the Neumann condition, and a similar condition may be applied, by symmetry, at the right end grid point at $l = N$ – the conditions are also distinct, meaning that computed solutions will be slightly different. In fact, the centered condition turns out to be a little more accurate.

These boundary conditions are simple – and indeed, all the boundary conditions given here lead to stable numerical solutions. In more involved settings however,

showing stability under a particular choice of numerical boundary condition can become far from trivial. von Neumann analysis may be extended, in the 1-D case, to handle numerical boundary conditions through the theory due to Gustafsson, Kreiss, Sundstrom and Osher (GKSO), which is explained in detail in the book by *Strikwerda* [19.20]. In more general settings in higher dimensions, where geometrical irregularities of the domain may play a role, then other techniques such as the energy method (not discussed in this chapter due to space considerations) are far more powerful. See, e.g., [19.21], and also [19.17].

Vector–Matrix Representation

Now that the scheme has been defined over a finite domain, it is perhaps worth spending some time describing the implementation of such a scheme. A very useful and compact way of representing finite difference schemes such as (19.17) is in a vector-matrix form. To this end, one should consolidate all the values of the grid function u_l^n at time step n that need to be updated into a column vector $\boldsymbol{u}^n$. In the case of Dirichlet conditions at both ends of the domain, the vector will have $N-1$ elements

$$\boldsymbol{u}^n = \left[u_1^n, \ldots, u_{N-1}^n\right]^{\mathrm{T}} .$$

For Neumann conditions at both ends of domain, the vector will contain $N+1$ elements

$$\boldsymbol{u}^n = \left[u_0^n, \ldots, u_N^n\right]^{\mathrm{T}} .$$

The difference operator δ_{xx} acting on the grid function u_l^n can clearly be represented as a square matrix $\mathbf{D}_{xx}$ when applied to the vector $\boldsymbol{u}^n$. Its form, however, depends on the numerical boundary conditions that have been chosen, which alter values in the extreme rows and columns of the matrix representation. Here are three distinct representations of $\mathbf{D}_{xx}$

$$\underbrace{\frac{1}{h^2}\begin{bmatrix} -2 & 1 & & & \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \\ & & & 1 & -2 \end{bmatrix}}_{\text{Dirichlet}}$$

$$\underbrace{\frac{1}{h^2}\begin{bmatrix} -1 & 1 & & & \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \\ & & & 1 & -1 \end{bmatrix}}_{\text{non-centered Neumann}}$$

$$\underbrace{\frac{1}{h^2}\begin{bmatrix} -2 & 2 & & & \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \\ & & & 2 & -2 \end{bmatrix}}_{\text{centered Neumann}} . \qquad (19.28)$$

The matrix corresponding to Dirichlet conditions is of size $(N-1)\times(N-1)$, and those corresponding to Neumann conditions are of size $(N+1)\times(N+1)$.

Regardless of the form of the difference matrix $\mathbf{D}_{xx}$, however, the scheme (19.17) may be written in vector-matrix update form as

$$\begin{aligned} \boldsymbol{u}^{n+1} &= \mathbf{B}\boldsymbol{u}^n - \boldsymbol{u}^{n-1} \\ \mathbf{B} &= 2\mathbf{I} + c^2k^2\mathbf{D}_{xx} , \end{aligned} \qquad (19.29)$$

where $\mathbf{I}$ is an identity matrix of the size of $\mathbf{D}_{xx}$. The update matrix $\mathbf{B}$ can be computed before entering into the runtime loop – furthermore, it is very sparse, with $O(N)$ nonzero entries.

19.2 The Ideal Bar Equation

The 1-D wave equation is very much an idealization – in the case of a string for example, it describes linear, lossless wave propagation and an assumption is that the material making up the string has no inherent stiffness, so that the restoring force is purely due to tensioning.

The opposite case, in which there is no tension in the medium, but a large stiffness, leads to models of metal bars, which are a starting point for models of musical instrument components such as xylophone or marimba bars. In the simplest case of a uniform, lossless and untensioned bar, and assuming that the bar is thin (relative to its length), transverse vibrations may be described by the ideal bar equation

$$\partial_t^2 u = -\kappa^2 \partial_x^4 u . \qquad (19.30)$$

Notice now that the PDE remains second-order in time, but is fourth-order in the spatial variable. The constant

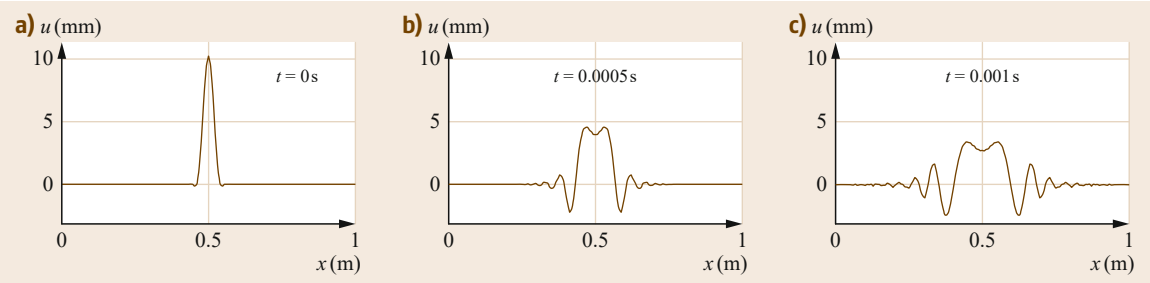

Fig. 19.6a–c Snapshots of the time evolution of the profile of a vibrating bar, at times as indicated. Here, the bar is of length $L = 1$, with $\kappa = 1\,\mathrm{m}^2/\mathrm{s}$, and is initialized with a raised cosine distribution

κ is defined by

$$\kappa = \sqrt{\frac{EI}{\rho}}\,, \tag{19.31}$$

where E is Young's modulus in Pa, ρ is again the linear mass density of the bar in kg/m, and I is the moment of inertia of the bar in m^4, which depends on the geometry of the cross-section. For a bar of circular cross-section and radius r, $I = \pi r^4/4$. Thin bar models have been shown to be more than sufficient for virtually all cases of interest in musical acoustics [19.22].

19.2.1 Solution Characteristics: Ideal Bar Equation

The ideal bar equation requires, as before, two initial conditions, of the form of (19.2). However, if the bar is defined over a finite interval such as $\mathcal{D}_L$, two boundary conditions are required at each endpoint. Examining the left endpoint at $x = 0$, here three sets that are of interest are

$$\begin{aligned} u = \partial_x u = 0 \quad &\text{(Clamped)} \\ u = \partial_x^2 u = 0 \quad &\text{(Pivoting)} \\ \partial_x^2 u = \partial_x^3 u = 0 \quad &\text{(Free)}\,. \end{aligned} \tag{19.32}$$

Solution Characteristics

In contrast to the case of the 1-D wave equation, the ideal bar equation does not possess wave solutions that travel without distortion. Indeed, wave propagation is highly dispersive, as can be seen from the dispersion relation in this case, which is, again examining wavelike solutions of the form of (19.7)

$$\omega = \pm\kappa\beta^2 \quad \Rightarrow \quad v_{\mathrm{phase}} = \kappa\beta = \sqrt{\kappa\omega}\,. \tag{19.33}$$

Here, wave speed is dependent on frequency, with higher frequencies traveling faster than lower frequencies. Figure 19.6 illustrates dispersion in a vibrating bar subject to an initial fixed distribution.

The modal frequencies of the bar are dependent on the boundary conditions in a nontrivial way – in general, they are not available in closed form. Under the pivoting conditions given in (19.32), however, they are available as

$$f_p = \frac{\kappa\pi p^2}{2L^2} \quad \text{for} \quad p = 1, \ldots\,. \tag{19.34}$$

Notice that they are not equally spaced, as in the case of the 1-D wave equation, but become more sparse with increasing frequency – this feature leads (perhaps counterintuitively) to decreases in computational cost for stiff systems in comparison with nonstiff systems; see Fig. 19.7.

19.2.2 Finite-Difference Schemes

Suppose again, for the moment, that the bar is defined over $\mathcal{D} = \mathbb{R}$, so that a corresponding difference scheme will be defined over $d = \mathbb{Z}$, again using a grid function u_l^n.

As before, the operator ∂_t^2 may be approximated by a second time difference operator δ_{tt}. For the fourth spatial derivative ∂_x^4, one may use the operator product $\delta_{xx}\delta_{xx}$, which behaves as

$$\delta_{xx}\delta_{xx}u_l^n = \frac{1}{h^4}\left(u_{l+2}^n - 4u_{l+1}^n + 6u_l^n - 4u_{l-1}^n + u_{l-2}^n\right). \tag{19.35}$$

Under these substitutions, the following scheme results

$$\delta_{tt}u_l^n = -\kappa^2\delta_{xx}\delta_{xx}u_l^n\,. \tag{19.36}$$

When the actions of the difference operators are expanded out in full, the scheme may be written as

$$\begin{aligned} u_l^{n+1} &= 2u_l^n - u_l^{n-1} \\ &\quad - \mu^2\left(u_{l+2}^n - 4u_{l+1}^n + 6u_l^n - 4u_{l-1}^n + u_{l-2}^n\right) \\ \mu &= \frac{\kappa k}{h^2}\,. \end{aligned} \tag{19.37}$$

This scheme is of a different character than (19.17) for the 1-D wave equation, in that updating at a given grid point requires access to values at neighboring grid points up to two grid spacings away; see Fig. 19.8. As one might expect, this has ramifications in terms of setting boundary conditions, but note that the ideal bar equation, as it is fourth-order in space, requires two boundary conditions at each end of the domain. The scheme is dependent on a sole parameter μ, which plays a similar role to that of the Courant number in scheme (19.17) for the wave equation, and particularly in terms of numerical stability!

Frequency Domain Analysis: Stability and Dispersion

Numerical stability analysis may be carried out in a manner similar to the case of the 1-D wave equation. Again examining discrete wavelike solutions of the form of (19.19), the characteristic equation in terms of z and β is now

$$z + \left(-2 + 16\mu^2 \sin^4\left(\frac{\beta h}{2}\right)\right) + z^{-1} = 0\,. \quad (19.38)$$

The solutions $z(\beta)$ are bounded by unity in magnitude under the condition

$$\mu \leq \frac{1}{2} \quad \Rightarrow \quad h \geq h_{\min} = \sqrt{2\kappa k}\,. \quad (19.39)$$

Note that the dependence of the grid spacing on the time step is now with the square root; the implication is that, as the sample rate is increased, the density of grid points increases much more weakly than in the case of the wave equation. This fact dovetails nicely with the notion, discussed earlier, of a reduced density of modes for increasing frequency, as illustrated in Fig. 19.7.

As in the case of the scheme for the 1-D wave equation, under stable conditions (given by (19.39)) one may again derive a numerical relation between frequency ω and wavenumber β which, in this case, is

$$\omega = \frac{2}{k} \sin^{-1}\left(2\mu \sin^2\left(\frac{\beta h}{2}\right)\right). \quad (19.40)$$

It is interesting to plot the numerical phase velocity in this case against that of the ideal bar equation itself, as shown at right in Fig. 19.8. The numerical phase velocity is too slow, and increasingly so at higher frequencies, by more than 30%! This means that, particularly for higher frequencies, modal frequencies will be underapproximated. These plots show dispersion error over the range of wavenumbers supported by the grid. One approach to obtain better accuracy is then to decrease the grid spacing, along with the time step, according to the stability condition for the scheme. But this entails operation at a higher sample rate, and can thus be a costly undertaking. More refined implicit designs can do a better job; see the end of Sect. 19.2 for a simple example.

Vector–Matrix Update Form

As in the case of schemes for the wave equation, scheme (19.36) may be written in a vector-matrix update form in the vector $\boldsymbol{u}^n$, again a column vector containing the values of the grid function u_l^n at time step n. Boundary termination is not discussed here, but as in the case of the scheme for the wave equation, values near the boundary may be omitted depending on the choice of numerical boundary condition. In all cases, however, the scheme may be written as

$$\begin{aligned} \boldsymbol{u}^{n+1} &= \mathbf{B}\boldsymbol{u}^n - \boldsymbol{u}^{n-1} \\ \mathbf{B} &= 2\mathbf{I} - \kappa^2 k^2 \mathbf{D}_{xxxx}\,, \end{aligned} \quad (19.41)$$

where $\mathbf{I}$ is an identity matrix, and where $\mathbf{D}_{xxxx}$ is the square matrix representation of the operator $\delta_{xx}\delta_{xx}$, including numerical boundary conditions.

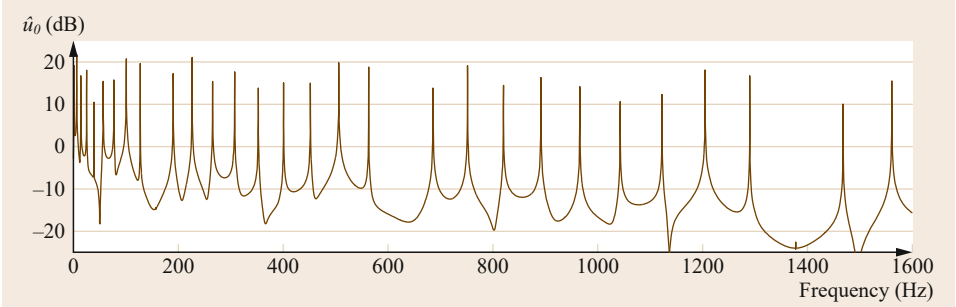

Fig. 19.7 Frequency response of the bar described in the caption to Fig. 19.6, obtained by taking the Fourier transform $\hat{u}_o$ of the bar displacement at a given grid location (here, approximately 0.2 of the way along the bar). Here the bar has been initialized with a raised cosine distribution, centered at approximately 0.3 of the length of the bar. Note the increasing spacing of modes with frequency

Implicit Schemes

The scheme presented above is what is referred to as explicit – values of the grid function u_l^n at time step $n+1$ may be calculated directly from values at time steps n and $n-1$. An interesting variation of this scheme is the implicit case. Consider the following family of schemes, dependent on the free parameter α

$$\delta_{tt}\left(1+\alpha h^2\delta_{xx}\right)u_l^n = -\kappa^2\delta_{xx}\delta_{xx}u_l^n\,. \tag{19.42}$$

There is now a new term, involving an operation $\delta_{xx}\delta_{tt}$ – notice that because the extra term is scaled by h^2, its effect disappears in the limit of small h or small k. (This notion is referred to as *consistency* with the underlying PDE in the numerical analysis literature [19.20].) The scheme reduces to the explicit scheme when $\alpha = 0$.

Why include this extra term? Indeed, it appears to greatly complicate the update, which is now of the form

$$\begin{aligned}\alpha\left(u_{l+1}^{n+1}+u_{l-1}^{n+1}\right)+(1-2\alpha)u_l^{n+1}\\ =2\alpha\left(u_{l+1}^{n}+u_{l-1}^{n}\right)+(2-4\alpha)u_l^{n}\\ -\alpha\left(u_{l-1}^{n-1}+u_{l+1}^{n-1}\right)-(1-2\alpha)u_l^{n-1}\\ -\mu^2\left(u_{l+2}^{n}-4u_{l+1}^{n}+6u_l^{n}-4u_{l-1}^{n}+u_{l-2}^{n}\right),\end{aligned}$$

so that the unknown values of the grid function to be updated at time step $n+1$ are coupled, and cannot be independently updated; see Fig. 19.9. Furthermore, the stability condition is now altered to

$$\mu \le \frac{\sqrt{1-4\alpha}}{2} \quad \text{and} \quad \alpha \le \frac{1}{4}\,. \tag{19.43}$$

Now, the numerical dispersion relation is given by

$$\omega = \frac{2}{k}\sin^{-1}\left(\frac{2\mu\sin^2\left(\frac{\beta h}{2}\right)}{1-4\alpha\sin^2\left(\frac{\beta h}{2}\right)}\right) \tag{19.44}$$

and depends on α – and strongly as it turns out. Now there is some design flexibility, and one may attempt to optimize the numerical phase velocity of the scheme to match that of the ideal bar equation. The results can be very good indeed – see Fig. 19.9, showing numerical phase velocity and percent error for various choices of the free parameter α, and where μ is chosen at the stability limit given by (19.43). For the special choice of $\alpha = 1/4 - 1/\pi^2 \approxeq 0.1487$, the scheme has a phase velocity error of under 1% over the entire range of wavenumbers. It is probable that such a scheme can be used, without perceptual artifacts, even at a standard audio rate.

The downside of such implicit methods is, of course, that they require more computational work.

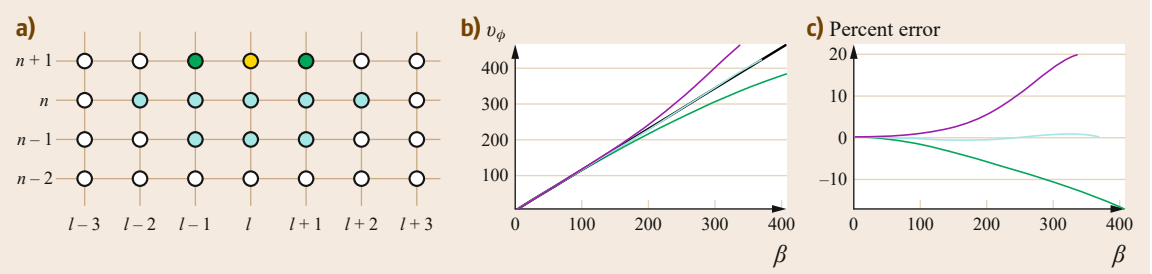

Fig. 19.9 **(a)** Computational grid for scheme (19.42) for the ideal bar equation, with the update point indicated in *yellow*, and dependency region in *cyan* (known values) and *green* (as yet unknown values). **(b)** Phase velocity for the ideal bar, with $\kappa = 1$, in *black*, and numerical phase velocity for scheme (19.42), with $\mu = 1/2$, plotted against wavenumber, for $\alpha = 0.1$ (*green*), $\alpha = 0.1487$ (*cyan*) and $\alpha = 0.18$ (*magenta*). **(c)** Percent error in phase velocity for the three choices of α

Consider the vector-matrix update form which, in contrast with (19.41), is now

$$\mathbf{A}\boldsymbol{u}^{n+1} = \mathbf{B}\boldsymbol{u}^{n} - \mathbf{A}\boldsymbol{u}^{n-1}$$
$$\mathbf{B} = 2\mathbf{A} - \kappa^2 k^2 \mathbf{D}_{xxxx}, \quad \mathbf{A} = \mathbf{I} + \alpha h^2 \mathbf{D}_{xx}\,, \tag{19.45}$$

where $\mathbf{D}_{xx}$ is an approximation to δ_{xx}, including boundary conditions, and is tridiagonal in this case. Thus, the scheme requires the solution of a linear system at each time step. There are many methods for performing such an operation – in this case, if $\mathbf{A}$ is diagonally dominant, a simple method such as Jacobi iteration [19.20] may be employed. A full analysis of the utility of implicit methods must then weigh increased accuracy against the cost of performing such linear system solutions – a typical trade-off in numerical method design.

19.3 Acoustic Tubes

So far in this chapter only spatially uniform systems, such as the 1-D wave equation and the ideal bar equation, have been considered – but there are various musical instrument components for which this not the case. The resonating components of wind instruments (woodwind and brass) and the human voice are characterized as volumes of air enclosed within a duct, or acoustic tube, and are indeed of variable cross-section [19.23]. Such instruments can often be of a complex form, incorporating bends of tubing present in, e.g., a trumpet. For applications in musical acoustics, the geometry can usually be simplified to that of a straight tube, aligned with a spatial coordinate x, and with axially symmetric cross-section $S(x)$, such as that presented in Fig. 19.10. These models are derived under the assumption that the wavelengths of interest are larger than the tube radius – which is true in most brass instruments, except in those with a very wide bell flare.

For lossless, small-amplitude wave propagation in a duct for which wavelengths are significantly larger than the radius, the dynamics of an acoustic tube can be described by *Webster*'s equation [19.24]

$$S\partial_t^2 \Psi = c^2 \partial_x (S \partial_x \Psi)\,, \tag{19.46}$$

where $\Psi(x,t)$ is often called the *acoustic potential* or *velocity potential* [19.18] and is related to the deviation of air pressure from atmospheric $p(x,t)$ and particle velocity $v(x,t)$ by

$$p = \rho \partial_t \Psi, \quad v = -\partial_x \Psi\,. \tag{19.47}$$

These definitions can be used to relate the second-order form of Webster's equation (19.46) to the first-order form (19.5) presented earlier in the case of a cylinder.

Equation (19.46) describes one-parameter waves on isophase surfaces within the tube; it is assumed that its value is constant across the tube area at position x along the tube. In the case of a cylindrical tube, where the tube cross-section is a constant, Webster's equation reduces to the 1-D wave equation. It can also be shown that for a cone described in spherical coordinates, Webster's equation reduces again to the 1-D wave equation.

Due to the spatially varying nature of the system, dispersion analysis cannot be carried out in the same manner as for the 1-D wave equation and the ideal bar equation – the main reason being that a decomposition of the solution into uniform traveling wave components is not very revealing! However, the effects of dispersion can be observed, locally, in the system. See Fig. 19.11 for an example of back-scattering of a wave approaching a constriction inside an acoustic tube.

In this section, Webster's equation is assumed defined for $t \in \mathbb{R}^+$, and $x \in \mathcal{D}_L = [0\,, L]$. As in the case of the 1-D wave equation, one boundary condition is required at each end of the domain.

The simplest realistic boundary conditions for this system are when an end is either open ($p = 0$) or closed ($v = 0$)

$$\partial_t \Psi = 0 \quad \text{(Open)}$$
$$\partial_x \Psi = 0 \quad \text{(Closed)}\,, \tag{19.48}$$

where the open end corresponds to a Dirichlet boundary condition and the closed end to a Neumann boundary

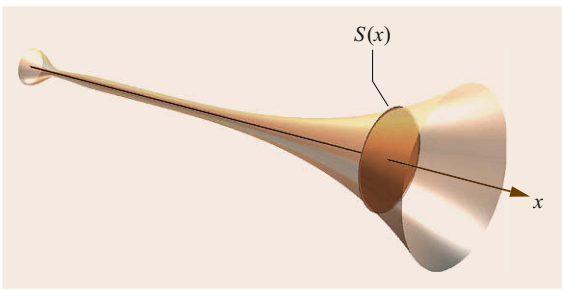

Fig. 19.10 Example of a bore with variable cross-sectional area along its length

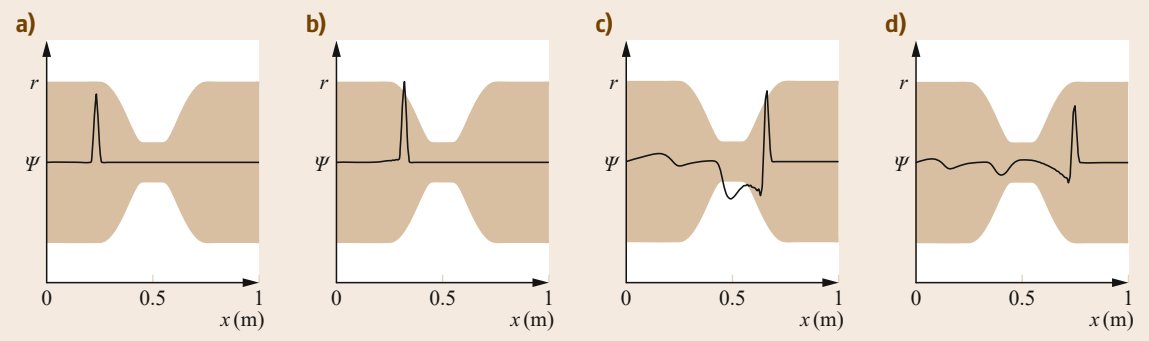

Fig. 19.11a–d Propagation of a pulse through an acoustic tube with a constriction at its center. The wave propagates from left to right and is shown in *black*. The *brown* region shows the tube profile radius $r(x) = \sqrt{S(x)/\pi}$. As the wave encounters the constriction, back-scattering of low frequencies can be seen as disturbances traveling in the opposite direction to that of the impinging wave

condition. Both of these boundary conditions are lossless – the total energy of the system is unchanged upon reflection at the boundaries. In realistic wind instrument modeling more complex boundary conditions are required, in particular at the radiating end where losses due to acoustic radiation must be modeled, and at the mouthpiece where complex coupling to an active device (the player's lips or a reed mechanism, driven by an input pressure) must be modeled as well.

19.3.1 Finite-Difference Schemes

It is rather straightforward to arrive at a finite-difference scheme simulating Webster's equation – note that as the system is not spatially uniform, it is to be expected that this feature will be carried over to the resulting scheme, so that the scheme parameters themselves vary from one grid point to the next. The simplest possible scheme, operating over d_N, is almost certainly

$$\bar{S}_l \delta_{tt} \Psi_l^n = c^2 \delta_{x+} \left(S_{l-1/2} \left(\delta_{x-} \Psi_l^n \right) \right) , \tag{19.49}$$

where δ_{tt}, δ_{x+} and δ_{x-} are the second-order time and first-order forward and backward spatial difference operators defined in Sect. 19.1.2. The scheme is dependent on two fixed grid functions S and $\bar{S}$, which approximate the tube cross-sectional area at interleaved locations. $S_{l-1/2}$ is assumed given, and perhaps sampled from an exact bore profile, $S(x)$, at positions $x = (l-1/2)h$. $\bar{S}_l$ is assumed averaged from the bore cross-sectional area

$$\bar{S}_l = \frac{S_{l+1/2} + S_{l-1/2}}{2} . \tag{19.50}$$

The update form of (19.49) is

$$\Psi_l^{n+1} = \frac{\lambda^2 S_{l+1/2}}{\bar{S}_l} \Psi_{l+1}^n + \frac{\lambda^2 S_{l-1/2}}{\bar{S}_l} \Psi_{l-1}^n + 2(1-\lambda^2)\Psi_l^n - \Psi_l^{n-1} , \tag{19.51}$$

where $\lambda = ck/h$ is again the Courant number for the scheme. Figure 19.12 shows the scheme update and the discretization locations of $S_{l+1/2}$ and $\bar{S}_l$. Due to the

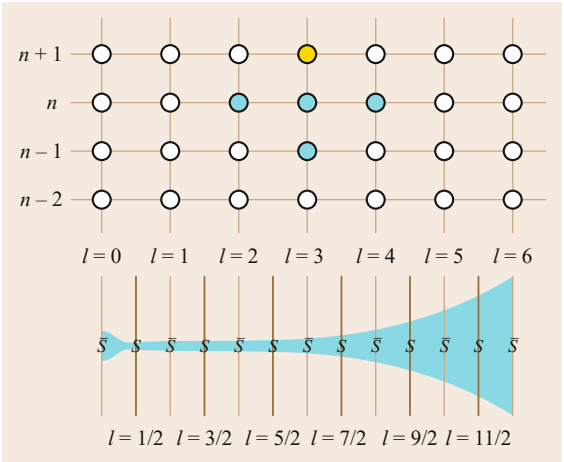

Fig. 19.12 *Top*: Computational grid and stencil for scheme (19.49), with current point in *yellow*, and dependency region in *cyan*. *Horizontal lines* show the time grid at integer time steps, separated by a time step k. *Vertical lines* show the spatial grid at integer spatial steps, separated by a distance h. *Bottom*: acoustic tube cross-section in *cyan* overlaid on a spatial grid. *Solid vertical lines* indicate the spatial grid at half-integer steps, separated by a distance h. Note that the positions of $S_{l+1/2}$ are interleaved with the positions of $\bar{S}_l$

spatial variation of the cross-section in this model, von Neumann analysis cannot be applied to the scheme in order to prove stability. Energy methods may be used for the scheme to show that $\lambda \leq 1$ is again a stability condition [19.17] – such a simplified condition, which is independent of the bore profile, depends on the particular choice of $\bar{S}$ as averaged from S.

Considering boundary conditions at $x = 0$, a numerical open (Dirichlet) condition corresponding to the first of (19.48) may be given simply as

$$\Psi_0^n = 0 \tag{19.52}$$

and for a closed (Neumann) tube corresponding to the second of (19.48) as

$$\begin{aligned} \Psi_0^n &= \Psi_{-1}^n \quad \text{(non-centered)} \\ \Psi_1^n &= \Psi_{-1}^n \quad \text{(centered)} \,. \end{aligned} \tag{19.53}$$

Vector–Matrix Representation

The scheme (19.49) can be written in a vector-matrix form similar to that presented in the case of the 1-D wave equation and ideal bar equation. Gathering all values of the grid function Ψ_l^n into a column vector $\boldsymbol{\Psi}^n$, which has $N-1$ elements for a tube open at both ends: $\boldsymbol{\Psi}^n = [\Psi_1^n, \ldots, \Psi_{N-1}^n]^{\mathrm{T}}$, and $N+1$ elements for a tube closed at both ends: $\boldsymbol{\Psi}^n = [\Psi_0^n, \ldots, \Psi_N^n]^{\mathrm{T}}$, an update can be constructed that has a similar form to that of the scheme for the 1-D wave equation and 1-D bar equation

$$\begin{aligned} \boldsymbol{\Psi}^{n+1} &= \mathbf{B}\boldsymbol{\Psi}^n - \boldsymbol{\Psi}^{n-1} \,, \\ \mathbf{B} &= 2\mathbf{I} + c^2k^2\mathbf{C} \,, \end{aligned} \tag{19.54}$$

where $\mathbf{I}$ is again an identity matrix of the appropriate size. $\mathbf{C}$ is a square matrix that contains the effect of the variation of the bore profile in scheme (19.49). As examples, the forms of this matrix are given below under three different sets of boundary conditions

$$\underbrace{\frac{1}{h^2}\begin{bmatrix} -2 & \frac{S_{3/2}}{\bar{S}_1} & & & & & \\ \frac{S_{3/2}}{\bar{S}_2} & -2 & \frac{S_{5/2}}{\bar{S}_2} & & & & \\ & \ddots & \ddots & \ddots & & & \\ & & \frac{S_{l-1/2}}{\bar{S}_l} & -2 & \frac{S_{l+1/2}}{\bar{S}_l} & & \\ & & & \ddots & \ddots & \ddots & \\ & & & & \frac{S_{N-5/2}}{\bar{S}_{N-2}} & -2 & \frac{S_{N-3/2}}{\bar{S}_{N-2}} \\ & & & & & \frac{S_{N-3/2}}{\bar{S}_{N-1}} & -2 \end{bmatrix}}_{\text{open}}$$

$$\underbrace{\frac{1}{h^2}\begin{bmatrix} -1 & \frac{S_{1/2}}{\bar{S}_0} & & & & & \\ \frac{S_{1/2}}{\bar{S}_1} & -2 & \frac{S_{3/2}}{\bar{S}_1} & & & & \\ & \ddots & \ddots & \ddots & & & \\ & & \frac{S_{l-1/2}}{\bar{S}_l} & -2 & \frac{S_{l+1/2}}{\bar{S}_l} & & \\ & & & \ddots & \ddots & \ddots & \\ & & & & \frac{S_{N-3/2}}{\bar{S}_{N-1}} & -2 & \frac{S_{N-1/2}}{\bar{S}_{N-1}} \\ & & & & & \frac{S_{N-1/2}}{\bar{S}_N} & -1 \end{bmatrix}}_{\text{non-centered closed}}$$

$$\underbrace{\frac{1}{h^2}\begin{bmatrix} -2 & 2\frac{S_{1/2}}{\bar{S}_0} & & & & & \\ \frac{S_{1/2}}{\bar{S}_1} & -2 & \frac{S_{3/2}}{\bar{S}_1} & & & & \\ & \ddots & \ddots & \ddots & & & \\ & & \frac{S_{l-1/2}}{\bar{S}_l} & -2 & \frac{S_{l+1/2}}{\bar{S}_l} & & \\ & & & \ddots & \ddots & \ddots & \\ & & & & \frac{S_{N-3/2}}{\bar{S}_{N-1}} & -2 & \frac{S_{N-1/2}}{\bar{S}_{N-1}} \\ & & & & & 2\frac{S_{N-1/2}}{\bar{S}_N} & -2 \end{bmatrix}}_{\text{centered closed}} \,. \tag{19.55}$$

Input Impedance

In musical acoustics investigations, a wind instrument is often described in terms of its input impedance [19.25], which is a complete characterization of the behavior of the tube in the frequency domain. The peaks of the magnitude of the input impedance curve correspond to resonances, and in the case of musical instruments give an indication of playable notes. The input impedance is defined as

$$\hat{Z}(\omega)_{\mathrm{in}} = \frac{\hat{p}(0,\omega)}{S(0)\hat{v}(0,\omega)} \,, \tag{19.56}$$

where $\hat{v}(0,\omega)$ and $\hat{p}(0,\omega)$ are the Fourier transforms of the particle velocity and acoustic pressure at $x = 0$. $S(0)$ is the cross-sectional area of the acoustic tube opening and ω is angular frequency. To test the validity of a finite-difference scheme modeling an acoustic tube, it is useful to construct an equivalent method for measuring the input impedance of the numerical acoustic tube. Defining

$$\delta_x . \Psi_0^n = -v_{\mathrm{in}}^n \tag{19.57}$$

and substituting into (19.51) for $l = 0$ gives

$$\begin{aligned} \Psi_0^{n+1} = {} & 2\lambda^2\Psi_1^n + 2(1-\lambda^2)\Psi_0^n - \Psi_0^{n-1} \\ & + \frac{2h\lambda^2 S_{-1/2}}{\bar{S}_0} v_{\mathrm{in}}^n \,, \end{aligned} \tag{19.58}$$

which is a usable termination for the scheme. Setting v_{in} as an impulsive time series (i. e., a 1 followed by zeros), and taking the Fourier transform of $p_{in} = \rho\partial_t \Psi_0$ gives a numerical approximation to the input impedance of the tube. Figure 19.13 shows some representative bore and impedance plots.

19.3.2 Energy Losses and Nonlinear Propagation

Although finite-difference schemes including energy losses and nonlinear propagation are not presented in this chapter, it is worth highlighting some modifications that can be made to the model to include these effects.

Viscothermal Losses

Viscothermal losses account for the main source of energy loss within an acoustic tube. These losses occur in the viscous and thermal boundary layers that lie along the interior of the bore with the wave as it propagates along the tube. Although a 3-D effect this can still be modeled in 1-D by using an impedance, Z, and admittance, Y, description of the acoustic tube in the frequency domain

$$\begin{aligned} \partial_x \hat{p} &= -Z\hat{v} \\ \partial_x (S\hat{v}) &= -YS\hat{p}\,. \end{aligned} \tag{19.59}$$

The frequency domain expressions Z and Y require transformation to the time domain, and various approximations are available [19.26–31].

For a second-order form of wave propagation the Webster–Lokshin model has seen extensive applications in the modeling of acoustics tubes, particularly in waveguide methods [19.32, 33].

Nonlinear Wave Propagation

Nonlinearity of wave propagation is responsible for the cuivre, or *brassy*, sound generated by brass instruments when played at high dynamic levels. This is a result of the deformation of the wave shape as it propagates along the tube, which adds additional harmonics to the sound spectrum. To model this effect, a new set of nonlinear equations are required of which there are several to choose from [19.34].

The most fundamental nonlinear model is given by the Navier–Stokes equations. These equations give a full description of the fluid, including effects from viscosity and temperature. However, due to their complexity they prove difficult to solve. The Euler equations are a set of conservation equations concerning mass, momentum and energy; they are also subset of the Navier–Stokes equations neglecting viscosity and heat conduction terms. Burger's equations can also be derived from the Navier–Stokes equations and are written in terms of one variable, often velocity.

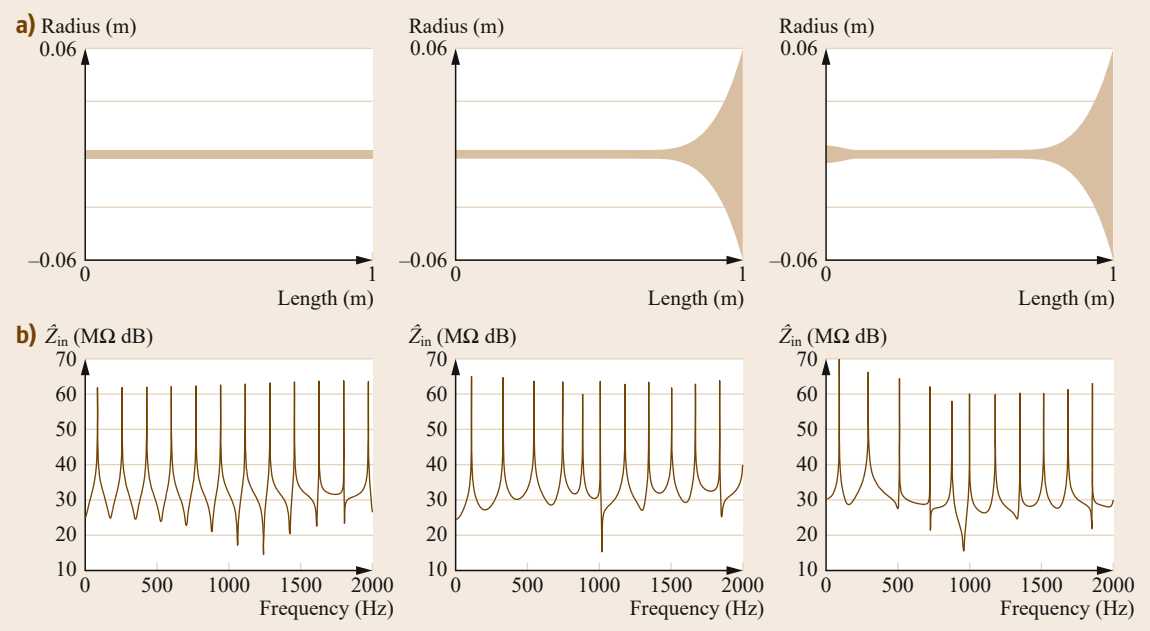

Fig. 19.13 **(a)** Selection of 1 m-long tube profiles. **(b)** Input impedance of the tubes with a closed end at $x = 0$ and an open end at $x = 1$. The tube is excited at $x = 0$ with an impulse and output is taken as the Fourier transform of $p_{in} = \rho\partial_t \Psi_0$. Simulations were run at a sample rate of 44.1 kHz and over a simulation time of 10 s with $c = 343$ m/s

All of the above models demonstrate the wave steepening required for harmonic generation as the wave propagates along the tube. However, stability and numerical distortion provide difficulties when trying to model the equations.

Complex Boundary Conditions

For musically interesting cases, more complex boundary conditions are required than those in (19.48). These new boundaries can either inject energy into the tube (such as a lip or reed model) or allow energy to leave (radiation model).

The simplest reed model is a single mass driven by the pressure difference between the mouth and the entrance of the tube [19.23]. This force causes the mass to move and change the channel height, which affects how much air is injected into the the tube and therefore the pressure difference over the boundary. This means that the motion of the reed is directly coupled to the pressure in the tube and requires the solution of simultaneous equations. Lip models for brass instruments can also be modeled in a similar way with two masses restrained to motion in one or two dimensions [19.35, 36].

The radiation properties of a tube are primarily affected by the surface area of the tube at the interface with the acoustic space but are frequency dependent. *Levine* and *Schwinger* [19.37] derived a frequency domain model for unflanged circular pipes, however this proves difficult to implement in the time domain and requires approximations.

A complete finite difference valved brass instrument synthesis system has been presented recently in [19.38, 39].

19.3.3 Relationship to Other Simulation Techniques

One of the earliest physical models of an acoustic tube is the *Kelly–Lochbaum* speech synthesis algorithm [19.8]. This algorithm assumes that the profile of the acoustic tube can be approximated by a series of joined cylinders, which reduces Webster's equation piecewise to the 1-D wave equation. This allows for traveling wave solutions in pressure and volume velocity, and by considering these values at the boundary of each cylinder segment a scattering matrix can be constructed. These scattering matrices can then be used to model the wave moving through the tube.

Related to scattering methods are digital waveguides, which have been a popular synthesis tool over the last 20 years and have been used in commercial music products such as the Yamaha VL1. Again these methods take advantage of separation of the solution into forward and backwards traveling waves and are therefore most suitable for 1-D linear systems. The traveling wave solutions are stored in two directional delay lines, which and are then shifted along their respective directions. This means that there are no arithmetic operations required, allowing a fast computation time. Excitation mechanisms can be connected to the model using scattering junctions and radiation effects can be added using filters [19.40]. Further modifications have been made to the waveguides models such as using the Webster–Lokshin model to add viscothermal effects [19.32, 33] and modeling quasispherical wavefronts [19.41].

Both the Kelly–Lochbaum and waveguide models of acoustic tubes can be shown to have finite-difference interpretations under specific conditions [19.17]. In the case of modeling the 1-D wave equation (a cylindrical acoustic tube), the digital waveguide can be shown to be equivalent to a finite-difference scheme with $\lambda = 1$. Similarly, the Kelly–Lochbaum algorithm is again a special form of a finite-difference scheme for an acoustic tube with $\lambda = 1$, where the scattering parameters are the update coefficients of the scheme.

19.4 The 2-D and 3-D Wave Equations

The ideal string, ideal bar, and acoustic tube covered in the previous sections are 1-D, meaning that their behavior may be adequately described by a PDE system written in terms of a single spatial coordinate. Such is obviously not the case for many structures of interest in musical acoustics, and certainly not when it comes to the modeling of acoustic wave propagation in real spaces!

A starting point for linear musical systems, such as membranes and also the acoustics of rooms, is the wave equation in spatial dimensions higher than one [19.18]. This second-order partial differential equation is written as

$$\partial_t^2 u = c^2 \Delta u \,. \tag{19.60}$$

Here, $u(\boldsymbol{x}, t)$ is the solution, t represents time, $\boldsymbol{x}$ is a spatial vector in 2-D or 3-D, and c is the wave speed in m/s.

The vector $\boldsymbol{x}$ may be written in terms of individual spatial coordinates as $\boldsymbol{x} = (x, y)$ in 2-D and $\boldsymbol{x} = (x, y, z)$

in 3-D. The operator Δ, usually called the Laplacian, is defined as

$$\Delta = \partial_x^2 + \partial_y^2 \quad \text{(in 2-D)}$$
$$\Delta = \partial_x^2 + \partial_y^2 + \partial_z^2 \quad \text{(in 3-D)}\,. \tag{19.61}$$

An equivalent formulation of (19.60) as a first-order system is also possible [19.18]. If (19.60) models the behavior of an ideal membrane, then u represents the transverse displacement; if it models acoustic wave propagation, then u represents a variable such as pressure or velocity potential.

As in the 1-D case, t is normally defined over $\mathbb{R}^+$, and $\boldsymbol{x}$ is defined in the domain $\mathcal{D}$, i. e., $\boldsymbol{x} \in \mathcal{D}$ where $\mathcal{D} \subseteq \mathbb{R}^2$ in 2-D and $\mathcal{D} \subseteq \mathbb{R}^3$ in 3-D. For practical purposes it is useful to define the rectangular regions $\mathcal{D}_{L_x,L_y} = [0, L_x] \times [0, L_y]$, where $\times$ denotes the Cartesian product, and $\mathcal{D}_{L_x,L_y,L_z} = [0, L_x] \times [0, L_y] \times [0, L_z]$. As before, the domains $\mathcal{D} = \mathbb{R}^2$ or $\mathcal{D} = \mathbb{R}^3$ are also useful for purposes of frequency domain analysis.

As in the 1-D case, the following initial conditions must be specified for the above equation

$$u(\boldsymbol{x}, 0) = u_0(\boldsymbol{x})$$
$$\partial_t u(\boldsymbol{x}, 0) = v_0(\boldsymbol{x})\,. \tag{19.62}$$

An initial condition that will be useful to illustrate the behavior of (19.60) is the following *raised cosine* initial condition

$$u_0 = \begin{cases} 0.5\left(1 + \cos\left(\frac{\pi|\boldsymbol{x}-\boldsymbol{x}_0|}{r_{\text{hw}}}\right)\right) & |\boldsymbol{x}-\boldsymbol{x}_0| \le r_{\text{hw}} \\ 0 & |\boldsymbol{x}-\boldsymbol{x}_0| > r_{\text{hw}} \end{cases}$$
$$v_0 = 0\,, \tag{19.63}$$

where r_{hw} is the half-width of the raised cosine and $\boldsymbol{x}_0$ is its center. Conditions along a boundary with normal $\boldsymbol{n}$ may be of the type

$$u(\boldsymbol{x}, t) = 0 \quad \text{(Dirichlet)}$$
$$\partial_n u(\boldsymbol{x}, t) = 0 \quad \text{(Neumann)}\,, \tag{19.64}$$

where ∂_n denotes a spatial derivative along the direction of $\boldsymbol{n}$. Dirichlet conditions are typically used to terminate the edge of a membrane, whereas Neumann conditions are a simple approximation to reflecting wall conditions in the setting of acoustic wave propagation.

As a first look into the behavior of the 2-D and 3-D wave equations, consider the raised cosine initial condition on the unit square $\mathcal{D} = \mathcal{D}_{1,1}$ and the unit cube $\mathcal{D} = \mathcal{D}_{1,1,1}$ domains, both with Neumann boundary conditions. The time evolution of the 2-D system is shown in Fig. 19.14. It can be seen that the raised cosine spreads out evenly over space, creating a circular wavefront. Figure 19.15 shows the time evolution of the 3-D system. It is slightly more difficult to completely visualize a 3-D field – this would require a fourth spatial dimension! – but one possibility is to view individual 2-D slices of the 3-D field, as illustrated here. Again, a circular wavefront propagates outward from the origin along the 2-D planes (a 2-D slice of a spherical wavefront in 3-D), but the wavefront decreases in amplitude more quickly in 3-D than in the case of the 2-D system.

19.4.1 Solution Characteristics

Another key difference between the behavior of the wave equation in 2-D and 3-D appears in the wake of the spreading wavefront, but this detail can be better

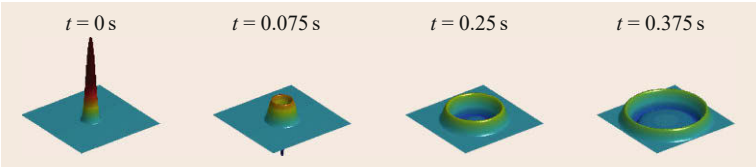

Fig. 19.14 Time evolution of a 2-D acoustical field, under a raised cosine initial condition with $r_{\text{hw}} = 0.1$, $\boldsymbol{x}_0 = (0.5, 0.5)$ and $c = 1\,\text{m/s}$ at times as indicated

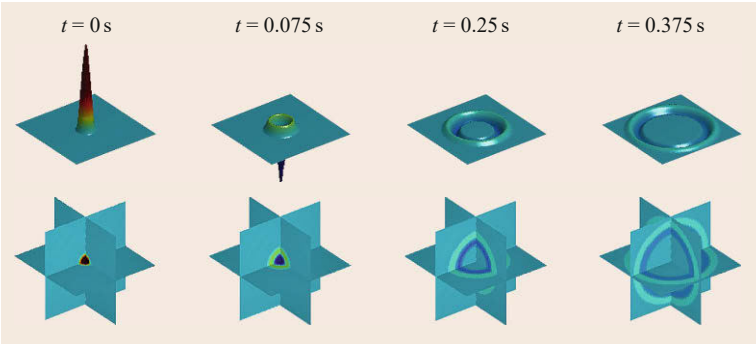

Fig. 19.15 Time evolution of a 3-D acoustic field under a raised cosine initial condition with $r_{\text{hw}} = 0.1$, $\boldsymbol{x}_0 = (0.5, 0.5, 0.5)$, and $c = 1\,\text{m/s}$, at times as indicated. *Top*: viewed along the 2-D-slice $z = 0.5$. *Bottom*: viewed along three 2-D slices: $x = 0.5$, $y = 0.5$, $z = 0.5$

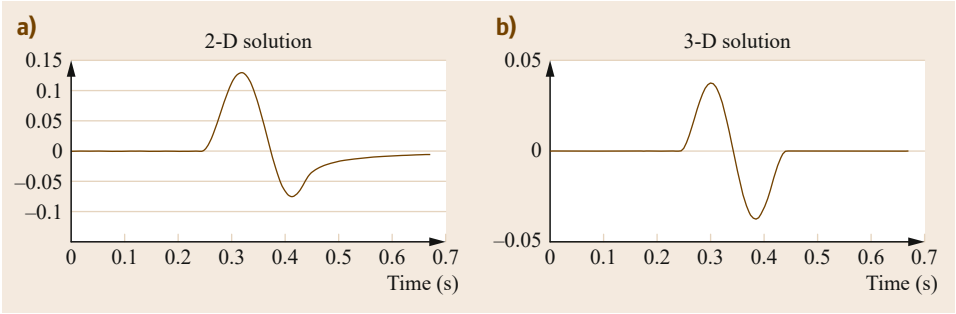

Fig. 19.16 **(a)** Time evolution of the displacement of a 2-D membrane at position $(0.25, 0.25)$ under a raised cosine initial condition with $r_{\text{hw}} = 0.1$ and $\boldsymbol{x}_0 = (0.5, 0.5)$. **(b)** Time evolution of a 3-D acoustic field at position $(0.25, 0.25, 0.5)$ with $r_{\text{hw}} = 0.1$ and $\boldsymbol{x}_0 = (0.5, 0.5, 0.5)$

seen by plotting the solution over time at a single output location. It can be seen in Fig. 19.16 that in the 2-D case the solution dips below zero after the initial pulse, but then fails to return to zero. On the other hand, in the 3-D case the solution returns to zero after the initial pulse. This behavior in 3-D, as well as the behavior in 1-D, is explained by *Huygens' principle*, which only applies in an odd number of spatial dimensions. The trailing *tail* phenomenon seen in the 2-D case is particular to even spatial dimensions. A useful musical analogy is provided in [19.42]:

> *A listener placed in* $\mathbb{R}^3$ *at distance* d *from a musical instrument hears at time* t *the note played at time* $(t-d)$ *and nothing else!* [. . .] *While in* $\mathbb{R}^2$ *he would hear a weighted average of all notes played during the time* $[0, t-d]$.

Solution Characteristics: Dispersion Relation

As in the 1-D case, it is useful to examine the behavior of the 2-D and 3-D wave equations with a plane wave solution of the form

$$u = \mathrm{e}^{j(\omega t + \boldsymbol{\beta}\cdot\boldsymbol{x})} \,. \tag{19.65}$$

Here, $\boldsymbol{\beta}$ is a wave vector in $\mathbb{R}^2$ or $\mathbb{R}^3$ representing a multidimensional spatial frequency, and its Euclidean norm (magnitude) $|\boldsymbol{\beta}|$ is known as the wavenumber, with units of radian/m. Inserting this solution into the wave equation results in the dispersion relation

$$\omega = \pm c|\boldsymbol{\beta}| \tag{19.66}$$

and the phase velocity $v_{\text{phase}} = \omega/|\boldsymbol{\beta}|$

$$v_{\text{phase}} = \pm c \,. \tag{19.67}$$

Thus, all plane waves (in 2-D and 3-D) travel with a constant wave speed c.

Solution Characteristics: Modes

Also as in the 1-D case, solutions to the 2-D and 3-D wave equations on bounded domains may be written as the sum of a set of modal functions

$$u(\boldsymbol{x}, t) = \sum_q U_q(\boldsymbol{x}) \left(a_q \sin(2\pi f_q t) + b_q \cos(2\pi f_q t)\right) . \tag{19.68}$$

Such spatial modes $U_q(\boldsymbol{x})$ may have analytic expressions, but in general these expressions are not easily derived unless the geometry of the domain $\mathcal{D}$ is regular, such as a rectangular or circular-spherical domain, and only when terminated by simple boundary conditions such as those of Neumann or Dirichlet type. On 2-D rectangular domains $\mathcal{D}_{L_x,L_y}$, under Dirichlet conditions at all boundaries, modal functions are separable into x and y components. These modes take the form

$$U_{\boldsymbol{p}}(\boldsymbol{x}) = \sin\left(\frac{p_x \pi x}{L_x}\right) \sin\left(\frac{p_y \pi y}{L_y}\right)$$
$$f_{\boldsymbol{p}} = \frac{c}{2}\left(\left(\frac{p_x}{L_x}\right)^2 + \left(\frac{p_y}{L_y}\right)^2\right)^{1/2} , \tag{19.69}$$

where $\boldsymbol{p}$ is a pair of indices, $\boldsymbol{p} = (p_x, p_y)$ with $p_x, p_y \geq 1$. Some of these spatial modes on the unit square $\mathcal{D}_{1,1}$ are illustrated in Fig. 19.17.

If, instead, Neumann conditions are used at the boundaries, one would have the following set of spatial modes on $\mathcal{D}_{L_x,L_y}$

$$U_{\boldsymbol{p}}(\boldsymbol{x}) = \cos\left(\frac{p_x \pi x}{L_x}\right) \cos\left(\frac{p_y \pi y}{L_y}\right)$$
$$f_{\boldsymbol{p}} = \frac{c}{2}\left(\left(\frac{p_x}{L_x}\right)^2 + \left(\frac{p_y}{L_y}\right)^2\right)^{1/2} , \tag{19.70}$$

where $p_x, p_y \geq 0$. These are illustrated in Fig. 19.18. The mode $\boldsymbol{p} = (0, 0)$ is known as the DC mode, and

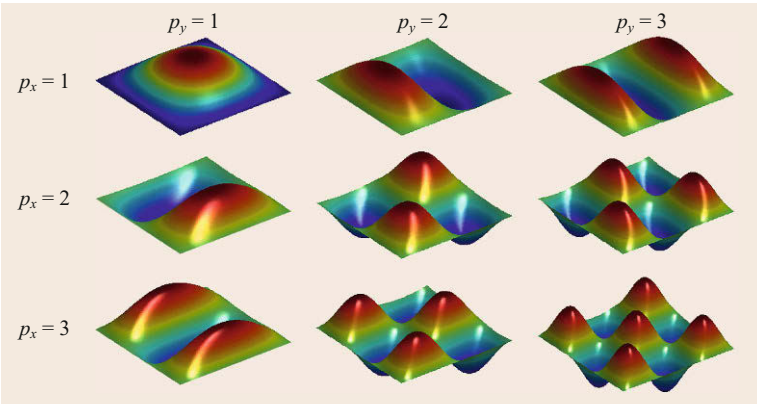

Fig. 19.17 Spatial modes of a 2-D acoustic field on $\mathcal{D}_{1,1}$ with Dirichlet boundary conditions

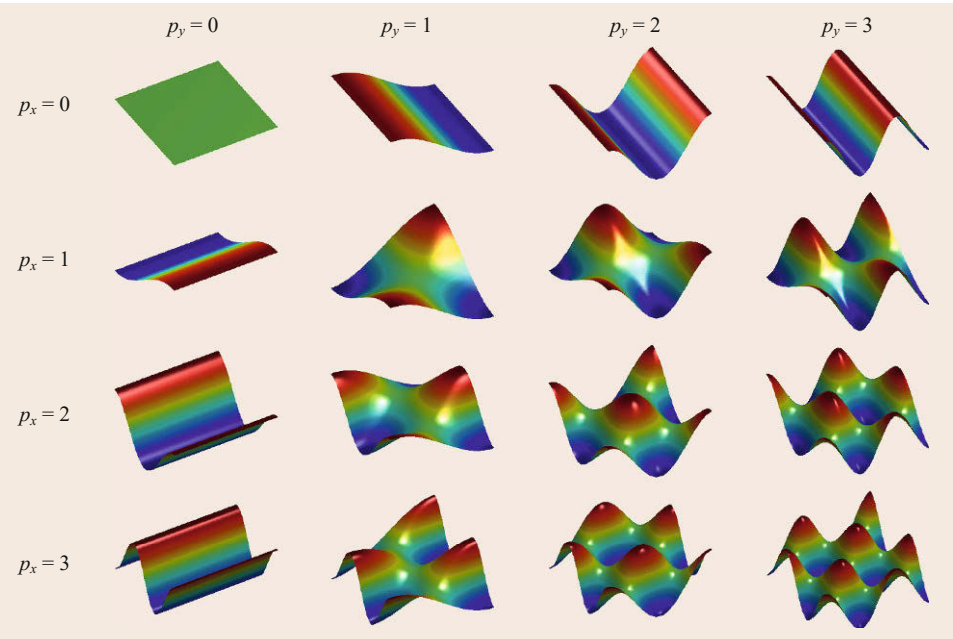

Fig. 19.18 Spatial modes of a 2-D acoustic field on $\mathcal{D}_{1,1}$ with Neumann boundary conditions

it is not permitted when Dirichlet conditions are specified at the boundaries, as well as modes $\boldsymbol{p} = (0, n)$ and $\boldsymbol{p} = (n, 0)$ where n is a positive integer. The DC mode corresponds to a linear drift in the solution, which may not seem physical in the context of musical acoustics, but is strictly valid for the model equation.

In 3-D, the modal shapes on $\mathcal{D}_{L_x,L_y,L_z}$ with respect to Neumann conditions take the form

$$U_{\boldsymbol{p}}(\boldsymbol{x}) = \cos\left(\frac{p_x \pi x}{L_x}\right) \cos\left(\frac{p_y \pi y}{L_y}\right) \cos\left(\frac{p_z \pi z}{L_z}\right)$$

$$f_{\boldsymbol{p}} = \frac{c}{2}\left(\left(\frac{p_x}{L_x}\right)^2 + \left(\frac{p_y}{L_y}\right)^2 + \left(\frac{p_z}{L_z}\right)^2\right)^{1/2}, \tag{19.71}$$

where now $\boldsymbol{p} = (p_x, p_y, p_z)$ with $p_x, p_y, p_z \geq 0$. A selection of modes on the unit cube are illustrated in Fig. 19.19.

Unlike the 1-D case, the temporal frequencies f_p that correspond to these modes are not all multiples of one fundamental frequency. This should be apparent from (19.70), (19.69) and (19.71). This can also be seen in the response of a typical room to an impulsive initial condition. Figure 19.20 shows such a response for a $10\,\mathrm{m} \times 20\,\mathrm{m} \times 30\,\mathrm{m}$ room ($\mathcal{D}_{10,20,30}$) with Neumann boundaries and $c = 340\,\mathrm{m/s}$. It can be seen that the lower frequency modes are sparse and that the density of modes increases at higher frequencies. This is a general trend, which is in contrast to the case of the 1-D wave equation where the density of modes is constant across frequencies, and the case

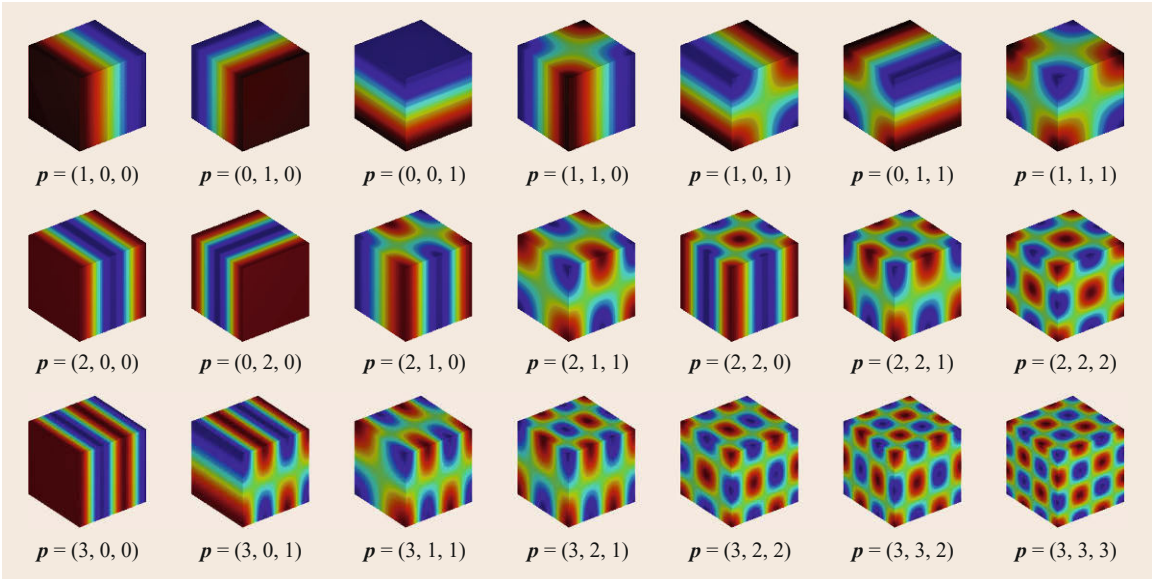

Fig. 19.19 Spatial modes of a 3-D acoustic field on $\mathcal{D}_{1,1,1}$ with Neumann boundary conditions, drawn on the surface of the unit cube

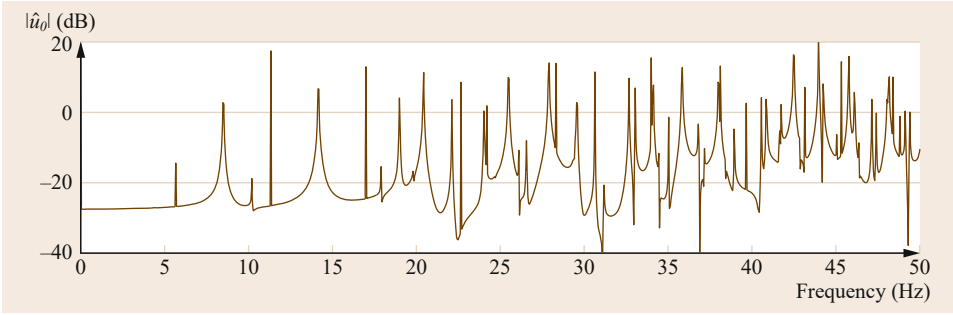

Fig. 19.20 Spectrum of response of a 10 m × 20 m × 30 m room to an impulsive initial condition with $c = 340$ m/s and Neumann boundaries. The output was read at a location near the center of the domain

of the ideal bar where mode density decreases with frequency.

19.4.2 A Grid and Difference Operators

As in the 1-D case, a grid function represents an approximation to the solution of interest – in this case it will be defined over a regular grid. In 2-D and 3-D there are various choices of regular spatial grids (lattices) [19.43], but the simplest and most straightforward choices are the integer lattices $\mathbb{Z}^2$ and $\mathbb{Z}^3$ scaled in each dimension by the spatial step h. The set of integer pairs or triples d represents the discrete analog of the continuous domain $\mathcal{D}$. For example, the rectangular region $\mathcal{D}_{L_x,L_y}$ could be represented by $d = d_{N_x,N_y} = \{0,\ldots,N_x\} \times \{0,\ldots,N_y\}$ where $N_x = L_x/h$ and $N_y = L_y/h$. Likewise, $\mathcal{D}_{L_x,L_y,L_z}$ could be represented by $d = d_{N_x,N_y,N_z} = \{0,\ldots,N_x\} \times \{0,\ldots,N_y\} \times \{0,\ldots,N_z\}$ with $N_z = L_z/h$. For simplicity it is assumed that L_x, L_y, L_z are common multiples of some h. These domains are illustrated in Fig. 19.21.

A grid function in 2-D can then be written as $u^n_{l_x,l_y}$ representing the approximation to $u(\boldsymbol{x},t)$ at $t = nk$, where k is the time step and $n \in \mathbb{Z}^+$, and at $\boldsymbol{x} = (l_x h, l_y h)$ and $(l_x, l_y) \in d \subseteq \mathbb{Z}^2$. Likewise, a grid function in 3-D may be written as $u^n_{l_x,l_y,l_z}$ with $\boldsymbol{x} = (l_x h, l_y h, l_z h)$ and $(l_x, l_y, l_z) \in d \subseteq \mathbb{Z}^3$.

The temporal difference operators δ_{tt} defined previously will be employed here, as will δ_{xx}, which acts on the 2-D and 3-D grid functions in the following manner

$$\delta_{xx} u^n_{l_x,l_y} = \frac{1}{h^2}\left(u^n_{l_x+1,l_y} - 2u^n_{l_x,l_y} + u^n_{l_x-1,l_y}\right)$$
$$\delta_{xx} u^n_{l_x,l_y,l_z} = \frac{1}{h^2}\left(u^n_{l_x+1,l_y,l_z} - 2u^n_{l_x,l_y,l_z} + u^n_{l_x-1,l_y,l_z}\right) . \quad (19.72)$$

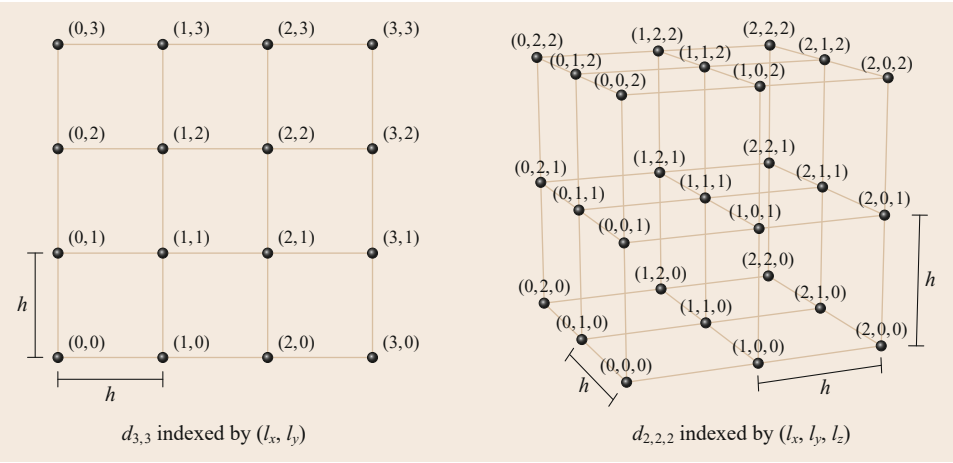

Fig. 19.21 Spatial grids in 2-D and 3-D

Similarly, the operator δ_{yy} in 2-D and 3-D may be defined as

$$\delta_{yy} u^n_{l_x,l_y} = \frac{1}{h^2}\left(u^n_{l_x,l_y+1} - 2u^n_{l_x,l_y} + u^n_{l_x,l_y-1}\right)$$
$$\delta_{yy} u^n_{l_x,l_y,l_z} = \frac{1}{h^2}\left(u^n_{l_x,l_y+1,l_z} - 2u^n_{l_x,l_y,l_z} + u^n_{l_x,l_y-1,l_z}\right) \tag{19.73}$$

and additionally in 3-D, δ_{zz}

$$\delta_{zz} u^n_{l_x,l_y,l_z} = \frac{1}{h^2}\left(u^n_{l_x,l_y,l_z+1} - 2u^n_{l_x,l_y,l_z} + u^n_{l_x,l_y,l_z-1}\right) . \tag{19.74}$$

At boundary locations, these spatial operators will sometimes address a tuple (l_x, l_y) or (l_x, l_y, l_z) that is not in d. Such a point is sometimes referred to as a *ghost point* and the grid function at this point must be set according to the appropriate boundary conditions.

19.4.3 A Simple Finite-Difference Scheme

The simplest finite-difference scheme for the 2-D wave equation is the classic scheme dating back to 1928 [19.1]. It is expressed as

$$\delta_{tt} u^n_{l_x,l_y} = c^2 \delta^{(2)}_{\Delta} u^n_{l_x,l_y} , \tag{19.75}$$

where $\delta^{(2)}_{\Delta} = \delta_{xx} + \delta_{yy}$ is a discrete Laplacian, which operates over a stencil of points. The stencil makes use of five spatial points, so it is called a five-point stencil. The two-step update equation for this scheme, obtained by expanding out the operators in full, is

$$u^{n+1}_{l_x,l_y} = 2u^n_{l_x,l_y} - u^{n-1}_{l_x,l_y} + \lambda^2\left(u^n_{l_x+1,l_y} + u^n_{l_x-1,l_y} + u^n_{l_x,l_y+1} + u^n_{l_x,l_y-1} - 4u^n_{l_x,l_y}\right) , \tag{19.76}$$

where $\lambda = ck/h$ is the Courant number. This update is illustrated in Fig. 19.22.

A straightforward extension of (19.75) gives the simplest scheme for the 3-D wave equation [19.3]

$$\delta_{tt} u^n_{l_x,l_y,l_z} = c^2 \delta^{(3)}_{\Delta} u^n_{l_x,l_y,l_z} , \tag{19.77}$$

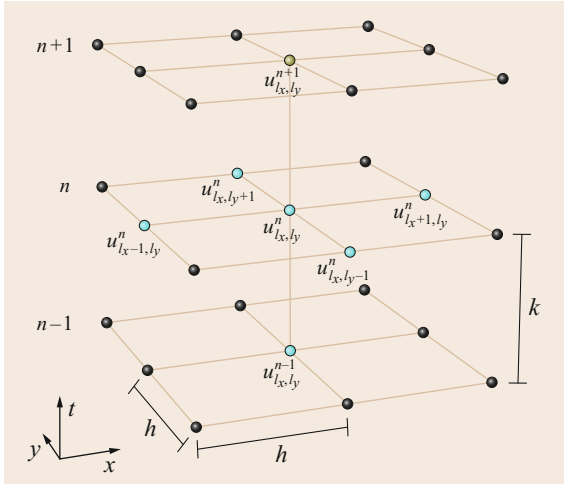

Fig. 19.22 Illustration of 2-D finite-difference update on a space-time grid. The update for the scheme, at the grid point marked in *yellow*, depends on previously calculated values at the grid points colored *cyan*

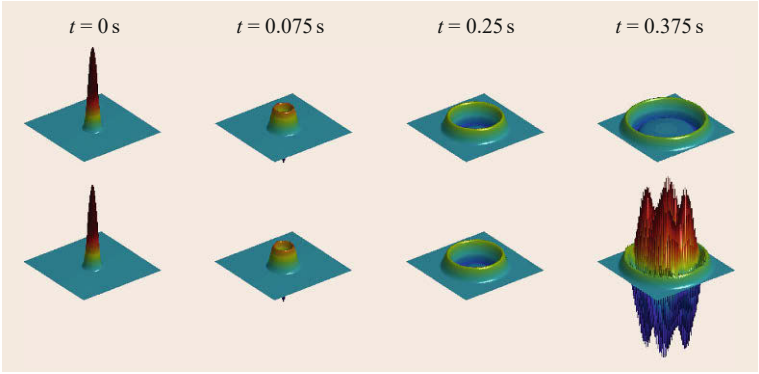

Fig. 19.23 Time evolution of $u^n_{l_x,l_y}$ on the unit square, under a raised cosine initial condition with $r_{\text{hw}} = 0.1\,\text{m}$, $\boldsymbol{x}_0 = (0.5, 0.5)$, $h = 0.01\,\text{m}$, and $c = 1\,\text{m/s}$, at times as indicated. *Top*: with $\lambda = \lambda_{\max}$. *Bottom*: with $\lambda = 1.0077\lambda_{\max}$. Compare with the solution in Fig. 19.14

where now $\delta^{(3)}_{\Delta} = \delta_{xx} + \delta_{yy} + \delta_{zz}$, which operates over a seven-point stencil. The update equation becomes

$$\begin{aligned} u^{n+1}_{l_x,l_y,l_z} &= 2u^n_{l_x,l_y,l_z} - u^{n-1}_{l_x,l_y,l_z} \\ &\quad + \lambda^2 \left(u^n_{l_x+1,l_y,l_z} + u^n_{l_x-1,l_y,l_z} \right. \\ &\quad + u^n_{l_x,l_y+1,l_z} + u^n_{l_x,l_y-1,l_z} + u^n_{l_x,l_y,l_z+1} \\ &\quad \left. + u^n_{l_x,l_y,l_z-1} - 6u^n_{l_x,l_y,l_z} \right) \end{aligned} \tag{19.78}$$

with $\lambda = ck/h$. Another formulation, using a first-order system for (19.60) as a starting point, adapted from the classic *Yee scheme* for electromagnetics [19.4] on staggered grids in space and time [19.44] is also possible. It can be shown that the staggered formulation is equivalent to (19.77) [19.45].

von Neumann Analysis and Stability

Stability analysis for the 2-D scheme over the infinite domain $d = \mathbb{Z}^2$ may be approached using von Neumann analysis, as in the 1-D case. In 2-D, a wavelike test solution (or *ansatz*) is

$$u^n_{l_x,l_y} = z^n \mathrm{e}^{j(\beta_x l_x h + \beta_y l_y h)} \quad z = \mathrm{e}^{sk} \tag{19.79}$$

for real wave vectors $\boldsymbol{\beta} = (\beta_x, \beta_y)$ and complex frequency $s = \sigma + j\omega$. Inserting this solution into (19.76) leads to the following characteristic equation in z

$$z + 4\lambda^2(s_x + s_y) - 2 + z^{-1} = 0\,, \tag{19.80}$$

where $s_x = \sin^2(\beta_x h/2)$ and $s_y = \sin^2(\beta_y h/2)$. The condition $|z| \le 1$ for all real $\boldsymbol{\beta}$ leads to stability of the scheme, and this will be true when

$$\lambda \le \lambda_{\max} = \sqrt{1/2} \quad \Rightarrow \quad h \ge h_{\min} = \sqrt{2}ck\,. \tag{19.81}$$

Numerical instability will arise if these conditions are not satisfied. Figure 19.23 demonstrates the effect of such instabilities – explosive (exponential) growth is quickly seen with λ only slightly larger than $\lambda_{\max}$.

It is straightforward to extend such von Neumann analysis to 3-D. Although omitted for brevity, this analysis leads to the following condition for the 3-D scheme

$$\lambda \le \lambda_{\max} = \sqrt{1/3} \Rightarrow h \ge h_{\min} = \sqrt{3}ck\,. \tag{19.82}$$

Numerical Dispersion and Mode Detuning

As in the 1-D case, numerical dispersion gives rise to a numerical wave speed that deviates from that of the wave equation itself. Inserting a plane wave solution $u = \mathrm{e}^{j(\omega nk + \beta_x l_x h + \beta_y l_y h)}$ into (19.75) gives the numerical dispersion relation for the 2-D scheme

$$\begin{aligned} \sin^2(\omega k/2) &= \lambda^2(s_x + s_y) \\ \Rightarrow \omega &= \pm\frac{2}{k}\sin^{-1}\left(\lambda\sqrt{s_x + s_y}\right). \end{aligned} \tag{19.83}$$

This relates temporal frequencies ω to spatial wave vectors $\boldsymbol{\beta}$ in the finite-difference scheme. The numerical dispersion relation is again dependent on the free parameter λ. As in the 1-D case, fixing the Courant number to $\lambda = \lambda_{\max}$ is generally a good idea, since this will maximize the temporal bandwidth that is produced by the scheme (this follows from (19.83)). This effect is also illustrated in Fig. 19.24, where a square domain is simulated using the 2-D scheme with three different choices of the Courant number. It can be seen that as the Courant number is reduced the scheme reproduces less temporal bandwidth.

It is also worth examining the numerical phase velocity ($v_{\text{phase}} = \omega/|\boldsymbol{\beta}|$) of the scheme in order to see how it deviates from the ideal c. The numerical phase velocity of the scheme is displayed in Fig. 19.25 for three choices of the Courant number. Note that, due to

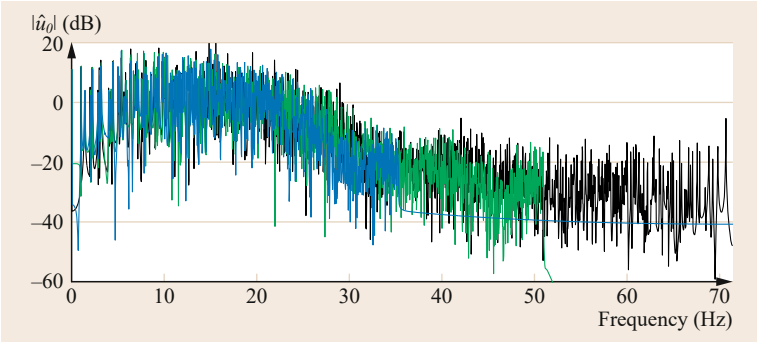

Fig. 19.24 Spectra of outputs from an impulsive initial condition (raised cosine) with Neumann boundaries on the domain $\mathcal{D}_{1,1}$ with $c = 1\,\mathrm{m/s}$ and $h = 0.01\,\mathrm{m}$. The outputs were taken at the center of the domain. The Courant number is set as $\lambda = \lambda_{\max}$ (*black*), $\lambda = 0.9\lambda_{\max}$ (*green*), and $\lambda = 0.7\lambda_{\max}$ (*blue*)

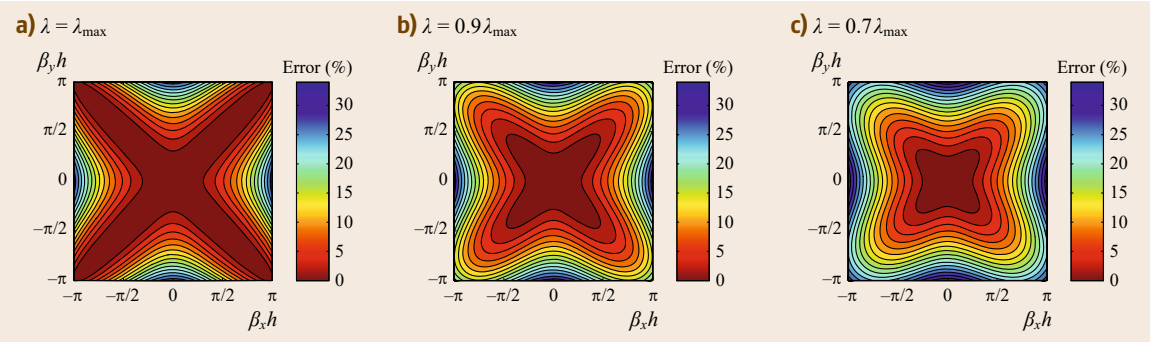

Fig. 19.25a–c Numerical phase velocity v_{phase} of 2-D scheme (19.75) as a function of spatial frequency with 2% contours, for various Courant numbers. **(a)** $\lambda = \lambda_{\max}$, **(b)** $\lambda = 0.9\lambda_{\max}$, **(c)** $\lambda = 0.7\lambda_{\max}$

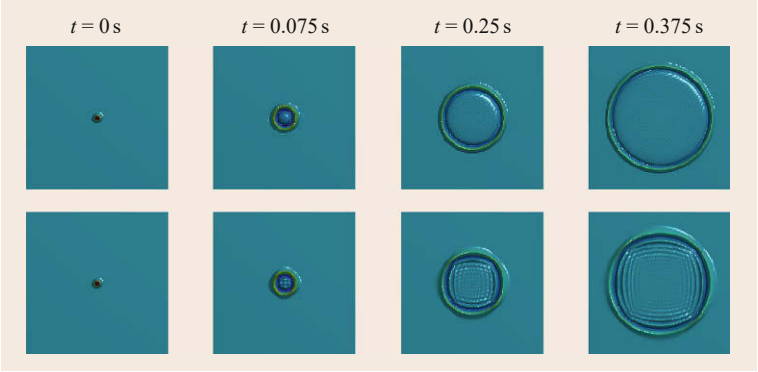

Fig. 19.26 Time evolution of a 2-D acoustic field viewed from above under a raised cosine initial condition with $r_{\text{hw}} = 0.025\,\mathrm{m}$, $\boldsymbol{x}_0 = (0.5, 0.5)$, and $c = 1\,\mathrm{m/s}$. *Top*: exact solution. *Bottom*: finite-difference approximation with $\lambda = \lambda_{\max}$ and $h = 0.01\,\mathrm{m}$

the discrete nature of the spatial grid, the spatial frequencies to consider are within a square cell centered about the origin with sides of length $2\pi/h$. In all three cases featured in Fig. 19.25, v_{phase} is correct at the origin ($|\boldsymbol{\beta}| = 0$, or the DC wavenumber), which follows from the consistency of the numerical scheme with the model equation. Beyond DC ($|\boldsymbol{\beta}| > 0$), v_{phase} exhibits increasing error with wavenumber along any given direction. Furthermore, the numerical phase velocity varies with the angle of propagation for a fixed wavenumber. This phenomenon is known as *anisotropy* of the scheme, as opposed to the ideal dispersion relation, which is isotropic, or independent of direction.

The effect of numerical dispersion on an approximated solution can be seen in Fig. 19.26. The exact solution propagates as a circular wavefront, whereas the approximated solution has ripples that (in this case) trail its circular wavefront due to numerical dispersion.

Similar effects are found in an analysis of the numerical dispersion of the 3-D scheme, which will be left out for the sake of brevity. It should be pointed out, however, that unwanted effects of dispersion are

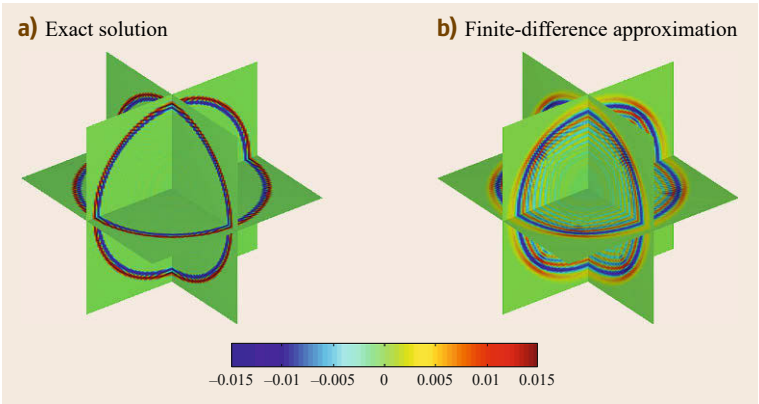

Fig. 19.27a,b Snapshot in time of 3-D acoustic field on $\mathcal{D}_{1,1,1}$ with $c = 1\,\mathrm{m/s}$, under a raised cosine initial condition with $r_{\mathrm{hw}} = 0.025$, $\boldsymbol{x}_0 = (0.5, 0.5, 0.5)$. The finite-difference approximation uses $h = 0.01\,\mathrm{m}$ and $\lambda = \sqrt{1/3}$. The snapshot shows $u^n_{l_x,l_y,l_z}$ after 75 time steps, at $t = 0.43\,\mathrm{s}$. **(a)** Exact solution, **(b)** finite-difference approximation

stronger than in the 2-D case, ultimately due to $\lambda_{\max}$ being smaller in the 3-D case. These effects are illustrated in Fig. 19.27, which compares a snapshot of an exact solution in 3-D to the approximation from (19.77), with $\lambda = \lambda_{\max}$. Again, the effect of numerical dispersion is exhibited as a series of ripples in the wake of the spreading wavefront.

Numerical Boundary Conditions

In order to terminate the grid one must impose numerical boundary conditions. In this section, the scheme (19.75) for the 2-D wave equation is assumed defined over the discrete rectangular region d_{N_x,N_y}.

The simplest such conditions are those of Dirichlet type (19.64), which do not require access to values at any ghost points. Over d_{N_x,N_y} these can be set along the boundary corresponding to $x = 0$ by

$$u^n_{0,l_y} = 0 \quad \text{for} \quad l_y = 0, \ldots, N_y \tag{19.84}$$

and similarly along the boundaries corresponding to $x = L_x$, $y = 0$, and $y = L_y$.

Neumann conditions (19.64) can be implemented in a similar fashion to the 1-D case. Here, along the boundary corresponding to $x = 0$, numerical Neumann conditions can be of the *centered* type or *non-centered* type

$$\begin{aligned} u^n_{-1,l_y} &= u^n_{0,l_y} \quad \text{(non-centered)} \\ u^n_{-1,l_y} &= u^n_{1,l_y} \quad \text{(centered)}\,, \end{aligned} \tag{19.85}$$

where $l_y = 1, \ldots, N_y - 1$ and u^n_{-1,l_y} are the ghost points. Substituting these conditions back into the 2-D update results in the following specialized updates for boundary nodes

$$\begin{aligned} u^{n+1}_{0,l_y} &= 2u^n_{0,l_y} - u^{n-1}_{0,l_y} \\ &\quad + \lambda^2 \left(u^n_{1,l_y} + u^n_{0,l_y+1} + u^n_{0,l_y-1} - 3u^n_{0,l_y} \right) \\ &\quad \text{(non-centered)} \end{aligned} \tag{19.86}$$

$$\begin{aligned} u^{n+1}_{0,l_y} &= 2u^n_{0,l_y} - u^{n-1}_{0,l_y} \\ &\quad + \lambda^2 \left(2u^n_{1,l_y} + u^n_{0,l_y+1} + u^n_{0,l_y-1} - 4u^n_{0,l_y} \right) \\ &\quad \text{(centered)}\,, \end{aligned} \tag{19.87}$$

where $l_y = 1, \ldots, N_y - 1$. For Neumann conditions along adjacent edges of the rectangular domain, corner nodes, such as at $l_x = l_y = 0$, require another specialized update with Neumann conditions; considering, additionally, a Neumann condition along the boundary corresponding to $y = 0$

$$\begin{aligned} u^n_{l_x,-1} &= u^n_{l_x,0} \quad \text{(non-centered)} \\ u^n_{l_x,-1} &= u^n_{l_x,1} \quad \text{(centered)}\,. \end{aligned} \tag{19.88}$$

The update at the corner node $l_x = l_y = 0$ would then be

$$\begin{aligned} u^{n+1}_{0,0} &= 2u^n_{0,0} - u^{n-1}_{0,0} + \lambda^2 \left(u^n_{1,0} + u^n_{0,1} - 2u^n_{0,0} \right) \\ &\quad \text{(non-centered)} \end{aligned} \tag{19.89}$$

$$\begin{aligned} u^{n+1}_{0,0} &= 2u^n_{0,0} - u^{n-1}_{0,0} + \lambda^2 \left(2u^n_{1,0} + 2u^n_{0,1} - 4u^n_{0,0} \right) \\ &\quad \text{(centered)} \end{aligned} \tag{19.90}$$

and similar updates may be worked out by symmetry for the other three corners of the domain d_{N_x,N_y}, as well as extensions to 3-D on d_{N_x,N_y,N_z}.

As in the 1-D case, these boundary conditions lead to stable numerical solutions. For irregular geometries, energy techniques should be employed in order to guarantee numerical stability. Finite volume techniques become very useful in this regard, but must be left out for the sake of brevity – see, e.g., [19.46, 47].

Vector–Matrix Representation

The 2-D and 3-D schemes, which are linear, may be compactly written in terms of matrix updates, as in the 1-D case – but, for such a representation, the multidimensional grid must first be represented as a vector. For

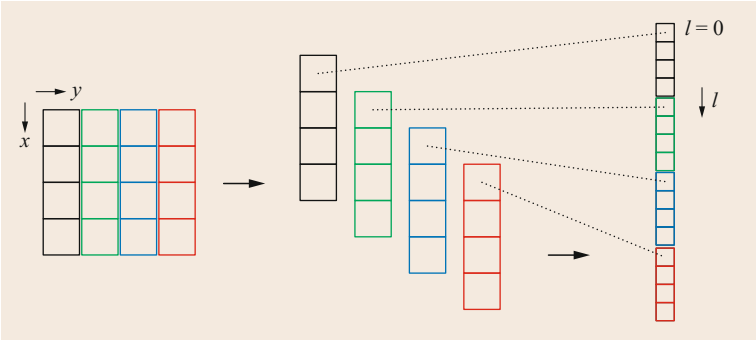

Fig. 19.28 Decomposition of $u^n_{l_x,l_y}$ on $d_{3,3}$ with Neumann conditions into column vector $\boldsymbol{u}^n$

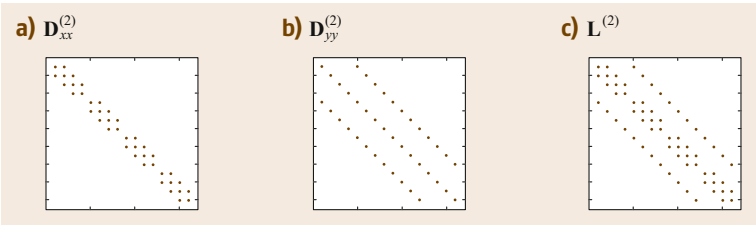

Fig. 19.29a–c Sparsity patterns for matrix operators with Neumann conditions on $d_{3,3}$. *Dots* represent nonzero elements of the matrix. **(a)** $\mathbf{D}^{(2)}_{xx}$, **(b)** $\mathbf{D}^{(2)}_{yy}$, **(c)** $\mathbf{L}^{(2)}$

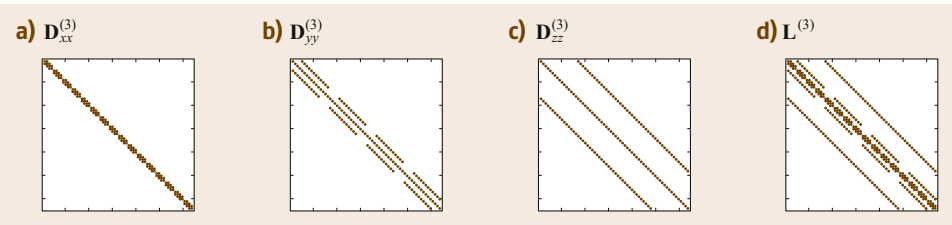

Fig. 19.30a–d Sparsity patterns for matrix operators on $d_{3,3,3}$ with Neumann conditions. **(a)** $\mathbf{D}^{(3)}_{xx}$, **(b)** $\mathbf{D}^{(3)}_{yy}$, **(c)** $\mathbf{D}^{(3)}_{zz}$, **(d)** $\mathbf{L}^{(3)}$

the 2-D grid function $u^n_{l_x,l_y}$, for example, one approach is to decompose the grid into vertical strips and then concatenate them into one column vector $\boldsymbol{u}^n$. In the case of Neumann conditions on $d_{N,N}$, the lth element $\boldsymbol{u}^n_l$ may be defined in terms of the 2-D grid function $u^n_{l_x,l_y}$, as

$$\boldsymbol{u}^n_l = u^n_{l_x,l_y} \quad \text{where} \quad l = l_x + l_y(N+1)\,. \tag{19.91}$$

This vector decomposition is illustrated in Fig. 19.28. Similar decompositions are possible for the 3-D case.

The matrix operators $\mathbf{D}^{(2)}_{xx}$, $\mathbf{D}^{(2)}_{yy}$ for the 2-D scheme can be constructed using the matrix $\mathbf{D}_{xx}$ given in the 1-D case in (19.28). On a square domain $d_{N,N}$, these matrices can be written as

$$\begin{aligned}\mathbf{D}^{(2)}_{xx} &= \mathbf{D}_{xx} \otimes \mathbf{I} \\ \mathbf{D}^{(2)}_{yy} &= \mathbf{I} \otimes \mathbf{D}_{yy}\,,\end{aligned} \tag{19.92}$$

where $\otimes$ denotes the Kronecker product, and where $\mathbf{I}$ is the identity matrix of appropriate size. The Laplacian matrix $\mathbf{L}^{(2)}$, representing the operator $\delta^{(2)}_{\Delta}$ and including boundary conditions on $d_{N,N}$, then becomes

$$\mathbf{L}^{(2)} = \mathbf{D}^{(2)}_{xx} + \mathbf{D}^{(2)}_{yy}\,. \tag{19.93}$$

The sparsity patterns of these matrices are shown in Fig. 19.29.

The update for the 2-D scheme can then be written in the by-now familiar compact form

$$\begin{aligned}\boldsymbol{u}^{n+1} &= \mathbf{B}\boldsymbol{u}^n - \boldsymbol{u}^{n-1} \\ \mathbf{B} &= 2\mathbf{I}^{(2)} + c^2k^2\mathbf{L}^{(2)}\,,\end{aligned} \tag{19.94}$$

where $\mathbf{I}^{(2)} = \mathbf{I} \otimes \mathbf{I}$. Matrices representing the operators δ_{xx}, δ_{yy}, δ_{zz}, $\delta^{(3)}_{\Delta}$ for the 3-D case can be constructed in a similar fashion, leading to the matrices $\mathbf{D}^{(3)}_{xx}$, $\mathbf{D}^{(3)}_{yy}$, $\mathbf{D}^{(3)}_{zz}$, $\mathbf{L}^{(3)}$ with sparsity patterns as shown in Fig. 19.30.

19.4.4 A Family of Implicit Finite-Difference Schemes

Recalling the case of the ideal bar, it may be advantageous to employ an implicit scheme as opposed to an explicit scheme – the point of introducing an implicit character to the scheme is to attempt to reduce unwanted effects of numerical dispersion.

A family of implicit schemes for the 2-D wave equation can be written as

$$\left(1+\alpha h^2 \delta^{(2)}_{\Delta,\gamma}\right) \delta_{tt} u^n_{l_x,l_y} = c^2 \delta^{(2)}_{\Delta,\gamma} u^n_{l_x,l_y} \,, \qquad (19.95)$$

where $\alpha \in \mathbb{R}$ is a free parameter. When $\alpha = 0$ the scheme is explicit, and otherwise implicit. It also helps to use a wider stencil of points, so here $\delta^{(2)}_{\Delta,\gamma}$ operates over a nine-point stencil

$$\delta^{(2)}_{\Delta,\gamma} = \delta_{xx} + \delta_{yy} + \frac{h^2}{2}(1-\gamma)\delta_{xx}\delta_{yy} \,, \qquad (19.96)$$

which has a free parameter $\gamma \in \mathbb{R}$, and which reduces to a five-point Laplacian when $\gamma = 0$ or $\gamma = 1$. It is common to choose the parameter $\gamma = 2/3$ [19.48], which reduces the directional dependence of the approximation error.

Analogous to the update shown in Fig. 19.22, the update for a given node $u^{n+1}_{l_x,l_y}$ is illustrated in Fig. 19.31. Though the analysis is more involved, stability conditions may be worked out in the same manner as for the explicit scheme. von Neumann analysis leads to the following conditions relating γ, λ and α

$$\gamma \geq 0 \quad \lambda \leq \lambda_{\max} = \begin{cases} \sqrt{1-4\alpha} & \text{if } \gamma \leq 1/2 \\ \sqrt{\frac{1}{2\gamma} - 4\alpha} & \text{if } \gamma > 1/2 \end{cases} \,,$$
$$\alpha < \begin{cases} \frac{1}{4} & \text{if } \gamma \leq 1/2 \\ \frac{1}{8\gamma} & \text{if } \gamma > 1/2 \,. \end{cases} \qquad (19.97)$$

The effect of choosing $\gamma = 2/3$ is seen in the numerical dispersion of the explicit scheme ($\alpha = 0$) in Fig. 19.32a. It can be seen that the numerical dispersion is more isotropic than that of the standard scheme as shown in Fig. 19.25.

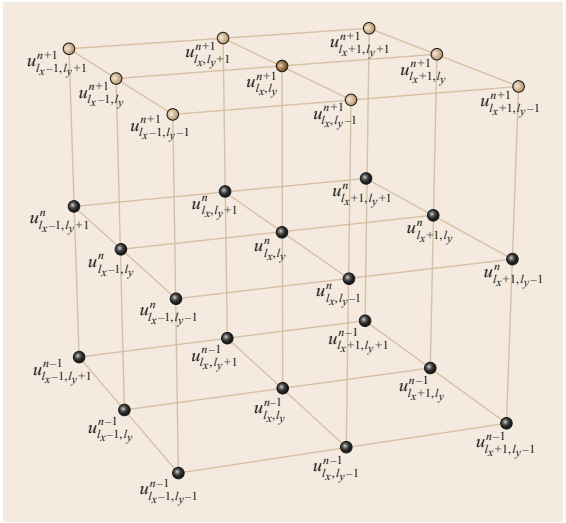

Fig. 19.31 Illustration of the implicit 2-D finite-difference update on a space-time grid. The update for the *highlighted point at the center* (in dark brown) depends on the unknown values of its neighbors (in light brown), as well as the known values (in gray)

For $\gamma = 2/3$, a good choice for an implicit scheme is $\alpha = 1/32$, which results in $\lambda_{\max} = \sqrt{5/8}$. It can be shown that this is in fact a fourth-order accurate scheme, which means that the approximation error is proportional to h^4 (implying, for a fixed $\lambda \leq \lambda_{\max}$, that it is also proportional to k^4), as opposed to the other schemes presented so far, which have an approximation error proportional to h^2 (and are thus second-order accurate). In other words, as the spatial step h is reduced, the approximation error in a fourth-order scheme decreases at a faster rate than in a second-order scheme. In terms of numerical dispersion, the effect of higher-order accuracy is seen mostly near the DC wavenumber, but the improvement in v_{phase} also extends to higher

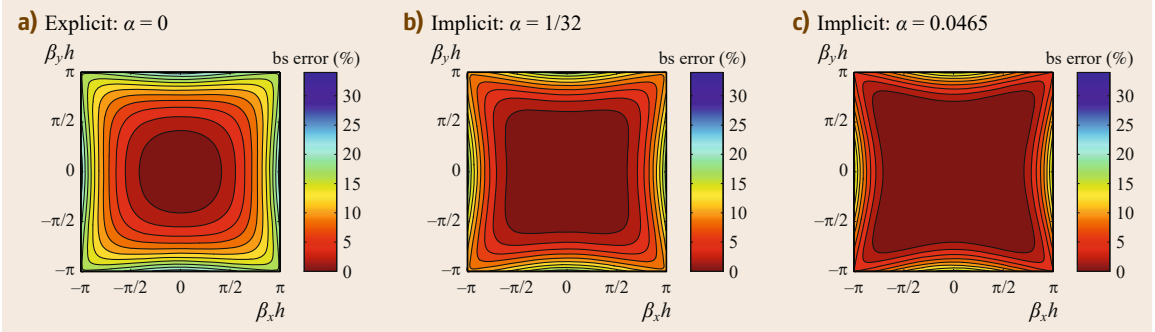

Fig. 19.32a–c Error in numerical phase velocity v_{phase} of 2-D scheme (19.95) with $\gamma = 2/3$ as a function of spatial frequencies with 2% contours. The Courant number is set as $\lambda = \lambda_{\max}$ in each case. **(a)** Explicit $\alpha = 0$, **(b)** implicit $\alpha = 1/32$, **(c)** implicit $\alpha = 0.0465$

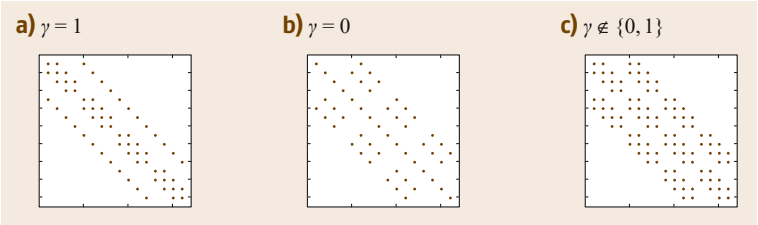

Fig. 19.33a–c Sparsity patterns of $\mathbf{L}_\gamma^{(2)}$ with centered Neumann conditions on $d_{3,3}$, for various γ. **(a)** $\gamma = 1$, **(b)** $\gamma = 0$, **(c)** $\gamma \notin \{0, 1\}$

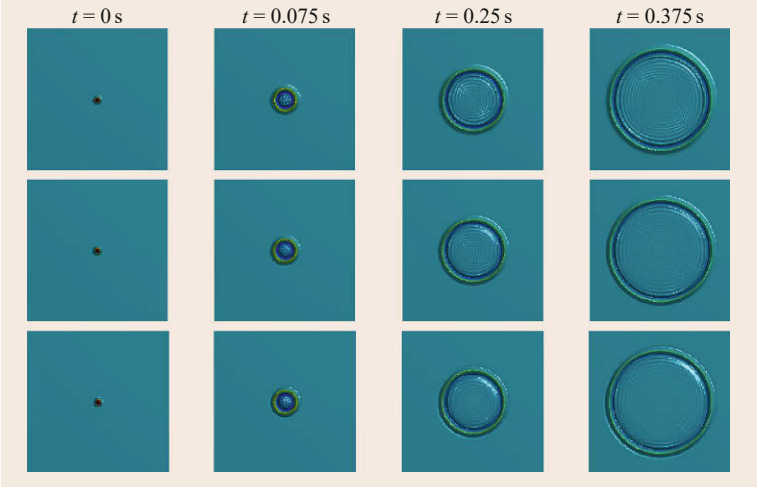

Fig. 19.34 Time evolution of 2-D approximations using a raised cosine initial condition with $r_{\text{hw}} = 0.025$ m, $\boldsymbol{x}_0 = (0.5, 0.5)$, and $c = 1$ m/s. For all schemes, $\gamma = 2/3$, $k = 7$ ms and $\lambda = \lambda_{\max}$. *Top*: $\alpha = 0$, *middle*: $\alpha = 1/32$, *bottom*: $\alpha = 0.0465$. Compare with the exact solution and approximation in Fig. 19.26

wavenumbers, as seen in Fig. 19.32b. It is also possible to choose α such that any improvement in v_{phase} is spread over a wider range of spatial frequencies. A good choice is $\alpha = 0.0465$, which provides less than 2% error in v_{phase} over nearly the entire range of discrete spatial frequencies, as seen in Fig. 19.32c.

As the update for the implicit scheme involves a linear system of equations, it is appropriate to write it in a vector-matrix form. The update on $d_{N,N}$ using centered Neumann conditions is then

$$\mathbf{A}\boldsymbol{u}^{n+1} = \mathbf{B}\boldsymbol{u}^{n} - \mathbf{A}\boldsymbol{u}^{n-1} , \tag{19.98}$$

where

$$\mathbf{A} = \mathbf{I}^{(2)} + \alpha h^2 \mathbf{L}_\gamma^{(2)} \tag{19.99}$$

$$\mathbf{B} = 2A + (c^2k^2 + 2\alpha h^2)\mathbf{L}_\gamma^{(2)} \tag{19.100}$$

$$\mathbf{L}_\gamma^{(2)} = \mathbf{D}_{xx}^{(2)} + \mathbf{D}_{yy}^{(2)} + \frac{h^2}{2}(1-\gamma)\mathbf{D}_{xx}^{(2)}\mathbf{D}_{yy}^{(2)} . \tag{19.101}$$

The sparsity patterns of $\mathbf{L}_\gamma^{(2)}$ with centered Neumann conditions on $d_{3,3}$ are shown in Fig. 19.33.

As in the 1-D implicit scheme (19.45), the system may be solved using the Jacobi method or other iterative methods, leading to a trade-off between accuracy and computational cost. The example featured in Fig. 19.26 is computed now with the three special cases of (19.98). Snapshots in time are displayed in Fig. 19.34.

Similar to the 2-D case, in 3-D a family of implicit-explicit schemes may be defined as

$$\left(1 + \alpha h^2 \delta_{\Delta,\gamma}^{(3)}\right) \delta_{tt} u_{l_x,l_y,l_z}^n = c^2 \delta_{\Delta,\gamma}^{(3)} u_{l_x,l_y,l_z}^n , \tag{19.102}$$

where $\alpha \in \mathbb{R}$ is a free parameter. The discrete Laplacian $\delta_{\Delta,\gamma}^{(3)}$ operates over a 19-point stencil

$$\delta_{\Delta,\gamma}^{(3)} = \delta_{xx} + \delta_{yy} + \delta_{zz} + \frac{h^2}{4}(1-\gamma)(\delta_{xx}\delta_{yy} + \delta_{xx}\delta_{zz} + \delta_{yy}\delta_{zz}) , \tag{19.103}$$

which has a free parameter $\gamma \in \mathbb{R}$, and which reduces to a seven-point stencil when $\gamma = 1$ and a 13-point stencil when $\gamma = 0$. This stencil is illustrated in Fig. 19.35. An isotropic approximation error in the discrete Laplacian can be obtained with the choice $\gamma = 1/3$ [19.49]. Similar to the 2-D case, $\delta_{\Delta,\gamma}^{(3)}$ may be written as a matrix operator, leading to a sparsity pattern as shown

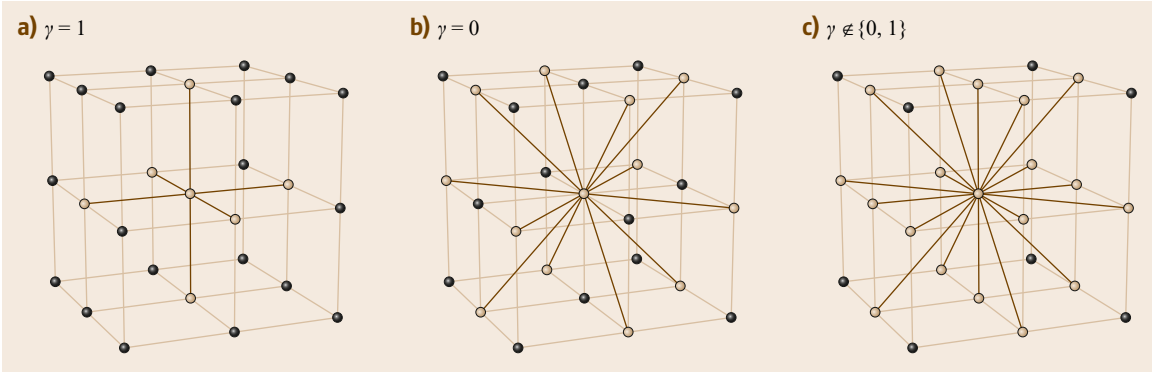

Fig. 19.35a–c Stencil of points for $\delta^{(3)}_{\Delta,\gamma}$. The spatial points used by $\delta^{(3)}_{\Delta,\gamma}$ are highlighted. **(a)** $\gamma = 1$, **(b)** $\gamma = 0$, **(c)** $\gamma \notin \{0, 1\}$

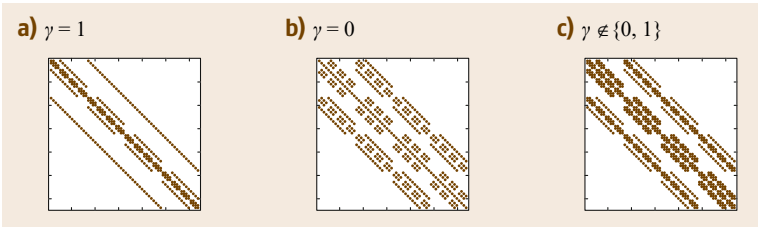

Fig. 19.36a–c Sparsity patterns of the matrix operator corresponding to $\delta^{(3)}_{\Delta,\gamma}$ with centered Neumann conditions on $d_{3,3,3}$, for various values of γ. **(a)** $\gamma = 1$, **(b)** $\gamma = 0$, **(c)** $\gamma \notin \{0, 1\}$

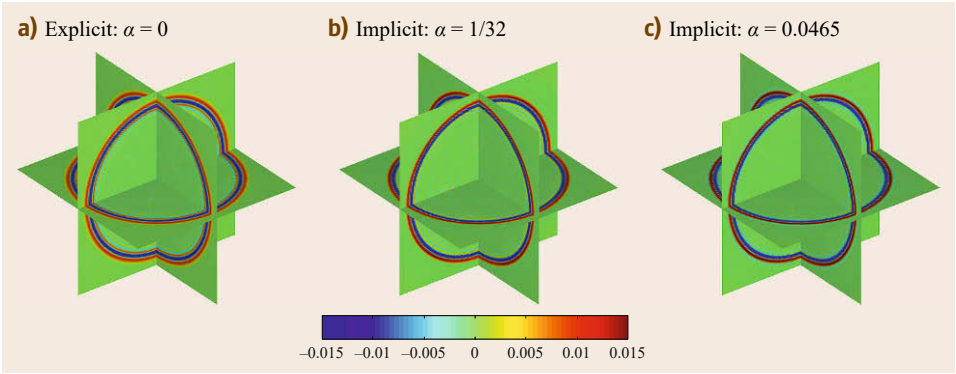

Fig. 19.37a–c Snapshot in time of 3-D approximation from (19.102) using $\gamma = 1/3$ and various values for α. In each case, $\lambda = \lambda_{\max}$ and $k = 0.057\,\mathrm{s}$. The approximation $u^n_{l_x,l_y,l_z}$ is shown after 75 time steps, at $t = 0.43\,\mathrm{s}$. Compare with Fig. 19.27. **(a)** Explicit $\alpha = 0$, **(b)** implicit $\alpha = 1/32$, **(c)** implicit $\alpha = 0.0465$

in Fig. 19.36. See [19.50] for the construction of this matrix.

Using a von Neumann analysis, the stability condition for this scheme is found to be

$$\gamma \geq 0\,,$$
$$\lambda \leq \lambda_{\max} = \begin{cases} \sqrt{\frac{1}{\gamma+1} - 4\alpha} & \text{if } \gamma \leq 1/2 \\ \sqrt{\frac{1}{3\gamma} - 4\alpha} & \text{if } \gamma > 1/2 \end{cases}$$
$$\alpha < \begin{cases} \frac{1}{4(\gamma+1)} & \text{if } \gamma \leq 1/2 \\ \frac{1}{12\gamma} & \text{if } \gamma > 1/2\,. \end{cases} \qquad (19.104)$$

As in the 2-D case, the value $\alpha = 1/32$ leads to a fourth-order accurate scheme, and the value $\alpha = 0.0465$ results in low dispersion error over a wide range of frequencies.

The example featured in Fig. 19.27 is now recalculated using the scheme (19.102) and $\alpha \in \{0, 1/32, 0.0465\}$ and illustrated in Fig. 19.37. An improvement over the simplest approximation in Fig. 19.27 can clearly be seen for all three cases, and the approximations obtained with the implicit schemes $\alpha \in \{1/32, 0.0465\}$ are, visually, close to the exact solution.

For much more on finite difference schemes for the 2-D and 3-D wave equations, see [19.51].

19.5 Thin Linear Plate Vibration

Stiff systems, such as the ideal bar described in detail in Sect. 19.2, require modeling techniques that are somewhat different from those used in the case of, for example, the wave equation. In 2-D, the direct analog of the bar is the plate, which is a thin, flat and stiff two-dimensional structure. When some curvature is present, as in the case of cymbals or gongs, such structures are usually referred to as shells, though shell structures will not be covered in this introductory tutorial. Plate vibration theory is a large research field with many applications in musical acoustics, and it is therefore useful to indicate some subcategories of interest.

While all plate structures are assumed to have a small thickness H relative to the lateral dimensions, a major distinction that can be made at the level of a model is whether the plate is considered to be thick or thin. The equation of motion for a thin plate was first proposed by *Kirchhoff* and *Love* [19.52] under various simplifying assumptions. *Mindlin* and *Reissner* [19.53, 54] subsequently proposed a more general (thick) model. In musical acoustics, thin models are often enough to describe the systems under consideration. These include, for example, gongs and cymbals [19.55], plate reverberation effects [19.56], violin or guitar bodies [19.57] and piano soundboards [19.58]; stiffness can also be included in models of drum membranes for a more realistic description of the dynamics [19.23].

It is the transverse vibrations of plates that are generally of interest, and they schematically fall into three different regimes. When the displacement u is small ($u \ll H$), the transverse motion can be uncoupled from the in-plane motion, and the resulting equations are linear. When $u \approx H$, in-plane and transverse vibrations become coupled and more complex, and nonlinear behavior arises [19.59]. This regime is well described by the von Kármán–Föppl equations [19.60]. For large deflections and rotations in the material, even this model loses validity. Such behavior, however, is generally never found in musical instruments under normal playing conditions.

Two additional properties of the material, namely spatial inhomogeneity and anisotropy, must also be taken into account, as they have major ramifications in terms of simulation. It is not uncommon, in fact, for gongs and cymbals to have a varying thickness, with a central region thicker than the rim. This is a typical example of spatial inhomogeneity. Wooden plates in string instruments or pianos on the other hand, even if spatially uniform, exhibit different behaviors depending on the direction, particularly regarding wave propagation speed, giving rise to anisotropic phenomena.

From a numerical simulation point of view, many possibilities are available. A widely adopted technique in engineering is the finite element method [19.61], which has proven to be very flexible and accurate for a diverse range of applications, including musical acoustics [19.62, 63]. Simulations of gongs and plate-like structures have also been attempted using digital waveguides [19.64]. Modal methods are an attractive option when the modes of vibration are known analytically. This technique has recently also been applied to imperfect plates and shells, i. e., surfaces with any type of defect [19.65], and nonlinear (von Kármán) plates [19.66]. Finite-difference approaches have also been adopted for the simulation of plates [19.67] and are easy to implement when simple geometries are involved. Examples include plate reverberation effects [19.68] and gong and cymbal simulations [19.69].

In this section, only the linear behavior of thin, spatially uniform and isotropic square plates will be considered in detail.

19.5.1 Equations of Motion

Consider a region $\mathcal{D} \subset \mathbb{R}^2$, and let $u(x, y, t)$ be the transverse displacement of the plate at position $(x, y) \in \mathcal{D}$ and time $t \in \mathbb{R}^+$. The equation of motion for a stiff plate is similar to that of the stiff bar equation presented in Sect. 19.2 and is usually referred to as the Kirchhoff model [19.70]

$$\partial_t^2 u = -\kappa^2 \Delta^2 u \,. \tag{19.105}$$

Here, Δ is the Laplacian operator introduced in Sect. 19.4, and $\Delta^2 = \Delta \cdot \Delta = \partial_x^4 + 2\partial_x^2\partial_y^2 + \partial_y^4$ is the biharmonic operator. The constant κ is defined as

$$\kappa = \sqrt{\frac{E H^2}{12\,\rho\,(1-\nu^2)}}\,, \tag{19.106}$$

where E is Young's modulus in Pa, H is the thickness in m, ρ is the density in kg/m^3 and ν is the dimensionless Poisson's ratio.

If the domain $\mathcal{D}$ is finite (such as, e.g., a square region of side length L, or $\mathcal{D} = \mathcal{D}_{L,L}$), it is necessary to complement equation (19.105) with suitable boundary conditions defined over the boundary of $\mathcal{D}$. Many possibilities are at hand, but only three are generally relevant in acoustics applications, namely clamped, simply supported and free conditions. They can be defined as

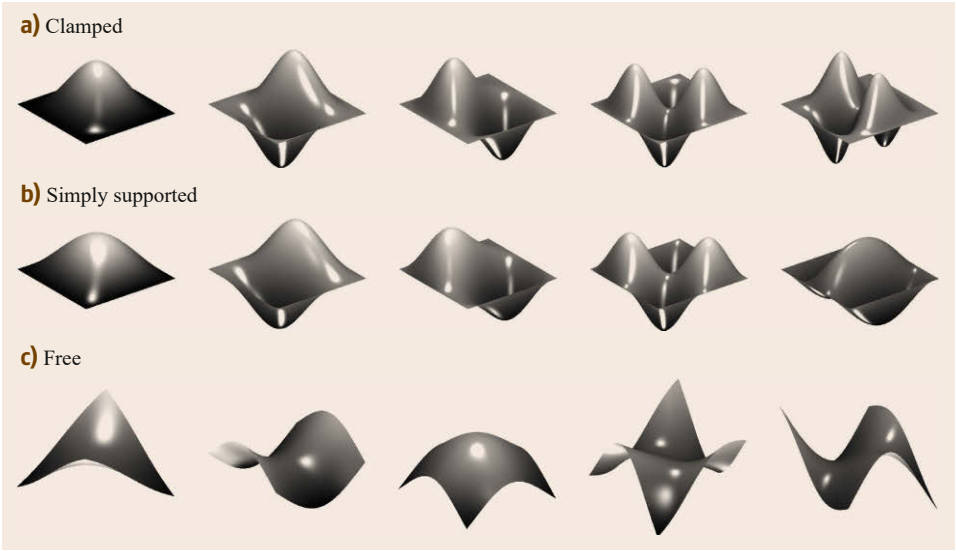

Fig. 19.38a–c First five modes in the modal series for three different boundary conditions: **(a)** clamped, **(b)** simply supported, and **(c)** free. In the free case, the first three modes corresponding to rigid body motion are not represented

follows, over a straight plate edge [19.71]

$$\begin{aligned} &u = \partial_{\boldsymbol{n}} u = 0 \quad \text{(clamped)} \\ &u = \partial_{\boldsymbol{n}}^2 u + \nu\, \partial_{\boldsymbol{s}}^2 u = 0 \quad \text{(simply supported)} \\ &\partial_{\boldsymbol{n}}^3 u + (2-\nu)\, \partial_{\boldsymbol{n}} \partial_{\boldsymbol{s}}^2 u = \partial_{\boldsymbol{n}}^2 u + \nu\, \partial_{\boldsymbol{s}}^2 u = 0 \quad \text{(free)}\,, \end{aligned} \tag{19.107}$$

where $\partial_{\boldsymbol{n}}$ denotes the directional derivative normal to the boundary oriented outwards, and ∂_s is the tangential derivative along the boundary. It is to be noted that two conditions need to be supplied, given that (19.105) is fourth-order in space, as in the case of the ideal bar.

The linearity of equation (19.105) allows a decomposition of the dynamics in terms of modal shapes. These have a simple, closed-form expression only in the simply supported case, in which case the plate equation is separable, and where each mode can be written as a product of sinusoidal functions, similarly to the case of the 2-D membrane. Figure 19.38 illustrates the lowest frequency modes for the three boundary conditions listed above. For the two fixed conditions (clamped and simply supported), the first modes look very similar, although a careful analysis reveals substantial differences at the boundaries, where different conditions on the derivative of the displacement are imposed. In the free case, three zero-frequency modes are also present, and they correspond to rigid body motions of the plate (two rotations and one rigid translation). These are not presented in the figure.

As in the case of the 1-D bar, the system is dispersive. This may be illustrated by inserting a test solution of the form

$$u = \mathrm{e}^{j(\omega t + \boldsymbol{\beta}\cdot\boldsymbol{x})}$$

into (19.105), where $\boldsymbol{\beta} = (\beta_x, \beta_y)$ is the wave vector and $\boldsymbol{x} = (x, y)$. One then obtains

$$\omega = \pm\kappa|\boldsymbol{\beta}|^2 \quad \Longrightarrow \quad v_{\text{phase}} = \kappa|\boldsymbol{\beta}|\,. \tag{19.108}$$

In other words, high-frequency waves travel faster than those at lower frequency. This can be seen in Fig. 19.39, where given an initial raised cosine impulse the disturbance gradually spreads, with the high-frequency components leading those of lower frequency.

It is now possible to derive a rough estimate of the number of modes up to a certain frequency. For simply supported conditions, in fact, the allowed frequencies can be written as [19.23]

$$f_{p_x,p_y} = \frac{\pi\kappa}{2L^2}\left(p_x^2 + p_y^2\right) \quad \text{with} \quad p_x, p_y = 1, \ldots\,. \tag{19.109}$$

Counting the number of modes N_{modes} as the area of the quarter of a circle of radius $|\boldsymbol{p}|$ gives an estimate of the modes below a certain frequency, f, in the limit as $f \to \infty$

$$N_{\text{modes}}(f) = \frac{fL^2}{2\kappa}\,. \tag{19.110}$$

Thus, the number of modes for the system scales linearly with the frequency, and the mode density is therefore constant. This can be seen in Fig. 19.40, where a typical spectrum for a clamped plate is shown. This feature of a very even response, lacking in early reflections, is at the heart of the characteristic sound of plate reverberation devices.

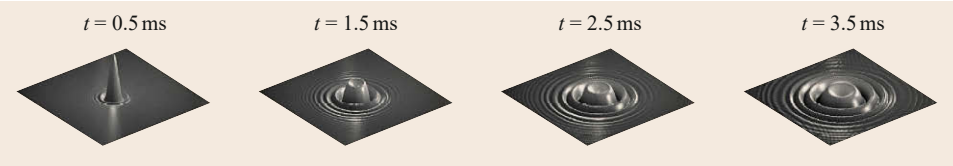

Fig. 19.39 Evolution of the displacement of a simply supported plate at times as indicated. The plate has stiffness coefficient $\kappa = 0.5\,\mathrm{m}^2/\mathrm{s}$ and $L = 1.2\,\mathrm{m}$. The initial condition is a raised cosine distribution at the center of the plate. The dispersive behavior of (19.105) is apparent

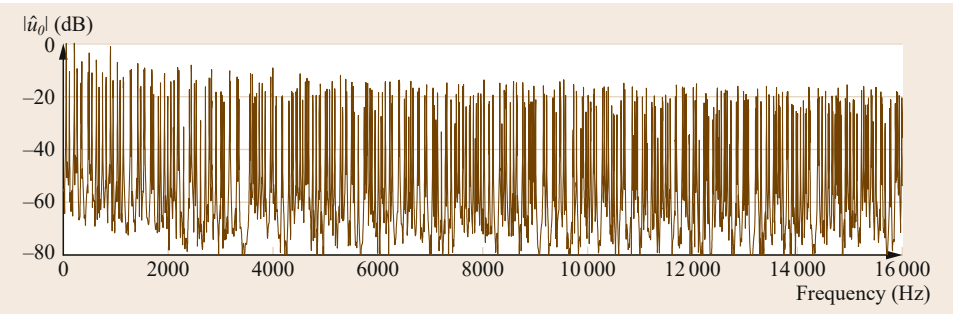

Fig. 19.40 Output spectrum for a square, thin plate with $\kappa = 10\,\mathrm{m}^2/\mathrm{s}$ and $L = 1\,\mathrm{m}$. An even distribution of modes at all frequencies is apparent

19.5.2 A Simple Finite-Difference Scheme

A simple finite-difference scheme for (19.105) can be obtained by introducing a grid function $u^n_{l_x,l_y}$ over a 2-D grid with grid spacing h (see Sect. 19.4.2) and by substituting continuous differential operators with discrete operators. Thus, one can write

$$\begin{aligned} \delta_{tt} u^n_{l_x,l_y} &= -\kappa^2 \delta_{\Delta,\Delta} u^n_{l_x,l_y}\,, \\ \delta_{\Delta,\Delta} &= \delta^{(2)}_{\Delta}\delta^{(2)}_{\Delta}\,, \end{aligned} \tag{19.111}$$

where the discrete biharmonic operator $\delta_{\Delta,\Delta}$ can be obtained by squaring the Laplacian operator $\delta^{(2)}_{\Delta}$ introduced in the previous section.

When expanded at an interior point, (19.111) takes the following form

$$\begin{aligned} u^{n+1}_{l_x,l_y} = {} & \left(2 - 20\mu^2\right) u^n_{l_x,l_y} \\ & + 8\mu^2 \left(u^n_{l_x,l_y+1} + u^n_{l_x,l_y-1} + u^n_{l_x+1,l_y} + u^n_{l_x-1,l_y}\right) \\ & - 2\mu^2 \left(u^n_{l_x+1,l_y+1} + u^n_{l_x-1,l_y+1} + u^n_{l_x+1,l_y-1} \right. \\ & \qquad \left. + u^n_{l_x-1,l_y-1}\right) \\ & - \mu^2 \left(u^n_{l_x,l_y+2} + u^n_{l_x,l_y-2} + u^n_{l_x+2,l_y} + u^n_{l_x-2,l_y}\right) \\ & - u^{n-1}_{l_x,l_y}\,, \end{aligned} \tag{19.112}$$

where $\mu = k\kappa/h^2$ is a dimensionless parameter, which will be restricted by stability conditions, as shown below, in a similar way to the case of the 2-D wave equation. The stencil for the spatial biharmonic operator $\delta_{\Delta,\Delta}$ is shown in Fig. 19.41a, together with the normalized weights of the various grid points, while the space-time update is shown in Fig. 19.41b.

It is possible to apply energy analysis techniques in order to obtain a numerical expression for the boundary conditions (19.107). The interested reader is referred to [19.17] for details. Regardless of the particular choice of boundary conditions, however, the scheme (19.111) can always be written in a vector-matrix form

$$\begin{aligned} \boldsymbol{u}^{n+1} &= \mathbf{B}\boldsymbol{u}^n - \boldsymbol{u}^{n-1}, \\ \mathbf{B} &= 2\mathbf{I} - \kappa^2 k^2 \mathbf{G}\,, \end{aligned} \tag{19.113}$$

where the biharmonic matrix $\mathbf{G}$ can be obtained by multiplying together two Laplacian matrices defined in Sect. 19.4.3. In the free case, particular attention must be paid to modifying the entries of the matrix $\mathbf{G}$ corresponding to the points near the boundaries.

Stability Conditions and Numerical Dispersion

Stability conditions for the scheme (19.111) can be easily obtained via von Neumann analysis techniques. The amplification polynomial can be found by inserting a test function

$$u^n_{l_x,l_y} = z^n\, \mathrm{e}^{j(\beta_x l_x h + \beta_y l_y h)}$$

into (19.111). This gives

$$z + 16\mu^2 (s_x + s_y)^2 - 2 + z^{-1} = 0\,, \tag{19.114}$$

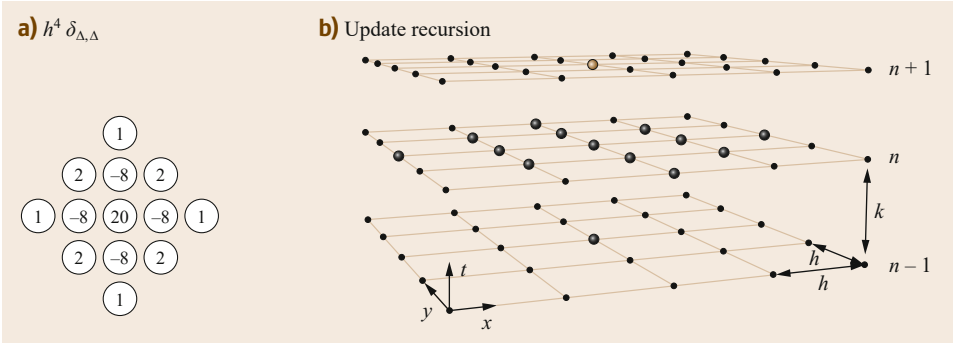

Fig. 19.41 **(a)** Stencil for the biharmonic operator $\delta_{\Delta,\Delta}$, scaled by a factor h^4. **(b)** Recursion stencil for the scheme (19.112). The update for the *highlighted point* at $n+1$ depends on the known values of the *gray* points at n and $n-1$

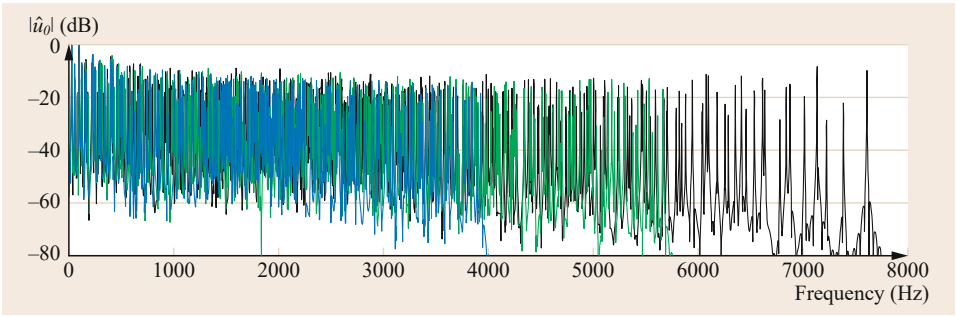

Fig. 19.42 Spectrum of the output given a raised cosine initial velocity at the center of a clamped, square plate with $L = 1\,\mathrm{m}$. The parameter μ was set as $\mu = \mu_{\max}$ (*black*), $\mu = 0.9\mu_{\max}$ (*green*) and $\mu = 0.7\mu_{\max}$ (*blue*). Also visible in the upper part of the spectrum is a decreasing density of modes due to numerical dispersion errors

where $z = \mathrm{e}^{(\sigma+j\omega)k}$, $s_x = \sin^2(\beta_x h/2)$ and $s_y = \sin^2(\beta_y h/2)$. In order for the solutions to be bounded at all times, the following conditions must be imposed

$$0 \le 4\mu^2(s_x + s_y) \le 1\,, \tag{19.115}$$

which ultimately lead to bounds on μ and h

$$\mu \le \mu_{\max} = \frac{1}{4} \Longrightarrow h \ge h_{\min} = 2\sqrt{\kappa k}\,. \tag{19.116}$$

Ideally, under stable conditions, one should recover the continuous relation (19.108) but, in practice, numerical errors always appear. The numerical dispersion relation, in fact, can be written as

$$\omega = \pm\frac{2}{k}\sin^{-1}\left[2\mu\left(s_x + s_y\right)\right]. \tag{19.117}$$

Note that, as in all the systems presented previously, the numerical dispersion relation depends on the parameter μ. Choosing values of μ far from the stability limit $\mu_{\max} = 1/4$ progressively reduces the bandwidth of the scheme. See Fig. 19.42 for an example.

Figure 19.43 shows the relative phase velocity (the ratio between numerical and theoretical values) for the Cartesian scheme. It is apparent that the phase velocity

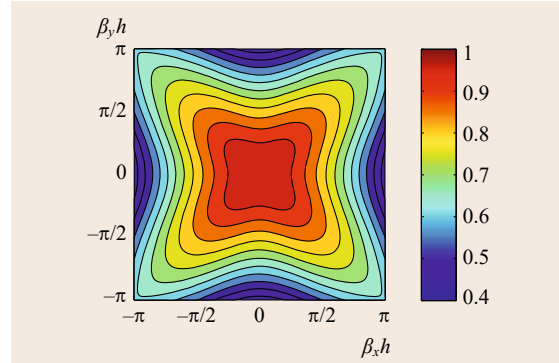

Fig. 19.43 Relative phase velocity for the numerical scheme (19.111) as a function of $\boldsymbol{\beta} \in [-\pi/h, \pi/h] \times [-\pi/h, \pi/h]$, with contours marking 5% deviations

differs from that of the model system even at relatively low frequencies. Note that this numerical dispersion is independent from the original dispersive behavior of the plate equation (19.105).

Another consideration concerns the isotropy of the numerical scheme. As can be noted from Fig. 19.43, contrary to the continuous case, the simple finite-difference scheme (19.111) exhibits a strong dependence on direction, with errors accumulating in partic-

ular along the grid directions. This is easily understood if one considers the anisotropy of the numerical Laplacian, which is now amplified by squaring the operator. One possible way to improve the behavior of the simulation is to use implicit schemes, which require the solution of a linear system, as has been carried out in the case of the wave equation scheme in Sect. 19.4. See [19.72, 73] for additional details.

19.6 Extensions to Nonlinear Systems

This chapter is intended as an introduction to finite-difference schemes for a variety of systems in musical acoustics. The systems covered here are basic, but very much representative – the construction techniques presented here can be applied to much wider classes of systems, incorporating many effects necessary for modeling real-world systems.

The systems examined here are all linear. In recent years, however, nonlinear effects in musical instruments have seen a great increase in interest in a variety of different settings, and time-stepping methods of a form similar to those presented here have been used. It should be obvious, though, that frequency-domain stability analysis along the lines of von Neumann must be ruled out in this case; much more powerful methods are based on the use of numerical energy conservation principles, which have not been discussed in this chapter. In virtually all cases, however, such construction techniques lead, in the nonlinear case, to implicit designs, and thus one can expect more computational work as a result.

One important family of nonlinearities is associated with geometrical nonlinearity in solid structures. Examples include string vibration under so-called tension modulation nonlinearity, allowing for the reproduction of effects such as pitch glides under high amplitude plucking excitation [19.74]. More detailed models of strings include longitudinal-transverse coupling, leading to the production of so-called phantom partials [19.75] in piano tones, which can also be approached using such methods [19.76, 77]. The simulation of nonlinear plate and shell vibration in 2-D can also be carried out using such methods [19.78], allowing for the rendering of effects such as crashes in gongs [19.79].

Another type of nonlinear behavior quite common in musical instrument acoustics involves collision, either of a lumped object with a distributed resonator (as in the case of hammer or mallet excitation) [19.11], or more involved collision between a distributed component with a barrier, as in the case of the sitar or tanpura [19.80] or a guitar string against a fretboard [19.81], and even the collision between two fully distributed components, as in the case of a wire vibrating against a membrane in the case of a snare drum. Finite-difference time-domain methods are also suited to such systems – a great variety of systems and related numerical schemes are described in [19.82]. The main distinguishing feature of numerical methods in this case is the reliance on iterative solvers such as the Newton–Raphson method.

Perhaps the most difficult nonlinearity to deal with, numerically, is that which is associated with high-amplitude playing in brass instruments, leading to increases in brightness due to shock wave formation [19.83]. Numerical methods associated with shock capturing have a long history in the mainstream numerical simulation community [19.84]; finite volume methods, which are closely related to the finite-difference schemes presented here are often used [19.85]. Numerical schemes of relevance in musical acoustics applications have been proposed recently [19.86].

20. Real-Time Signal Processing on Field Programmable Gate Array Hardware

Florian Pfeifle

Over the last 50 years, advances in high-speed digital signal processing (DSP) and numerical methods for audio signal processing in general were fueled by the rising processing capabilities of personal computers (PCs). Added to this was the advent of specialized coprocessing platforms like general purpose graphics processing units (GPGPUs), central processing unit (CPU)-based accelerators like Intel's Xeon Phi platforms as well as high-performance digital signal processing (DSP) chips like Analog Devices' TigerSHARC. Still, there are applications that are not realizable on the mentioned devices in real time or even close to real time. This chapter gives an introduction to field programmable gate array (FPGA) hardware, a flexible computing platform with massively parallel logic capability that is applicable for problems of high data throughput, high clock rates and high parallelism. After an introduction to the basic structure of FPGAs, several features that enable high-throughput DSP applications are highlighted. An introduction to development platforms as well as the development methodology is given, along with an overview of current FPGA devices and their specific capabilities. Two application examples and an outlook and summary complete this chapter.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_20

20.1 Overview

Sometime in October 2013 the number of mobile devices equaled the number of humans on planet Earth. This means we have more than 7.4 billion mobile phones, portable computers or other gadgets on our planet, not including the vast amount of nonmobile digital devices, and this number is constantly rising [20.1]. In every single one of them some sort of digital signal processing (DSP) takes place. Take for instance a mobile phone where we have a microphone that transfers the pressure variations in air to an electric signal, which is then transformed to a digital signal by an analog-to-digital converter (ADC). The digitized signal is then processed, converted again, and sent via the phone's antenna to a mobile phone mast where it is transfered to another cell phone. This example should illustrate how we are constantly surrounded by small or large devices performing DSP operations without our direct interaction and that DSP applications have become an important part of our daily lives.

In the humanities, especially in systematic musicology and related research areas, the application of DSP methods for recording, processing, analyzing and auralizing acoustic music or speech signals has become indispensable and is a central component of a musicologist's toolbox. This is mainly due to the rising computational throughput of standard personal computers and easily accessible accelerators like DSP chips or GPUs. Nonetheless, there are certain restrictions when using classical hardware devices to compute signal processing methods. One huge and very annoying problem is sample latency introduced by a digital system in a music processing tool-chain. Another problem is the high data throughput of modern high-sample-rate, multichannel audio and/or video streams, which stretches the computational capacity of common hardware devices. Field programmable gate arrays, being equipped with massively parallel logic circuitry, can be used to minimize or even dissolve the aforementioned bottlenecks.

This chapter tries to elucidate the usage of field programmable gate array (FPGA) hardware for high-throughput high-sample-rate problems, gives an introduction to FPGAs and shows some design practices that have been shown to yield good results when applied to signal processing algorithms. The focus is put on a real-time applicability of DSP implementations in recent FPGA platforms and hardware and the structural features that enable this functionality, as well as certain design aspects of hardware models for signal processing applications.

20.1.1 Technology Overview

The umbrella term digital signal processing is commonly used as a description for conceptually comparable numerical methods that are mainly concerned with measuring, digitizing, processing and evaluating analog signals using digital hardware systems of varying kinds. DSP techniques and appliances are used in numerous areas of engineering including measurement and control systems [20.2], analysis applications in medical imaging [20.3] and audio processing applications [20.4] as software synthesizer or digital hardware effect units [20.5, 6].

Despite the varied application areas of DSP techniques there are several conjoining properties regarding the respective processing steps. In its basic form, the processing chain in most DSP applications can be summarized as: (1) An analog signal of some sort is (2) digitized using an ADC, which leads to a one- or multidimensional array of (3) discrete values, which represent the analog signal. (4) The digitized values are subject to some kind of numerical processing like filtering or analyzing. (5) After the data-processing step, the values are transformed to a humanly comprehensible representation like a graphic depiction on some scale or (6) are converted back to an analog signal again using a digital-to-analog converter (DAC). This basic processing chain is depicted in Fig. 20.1.

A practical example could be a digital effects unit with an integrated spectral analyzer. Here, a physical value, like the alternating current produced by an electronic guitar pickup, is converted to a digital representation via an ADC. In a further processing step, the frequency content of the digitized guitar signal is analyzed using a spectral transform. Finally the results of the frequency analysis are depicted in a graph on a display, representing the frequency content of the signal.

In this not-so far-fetched example the throughput of the system depends on three factors at least: the sampling rate i. e., the acquisition of discrete values; the latency of the numerical method; and the latency introduced by the data representation method. Depending on the respective DSP application, one of these three stages can act as a bottleneck for data throughput. This is one of the reasons that highly optimized and specialized DSP chips, like the high-throughput series of Analog Devices' TigerSHARC processor or Texas Instruments' C66x series chips, are applied when signal processing operations are used in timing-critical, high-data-throughput applications.

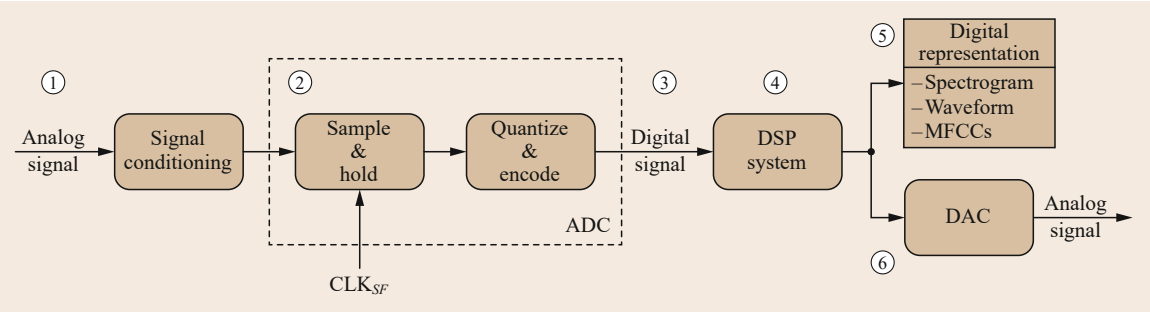

Fig. 20.1 A schematic view of a DSP chain

Getting back to our example, imagine that now 500 channels should be analyzed at once, or the system should be able to sample the input with a sample rate of several MHz. This somewhat contrived example should illustrate that, as electronic systems are getting ever more elaborate, there are applications that are not realizable with feasible effort using conventional DSP chips.

As a subclass of microprocessors with a Harvard memory architecture, DSPs are specifically designed for serial signal processing applications. This means they are especially well suited for high throughput rates in algorithm-intensive computations. In particular, they are very well adapted to perform sequential multiply-and-accumulate (MAC) operations on discrete data streams. This means that the only way to create parallelization would be to use multiple DSPs, but this practice would become unpractical very quickly due to the rising interface complexity and the additional power demands of multiple DSPs.

Using FPGAs – programmable devices with massively parallel hardware logic – for such tasks has been shown to provide a valid alternative for DSP applications where parallel processing power or high sample rates are needed.

FPGAs are applied in various fields of engineering and information technology, as well as other scientific areas for appliances with particular requirements regarding interface flexibility, computational throughput or unusual circuit structure. In integrated hardware designs they are utilized as special function chips for glue-logic (interface-logic), specialized computation cores or design-specific function registers. FPGAs can be found as processing cores in sound cards as a replacement for DSP chips or as processing cores of high-accuracy high-sample-rate oscilloscopes.

By applying FPGA hardware, it is possible to accelerate certain classes of DSP applications, thus making them realizable on a single hardware chip or enhancing their real-time capabilities. This is mainly due to the parallel and flexible hardware layout of FPGA chips. This means that a specialized design can be realized on a FPGA without the constraints of a certain processor architecture like the common *Harvard* architecture used in many DSP chips or the *von Neumann* architecture found in many other microprocessor designs – as a historical side note it is necessary to mention that the *von Neumann* architecture, named after the Hungarian-American scientist John von Neumann, was used in an earlier computer design by *Konrad Zuse* in his Z1 computer [20.7]. Every conceivable form of logic circuit is realizable with a FPGA depending only on the size and the logic capabilities of the FPGA hardware device. When designing for FPGA hardware, it is possible to have control over implementation details from a comparably high abstraction level down to the bare metal implementation on the FPGA chip itself. Unlike other platforms, where certain steps in the development cycle are hardly accessible (like compile-time optimizations) or assessable (like undefined runtime behavior of a software implementation on a PC due to unknown scheduling behavior of an operating system), freely programmable logic devices make it possible to have control over every last part of an algorithm.

Another benefit of FPGA implementations, which is an important deliberation in current high-performance computing applications, is their comparably low power profile. When comparing implementations of algorithms on GPUs, CPUs and FPGAs the number of instructions per Watt are orders of magnitude better in FPGAs [20.8]. On the other side of the performance spectrum, low-power FPGAs could play a central role in small intelligent devices used in the Internet of things or in the growing do-it-yourself (DIY) electronics community where open-source hardware projects are gaining a lot of interest on crowd-funding platforms. An example of a crowd-funded programmable hardware board is the *Snickerdoodle*, which has a FPGA with an included microprocessor on a development board.

20.2 Digital Binary Logic

Binary digital logic is the building block of all logic devices used today ranging from *plain* circuitry like small music chips in children's books, digital watches, or control hardware in cars, to more elaborate designs as found in microprocessors, graphics cards or CPUs of modern personal computers. In this chapter a short introduction and a small amount of background information regarding binary logic is given.

20.2.1 History of Binary Logic

One of the earliest philosophical and mathematical contemplations regarding binary logic in the European science tradition was published by *Gottfried Wilhelm von Leibnitz* (1646–1716) [20.9]. In this treatise he describes a binary number system, using the values 0 and 1, and develops rules for four fundamental algebraic operations: addition, subtraction, multiplication and division. In the same text, he relates this number system to the hexagram figures found in the ancient Chinese scripture *I-Ching* [20.10, pp.117]. A comparable algebraic system as used for the binary number system published by Leibniz was developed almost two centuries later by *George Boole* (1815–1864) in his two publications [20.11, 12]. Contrary to modern belief, it was not exclusively developed for *binary* number systems but was a general description of an algebra of logic [20.13], aimed at extending Aristotelean syllogism [20.14]. Nonetheless, it was shown in the 1930s in the master's thesis of *Claude Shannon* that the formal logic calculus of Boole could be applied to describe and construct electric circuits using algebraic (mathematical) means [20.15]. Nowadays, the binary logic system is applied as the basis for all digital logic devices. In honor of George Boole, its appertaining calculus is called Boolean algebra or, as proposed by Shannon, switching algebra. Similar to a decimal number system, the binary number system is a positional number system that allows the representation of numbers as position-relative digits of powers of two.

Using Boolean algebra, complex algorithms can be represented in digital hardware by using only two discrete states: 1 and 0. When dependent on formal logic they can also be interpreted as two logical truth values: *true* and *false*. In physical terms this can be related to an open or closed switch, a flowing current versus a nonflowing current or a high and low voltage level as shown in [20.15]. In modern digital systems the two logical values 1 and 0 are commonly realized by high and low voltages using specific transistor circuits, which are called logic gates.

20.2.2 Binary Logic

The fundamental algebraic functions that can be expressed in binary logic are logic conjunction *AND*, logic disjunction *OR*, exclusive disjunction *XOR* and logic negation *NOT*. Combining the negation with the other logic functions gives *NAND*, *NOR* and *XNOR*. Written in a truth table, two-input logic gates can produce the outputs given in Table 20.1.

20.2.3 Binary Logic in Hardware

The logical values given in Table 20.1 are the building blocks of digital circuitry of FPGA hardware as well as all other digital hardware chips. Depending on the device and on the vendor, there are different methods for how binary logic is realized in hardware. Early hardware systems used relays as on/off switches, as for instance used in *Konrad Zuses*' Z3 computer [20.7]. Another technique used in the first computers was electron tubes, as for instance in the code deciphering machine *Colossus* [20.16]. During the 1950s the large, error-prone electron tubes were gradually replaced by transistors, which were smaller and required less energy [20.17, pp. 65–75]. Modern integrated chips almost exclusively use transistor circuits to yield the logic values given in Table 20.1. The underlying design may differ depending on the type of the transistor, but their overall yield is the logic values given in Table 20.1. This means that the logic functions of a transistor circuit can be viewed on a more abstract level by only taking the logic value into consideration and moving structural design considerations to a lower abstraction layer.

A logic gate representation of basic Boolean algebra functions in gate logic is given in Fig. 20.2. The plain combination of two logic inputs can be extended

Table 20.1 Logic values for two-input (P,Q) Boolean functions

P	Q	AND (∧)	OR (∨)	XOR (⊕)	NAND	NOR	XNOR
0	0	0	0	0	1	1	1
0	1	0	1	1	1	0	0
1	0	0	1	1	1	0	0
1	1	1	1	0	0	0	1

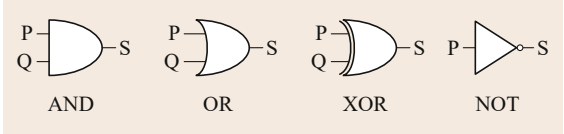

Fig. 20.2 Basic logic operations in gate logic

to more complex circuity if one wants to model an algebraic function of higher order using a data type that is wider than 2 bit. This means that complex functions can be realized by an interconnection of multiple basic gates. Indeed, modern microchips are based on simple logic gates made of transistors but are so complex that they can have up to several billion transistors on one die. Using the equivalent representations of Fig. 20.2 and Table 20.1 logic circuitry can be constructed by applying rules of Boolean algebra. To implement a 2 bit adder one can start by writing down the inputs and the outputs of the respective circuit and truth table.

By inspecting the output values and comparing them with the truth table given in Table 20.1 it is clear that the output signal S can be realized with an *XOR* gate and the output C_{Out} by an *AND*. An equivalent representation of this circuit using logic gates is given in Fig. 20.3.

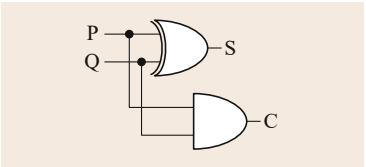

Fig. 20.3 An equivalent logic gate representation of the binary adder given in Table 20.2

Table 20.2 Truth table of a binary adder with input signals P and Q, output S and carry output C

P	Q	S	C_{out}
0	0	0	0
0	1	1	0
1	0	1	0
1	1	0	1

20.2.4 Number Systems in Digital Hardware

Besides the algebraic implementation details of an algorithm in hardware, another important factor that influences a system's throughput is the number representation in the digital domain. As will be shown in Sect. 20.3, the choice of the right data type can speed up and/or optimize the throughput of a signal processing method considerably.

In DSP applications and on dedicated DSP hardware chips there are several standard data types and some not-so-standard data types, which can be used to represent digitized signals. All data types can be divided in two main classes: (a) fixed-point and (b) floating-point. Because FPGAs are freely programmable logic chips, the data type is not fixed upfront but can be chosen according to the respective type of application. On the one hand, this flexibility allows for highly specialized design decisions, but on the other hand it can lead to a heightened development expense because different data types have to be assessed regarding their applicability for a certain problem before the actual design phase.

Fixed-Point Number Representation

Fixed-point data types are commonly used in older DSP hardware as well as in low-power devices, which do not have a floating-point unit. Their strength lies in their simplicity, as the number representation is amenable to representation by binary digital hardware. As a rule of thumb one can state that in comparison to floating-point, fixed-point arithmetic is faster but lacks the dynamic range of floating-point. This means if an application calls for a large data range floating-point should be preferred, otherwise one is most likely to get the better performance out of a fixed-point implementation.

There are several fixed-point data types used to represent numbers in binary code. They can be divided into:

- Unsigned integer representations
- Signed integer representations.

Table 20.3 shows a 4 bit representation of several numbers in signed and unsigned formats.

As given in Table 20.3, the data range of unsigned is 0 to $2^N - 1$, with N the bit width. One's complement (1C) can represent data in the range of $-2^{N-1} + 1$ to $2^{N-1} - 1$; two's complement (2C) in the range -2^{N-1} to $2^{N-1} - 1$.

One's complement numbers have a bit-by-bit complement representation of positive and negative values, and this includes the redundant representation for -0. This means the inversion can be realized in logic by replacing every bit by its logical inverse using a *NOT* gate as illustrated in following short example.

$$\begin{aligned} 1011 &= -4 \\ 0100 &= 4 \end{aligned} \tag{20.1}$$

The inversion of 2C numbers is comparable to the 1C inversion but needs an additional step: an addition of 1 to the inverted number.

$$\begin{aligned} 1011 &= -5 \\ 0100 &= 4 | + 1 \\ 0101 &= 5 \end{aligned}$$

A feature that makes 2C numbers the most widely used fixed-point signed number representation in digital hardware is the property that when summing 2C numbers, all overflows of intermediate computations can be ignored as long as the final sum is in the bit range N.

Table 20.3 Comparison of unsigned, signed one's complement, and two's complement data types

Bit values	Unsigned	One's complement	Two's complement
1000	8	−7	−8
1001	9	−6	−7
1010	10	−5	−6
1110	14	−1	−2
1111	15	−0	−1
0000	0	0	0
0001	1	1	1
0010	2	2	2
0011	3	3	3
0100	4	4	4
0111	7	7	7

Floating-Point Number Representation

In most modern DSP applications that are implemented on a PC, numbers are represented by the floating-point number system. Most recent microprocessors and CPUs have a dedicated floating-point unit, which performs optimized floating-point arithmetic. The number system which is defined in the IEEE-754 (Institute of Electrical and Electronic Engineering) standard was designed to represent numbers over a large range, making it possible to represent values in several magnitudes by using only small bit sizes. One drawback of the this large range is the resolution inside the range, which follows a nonlinear distribution. Smaller numbers have a higher resolution than the larger ones. Floating-point number representation can be imagined as a special type of logarithmic number representation. Computations with logarithms, multiplication, division and exponentiation are comparably easier to perform than additions or subtractions. This is why they are often used for scientific calculations where values from a large range should be representable and the multiplication operation is important. A floating-point number consists of a sign bit S, an exponent E and an unsigned mantissa M and is structured as

20.3 FPGA – A Structural Overview

To fully understand the particular features that enable FPGAs to be the highly versatile, high-performance processors of choice for DSP and other areas of scientific computations today, an overview of structural design aspects is presented in this section. A short overview of their historical evolution is given and the associated design changes that are essential for the understanding of modern FPGA chips are highlighted. A focus is put on hardware features that are convenient for signal processing applications. In particular, features that can be used in real-time audio processing applications are of concern here. Additionally, several input/output (I/O) protocols are presented to illustrate how communication with FPGA hardware can be realized.

20.3.1 History of FPGAs

The historic development of FPGA devices is closely linked to the evolution of integrated digital circuits in the late 1960s, 1970s and early 1980s. The development of logic devices of that time period was mainly driven by the manifold advances in transistor and integrated circuit technologies. For an encompassing overview see for instance [20.18].

Custom logic devices of that time period can roughly be divided into two categories:

1. Programmable logic devices (PLDs)
2. Nonprogrammable devices like application-specific integrated circuits (ASICs) or application-specific standard parts (ASSPs).

The difference between both device classes can be found in their central structure. PLDs are only partially wired, whereas logic functions of ASICs are hardwired in the production process. This means that a specific function of an ASIC is *fixed* and cannot be altered by a designer after the production state, while a PLD can be programmed later.

These fundamental differences lead to differing design and implementation practices and thus to differing fields of applications. In comparison to PLDs, ASICs have a higher logic gate count and are mainly used to implement highly specialized functions, but have the drawback of long production cycles for implementation, prototyping and debugging. If an ASIC has inherent design errors, they often surface *after* a first prototype is manufactured and the appliance is running under realistic conditions in the respective field of application. PLDs and programmable read-only memory (PROMS) devices can be programmed after the production state, which has the advantage that a faulty chip design does not lead to a completely erroneous production charge. Still, compared to most ASICs, PLDs have considerably smaller logic capabilities.

The first programmable devices had a transistor array structure that could be flashed with different logic

circuit designs by adding connections (antifuse technology) [20.18, p. 12], or removing connections (fusible link technology) [20.18, p. 10]. The added or removed links were permanent, so the devices could only be programmed once. Due to this, they were capable of performing specially designed tasks with very high clock rates, but they could not be reconfigured after a design was implemented on the device.

Further advances in the field of programmable integrated circuits led to technologies that made it possible to erase an initial design and reprogram the device. The most prominent technologies among these devices are erasable programmable read-only memory (EPROM) or electrically erasable PROM (EEPROM). Devices incorporating these technologies could be programmed and reprogrammed multiple times by removing the connections of the design on the metal layer by exposing it to ultraviolet light or to a certain voltage respectively.

Up to this point, there always existed a gap between the logic capabilities of the different hardware device classes. On the one hand there were PLDs, which were highly configurable but could only perform a small amount of logical tasks, and on the other hand there were ASICS, which could perform highly complex logic circuits but were not reconfigurable, and were expensive and demanding to develop for.

The next large leap in the evolution of freely programmable hardware was sparked by research done by Ross Freeman and Bernard Vonderschmitt, the founders of Xilinx, who were the first to develop and produce freely programmable hardware-gate logic on a large scale [20.19]. In 1985 the first commercially available programmable logic chip was the XC2064, called a FPGA. Field programmable literally means programmable in the field, outside of the laboratory. The name FPGA is still used today for logic devices of similar design structure and logic capabilities. The first FPGA device had 64 programmable and freely connectible logic blocks (CLBs) and an aggregate gate count of 1200 logic gates, modern FPGAs, like a Virtex-7 for instance, often contain several million logic blocks. FPGAs were developed as a devices that combined the programmability of PLDs, the reconfigurability of EEPROMS, and the high logic-gate count of ASICS [20.18, pp. 49 ff.]. This period of time is often regarded as the starting point for the development of more advanced FPGA devices by Xilinx and other vendors. At the present day, the biggest FPGA chip vendors are Xilinx and Altera among other smaller companies such as Lattice Semiconductor or Microsemi [20.18, pp. 161 ff.].

The development tools provided by the mentioned vendors helped establish modern FPGAs as highly flexible, programmable hardware platforms, ideal for developing custom high-throughput circuit designs. But this is only part of their strength: modern FPGAs have evolved from the plain logic devices of early days so tremendously that they are now able to host multiple high-performance microprocessor architectures on one chip [20.20]. In addition to the flexibility of the freely programmable logic, the mix of on-board memory resources and additional special function logic blocks enhanced the capabilities of FPGA devices but also increased the complexity of the design process. This means that the full potential can only be realized if the special, massively parallel, chip structure is fully utilized in a design.

A more recent development in FPGA technology is the acquisition of Altera, the second largest FPGA vendor, by Intel and the announced cooperation between IBM and Xilinx in 2015. This follows a current trend in high-performance computing and data-center-based cloud computing applications that focuses on flexible, energy-efficient infrastructure, which is planned to be realized by a proposed combination of CPUs and FPGAs in servers as well as in user devices [20.21, 22].

20.3.2 Structural Layout of FPGA Hardware

In modern FPGA devices logic gate functionality is realized by look-up tables (LUTs) (LUTs are also called logic function generators [20.23, p. 2 ff.]), which are, in a sense, addressable function generators. This means that they can be programmed to perform different logic functions on a set of inputs.

These basic logic cells are part of a larger logic conjunction, which is called a *slice* in Xilinx devices. All slices contain one LUT, eight storage elements, multiplexers and carry logic [20.24]. Some Xilinx slices, called *slicem* [20.24], additionally contain functions to store data as distributed random access memory (RAM) and have 32 bit-wide shift registers.

Two slices form a configurable logic block (CLB), as is depicted in Fig. 20.4. It shows a (LUT)-based CLB, as commonly found in Xilinx FPGAs. Earlier Xilinx FPGAs, such as the Virex-II pro, contained LUTs with four inputs. Newer Virtex-7 devices have configurable six-input LUTs.

The LUTs inside a CLB can operate in several different input/output modes depending on the device class and generation. In addition to being connectible as six-input two-output LUTs, they can be configured as shift registers, RAM blocks or first-in/first-out memory. In some CLBs there are additional latches and in others are flip-flop cells [20.24], which can be used as asynchronous or synchronous registers.

The outputs of the single CLBs are connected to a programmable interconnection network, which is at-

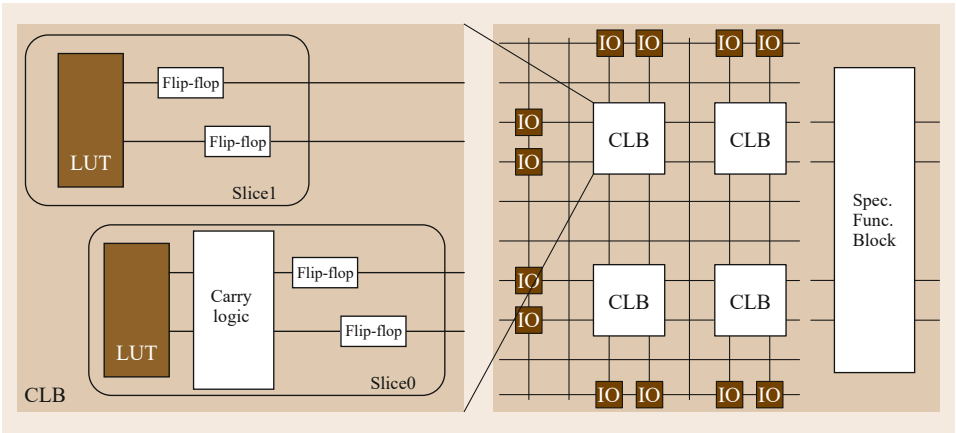

Fig. 20.4 Schematic overview of a FPGA showing an exploded view of a CLB, the interconnect network, in/out ports and special function registers

tached to a multiplexer on the output stages, multiplexing output signals to input stages of other CLBs. This cascading of CLBs allows for more complex logic functions, larger RAM blocks or longer shift registers.

In Altera devices, the large-scale structure of basic logic units is comparable to Xilinx setups, but differs in several stages of internal structure. The equivalent of a Xilinx CLB in a Stratix-V is called a *logic array block*, which contains 10 *adaptive logic modules* (ALMs) [20.25]. Each ALM is composed of two LUTs, each with six inputs. In addition to this, an ALM can contain extra logic, like programmable registers or full adders. How the input/output routing of an ALM is configured depends on the mode of operation of an ALM:

- Normal mode: Two functions in one ALM with up to eight inputs or one function with six inputs are realizable.
- Extended LUT mode: Conditional if-else statements are realizable with seven inputs and one input for register packing.
- Arithmetic mode: The internal adder or other arithmetic functions like counters or accumulators can be implemented.
- Shared arithmetic mode: The ALM functions as a three-input adder or carry bit circuit.

20.3.3 Special Function Blocks

Besides the basic logic cells, FPGAs contain other functional logic blocks that differ from vendor to vendor and from device generation to device generation. Some additional logic blocks that are typically found in most modern FPGAs are memory blocks in the form of random access memory (RAM), first in/first out (FIFO) memory blocks or other kinds of unregistered or registered memory. Logic blocks that extend basic FPGA logic by integrated circuit implementations of arithmetic function are for instance DSP blocks with integrated MAC circuitry. All special function blocks are on the FPGA die in close proximity to the logic gate resources and can be connected to the same high-speed interconnection network the core logic is connected to, as is shown in Fig. 20.4.

In modern Xilinx FPGAs the CLBs and the special function blocks are arranged in a column layout. Figure 20.5 depicts a schematic overview of the arrangement of DSP48e1, block RAM (BRAM) and logic slices.

DSP Blocks

Most modern FPGAs by the vendors Xilinx or Altera have special logic blocks that are designed to perform DSP typical operations. They are implemented on the same structural level as CLBs, which means that the data transfer between gate-based logic and DSP cores can be realized by the high-speed interconnect network.

Figure 20.6 depicts a schematic overview of a DSP48e1 slice, which is part of most modern Xilinx FPGAs. It consists of four inputs, a pre-adder, a 25 bit × 18 bit multiplier, a 48 bit accumulator and a pattern detector that can be used to efficiently compare values.

To derive benefit from the fast MAC operation there are several guidelines when designing with DSP

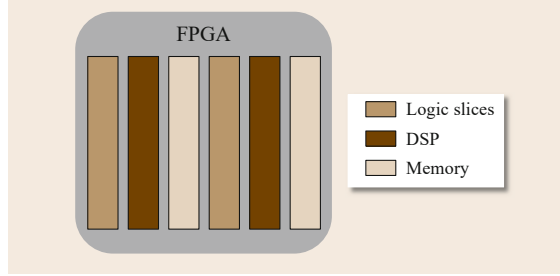

Fig. 20.5 Schematic overview of Xilinx column design

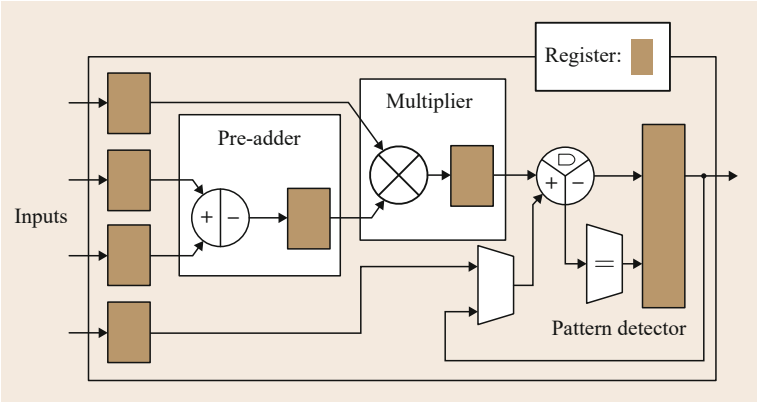

Fig. 20.6 Schematic overview of a Virtex-6 DSP48e1. *Blue blocks* are registers

blocks that, when followed, can lead to highly performant algorithms. To obtain optimal results, several recommendations for using DSP48E1 slices in a design should be followed, which include:

- Filter coefficients or constant multiplicands are best stored in a BRAM block.
- If possible, the design should be pipelined.
- Using a fixed-point signed data type yields the highest throughput.
- Small multipliers should be implemented in CLB logic.
- A time-multiplexed design should be implemented if applicable.

If all these recommendations can be followed and the design makes use of all DSP slices, it is possible to achieve a sustained throughput of several TMACS (tera multiply-and-accumulates per second) on modern FPGA devices.

RAM Blocks

Another important factor when designing DSP applications on FPGAs is the availability of memory resources. In modern Xilinx devices RAM can be implemented by combining several CLBs, which is called distributed RAM or DisRAM. Another sort of dedicated RAM on Virtex FPGAs is called block RAM (BRAM). It can be configured to different sizes and different function modes. Every BRAM block can perform in dual-port mode facilitating 36 Kb of memory. A similar dedicated RAM is present in Altera devices and is called a M20 memory block.

Table 20.4 Comparison of Xilinx FPGA generations

FPGA device	Slices	Logic cells	Max. RAM (kB)	Max. DSP slices
Virtex-II Pro	44 096	99 216	1378	444[a]
Virtex-5	51 840	331 776	3420	192
Virtex-6	118 560	758 584	8280	2016
Virtex-7	305 400	1 954 560	67 680	3600
Virtex-Ultrascale		5 541 000	132 900	5520
Virtex-Ultrascale+		3 763 000	354 500	11 904

[a] Number of integrated 18 × 18 bit multipliers

Table 20.5 Comparison of several Altera FPGA generations

FPGA device	Logic cells	Max. RAM (kB)	Max. DSP blocks	18 × 18 wide mults.
Max 10	50 000	1638	–	144
Cyclone-4	150 000	6480	–	360
Stratix-IV	813 000	33 300	–	1288
Stratix-V	952 000	51 670	1963	3926
Stratix-10	5 510 000	166 000	5760	11 520[a]

[a] The Stratix-10 has 18 × 19 multipliers

Both configurable memory blocks can be used as memory of variable bit width and depth. Similar to the DSP blocks, the special RAM blocks are located on the FPGA chip and are connected to the CLBs via the internal routing network, which makes the communication and data transfer faster compared to communication with a peripheral RAM, which can be implemented on a hardware board connected to the FPGAs I/Os; see Fig. 20.5.

Tables 20.4 and 20.5 show the available DSP block and memory resources of different device generations from Xilinx and Altera.

20.4 Hardware Description Language (HDL)

In the early years of programmable hardware (the 1960s), digital logic circuits were designed, similar to analog electronic circuits, using pencil and paper. Gate-level logic functions, analogous to those shown in Fig. 20.2, were drawn and optimized by hand before being implemented in hardware. An advance in design methodology was the development of hardware description languages (HDLs), which were used to describe hardware functions on a syntactically higher abstraction level. Early versions of HDLs were used in the 1960 to describe functional parts of logic devices on a gate level. It was not until the late 1980s that HDLs began to replace the practice of schematic-based design of the increasingly complex ASIC circuitry of the time [20.26]. During the first stages of their development, the functionality and language design of HDLs were not standardized and most functions were vendor- and application-hardware-specific.

Today, there coexists two commonly applied hardware implementation methodologies for FPGA designs. One is more related to the older design techniques, but instead of using pencil and paper drawings a computer-aided design (CAD) program is used to draw schematic versions of a hardware implementation. This means it is possible to develop a schematic of connected logic gates, logic blocks or special function registers representing a special function of a hardware implementation. The other practice uses a HDL to describe the functionality of the hardware circuit [20.27]. There are two standardized HDLs commonly used in FPGA design: (1) Verilog and (2) VHDL (very high speed integrated circuit hardware description language). Both languages incorporate similar concepts, which can be categorized into *low-level* programming features like:

- Bitwise declaration of signals
- Control over electronic signal levels
- A direct access to electronic signals via physical input and output ports of the hardware development board.

and *high-level* language concepts like for instance:

- Object-oriented programming techniques
- Pointers to data types
- Procedural programming.

among other features.

To describe the complete range of functions of VHDL is far beyond the scope of this chapter and the interested reader is referred to the excellent publications regarding this subject area such as [20.28] or one of the other encompassing introductions to VHDL that can be found in [20.29–31].

Nonetheless, a few basic traits and characteristics shall be explained here. One fundamental differences of a HDL compared to other programming languages is the trait that it enables the developer to directly design hardware functionality using software statements. This means that lexical instruction are represented by gate logic equivalents on the respective hardware platform. Another difference, which is a regular pitfall for engineers with programming experience in a *high-level* language, is the fact that all code is evaluated concurrently. This means that instead of sequential code evaluation like in a compiled high-level language (C, C++, Java, Python, etc.) all instructions in the code are translated into a hardware function and evaluated at the same clock instance, if not specifically designed otherwise. Sequential statements can be implemented by a finite state machine (FSM).

20.4.1 Finite State Machine

A FSM is a clocked sequential circuit that switches its discrete states depending on the value of certain status signals. Therefore, sequential statements that need to be evaluated successively can be controlled in a synchronized way. There are different standard implementations of FSMs commonly used in hardware designs. The two most prominent are known as [20.32]:

1. Moore finite state machine – a state machine where the output only depends on the state
2. Mealy finite state machine – a state machine where the output depends on the state and an input signal.

In a real design implementation both FSM architectures can be mixed and distinguish themselves mostly by their underlying implementation in binary logic.

As an example of a FSM-controlled circuit take for instance the model of a signal generator that is able to generate sine, rectangular or triangular waves controlled by three switches. This means we have three switches that are on (1) or off (0). If two or three switches are simultaneously (1) then the output should be that of the last state. Figure 20.7 shows a FSM depiction of the single states.

20.4.2 VHDL Structure

A hardware model expressed in VHDL consists of several building blocks that follow a certain structure. The topmost level of a VHDL program is called an *entity*. An *entity* is a description of a circuit performing a certain logic function. An *entity* in VHDL can be seen as a box performing a certain logic function. It can consist of several input and output ports and has an embedded functionality defined inside the *entity*. An *entity* declaration of a 2 bit adder as presented in Sect. 20.2 can be formulated as shown in Fig. 20.8.

The example given in Fig. 20.8 shows the basic structure of an *entity* declaration with two input ports P and Q, and two output ports: S, the sum, and C, the carry bit. The functional behavior of an *entity* is defined inside its *architecture*. The body of the architecture consists of instructions that describe the logic functions of an *entity*. When describing the functional behavior of an *entity*, there are two fundamental design strategies, which can be labeled as: (a) structural modeling and (b) behavioral modeling. Approach (a) leads to a design that performs its function as a result of several substructures, which are *entities* as well. These substructures can be abstract components performing certain logic functions; by connecting several substructures a larger logic circuit can be realized. Approach (b) is a series of instructions that perform a certain logic function. It is comparable to functional programming in a high-level language, and in VHDL the functions are realized by several independent processes that perform the specific function. An architecture body following the entity declared in Fig. 20.8 can be constructed using the two logic gates given in Table 20.2. The two gates can be implemented as separate entities following design approach (b). A functional description of an *AND* gate and *XOR* gate can be written as shown in Fig. 20.9.

Combining both logic gates declared in Fig. 20.9 the *architecture* of the 2 bit adder can be realized following design approach (a) as presented in Fig. 20.10

Figure 20.10 connects the declared logic ports to execute the function of a binary adder.

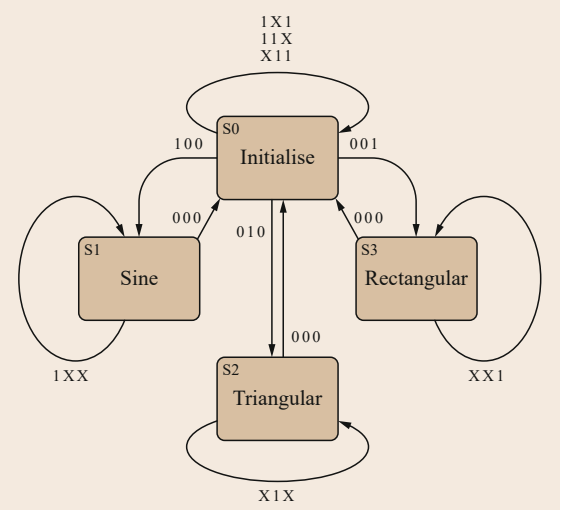

Fig. 20.7 A finite state machine of a simple signal generator. The binary values beside the arrows indicate the position of the three switches. X indicates a *don't care* value, meaning either binary value is possible

20.4.3 Design Flow I: Register Transfer Level (RTL)-Based Designs

Designing a hardware model for a FPGA consists of several steps resulting in a specific design flow. In contrast to the development cycle of *high-level* language implementations there are several significant differences when coding for FPGA hardware. The design flow for hardware models can be divided into six different steps:

1. Design a hardware model in VHDL or by a RTL schematic.
2. Synthesize the model for a certain FPGA hardware chip.
3. Perform a functional simulation of the synthesized system with a VHDL simulation environment.
4. Debug the code using the simulation tool and the synthesis reports. If the model works as expected proceed, otherwise go to step 1.

```
1 entity add2B is
2   port(
3     P : in bit;
4     Q : in bit;
5     S : out bit;
6     C : out bit
7   );
8 end entity add2B;
```

   and2Process : process is
   begin
     Sa <= Pa and Qa after 3 ns;
     wait on Pa, Qa;
   end process and2Process;
  end architecture behavioural;

entity xor2 is
   port(
     Px : in bit;
     Qx : in bit;
     Sx : out bit
);

architecture behavioural of xor2 is
begin
   xor2Process : process is
   begin
     Sx <= Px xor Ox after 3 ns;
     wait on Px, Qx;
  end process xor2Process;
end architecture behavioural;
```

Fig. 20.9 An *entity* and *architecture* declaration of an *AND* and *XOR* gate

5. Perform placing and routing of the model for FPGA hardware.
6. Perform a timing simulation. If the timing is as expected proceed, otherwise go to step 4.
7. Create and flash a binary file (bit file) to the specific hardware.

Alongside the functional description of the model, in VHDL source code the place and route process (5) routes external ports to internal buses and vice versa. The declaration of the signal I/O ports is put into a ucf, a *user constraint file*. Here, all input and output signals are routed to the respective hardware addresses of the respective FPGA board.

20.4.4 Design Flow II: Intellectual Property (IP) Core-Based Designs

When following the design process outlined in Fig. 20.11 the efficiency of the resulting hardware model depends to a large extent on the designer's

```
entity add2B is

   );
  end component xor2;

begin
    gateAND : and2
    port map (
        Pa => P,
        Qa => Q,
        Sa => C
        );

    gateXOR : xor2
    port map (
        Px => P,
        Qx => Q,
        Sx => S
        );
end architecture behavioural;
```

Fig. 20.10 An *entity* and *architecture* declaration of a 2 bit adder

knowledge of the FPGA he is designing for. In the early days of FPGA programming, when the devices where smaller and a developer could remember each logic gate by its name, this design approach was state-of-the-art even for *larger* hardware models. Newer device generations have several magnitudes more dedicated logic and additional special functionalities, so this approach is becoming more and more unpractical for larger heterogeneous designs. Therefore modern design approaches rely on core-based implementations.

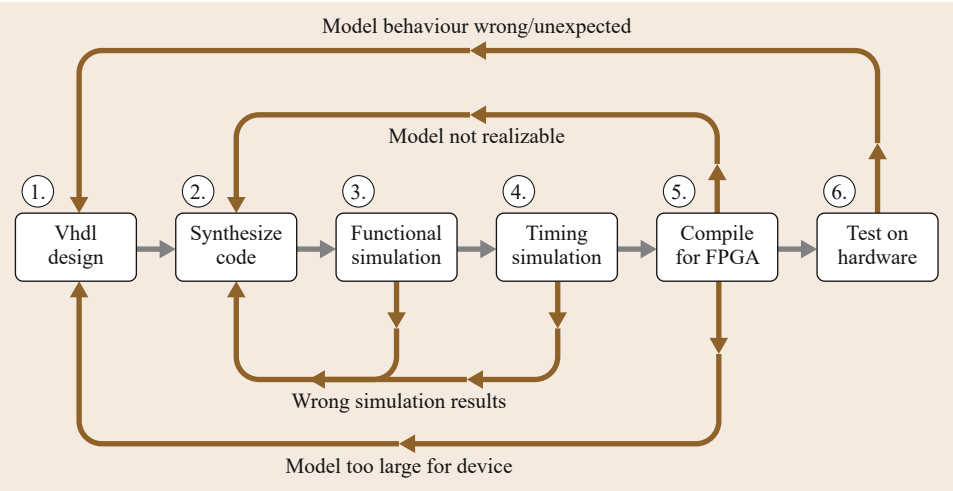

Fig. 20.11 Implementation cycle for FPGA design. The *gray path* indicates successful completion of the preceding step, *brown paths* indicate an error in the respective step

This means, instead of implementing a model from scratch and treating the FPGA as a cluster of freely programmable logic gates, this second design strategy employs reusable HDL blocks called intellectual property (IP) cores, which are *black boxes* accomplishing certain defined functionalities. On a structural level, they are comparable to software libraries of high-level languages, like the Fourier-transform library FFTW (Fastest Fourier Transform in the West) or a linear equation solver library like BLAS (Basic Linear Algebra Subprograms). IP cores facilitate code reutilization and can minimize model design and implementation time, because they are tested and provide defined I/O behavior. There exist IP cores for multiple different problem areas and they are provided by many different vendors. In addition to commercially available IP cores there exist freely available open-source IP cores for various problems. For signal processing applications there are cores like FIR/IIR (finite impulse response/infinite impulse response) filter designs, various transforms like Fourier-transform or Hadamart-transform cores as well as linear algebra cores.

20.5 FPGA Hardware Overview

Alongside a comparable evolution of other digital hardware platforms, the computational throughput and processing power of FPGA chips has evolved drastically over the last 30 years. From the earliest devices, like the Xilinx XC2064-33 containing 64 logic blocks, to modern devices, like the XCVU440, which includes about 4.4 million logic cells and has a throughput in the TMACS range for systolic, symmetric FIR filters using a fixed-point data type, FPGA designs have become a viable solutions in modern high-performance computing (HPC) as well as in data-center applications. This section gives an overview of several FPGA chips and a comparison regarding their applicability to DSP problems. Thereafter, two FPGA hardware development boards are presented with a focus on additional on-board hardware extensions that can be used in DSP design.

20.6 FPGA Chips

In their early years ($\approx$ 1984–1991), FPGA were mainly used as flexible glue logic devices connecting and interfacing logic components in larger, more complex system. Nowadays, FPGA chips are sophisticated systems themselves, which can consist of various hardware extensions, such as distributed arithmetic, soft/hard microprocessor cores, and distributed memory resources, in addition to the basic programmable logic. Thus, a modern FPGA can effectively be seen as a heterogeneous computing platform on one chip.

The structural differences between FPGA chip generations and different chip classes more or less define their general fields of application. For DSP-centric designs there are four logic resources that affect

the throughput of computationally demanding algorithms.

Besides the raw number of logic gates, there are three logic blocks that are of central interest in DSP designs: (1) internal RAM, (2) hard-wired multipliers and (3) DSP logic blocks like the *DSP48* or DSP48e1 slice in Xilinx devices or the *variable precision DSP blocks* in Altera devices. An overview of the availability of these blocks gives a first global view of the capabilities of a FPGA chip for DSP applications.

To this end, an overview of some FPGA devices by the two main vendors, Xilinx and Altera, is given. A focus is put on the processing capabilities of the FPGA devices for DSP-centric applications:

- *Xilinx devices* Table 20.4 gives an overview of several recent and not-so-recent FPGA devices by the manufacturer Xilinx.
- *Xilinx Virtex-II Pro* The Virtex-II Pro was released in 1998 and incorporated several features that were different to other FPGA devices of that time, one being the possibility of programming the chip via an USB (Universal Serial Bus) port from a standard PC with a point-to-point flash protocol JTAG (Joint Tag Action Group). As such, it was the first easily programmable FPGA chip commercially available. The maximal logic resources of a Virtex-II Pro are presented in Table 20.4.
- *Xilinx Virtex-6* A more recent FPGA device, which is part of a design presented in Sect. 20.8, is the Virtex-6 FPGA. It contains multiple integrated hardware components like peripheral component interconnect express (PCIe) blocks, high-speed transceivers and, compared to older devices, enhanced DSP resources. The logic resources available on a Virtex-6 device that are utilized in this work are summarized in Table 20.4.
- *Xilinx Ultrascale+* The Ultrascale+ FPGA is the most powerful Xilinx FPGA device available at the time of writing. As can be seen from Table 20.4 it contains up to 11 904 specialized DSP blocks and a larger amount of high-speed connectible RAM. When running in an optimal design and at maximum clock rates, it is possible to perform ≈ 21 TMACS.
- *Altera Devices* The devices listed in Table 20.5 give an overview of several generations of FPGA devices by Altera. There are only minor differences regarding the nomenclature of FPGA parts of this manufacturer.

  The largest of the Altera devices, the Stratix-10, has a computational throughput of 23 TMACS for fixed-point data and 9.2 TFLOPS (tera floating point operations per second) for a single precision floating-point data type. From Tables 20.4 and 20.5, it can be seen that the number of dedicated DSP slices rises with each device generation, indicating the importance of the high-performance signal processing applicability of FPGA devices. Extrapolating this trend onto future devices and future hardware generations, FPGAs will continue to be viable alternatives for high-performance DSP applications.

20.6.1 Development Boards

In this section an overview of FPGA development boards of different vendors is given. A focus is put on the applicability of the respective board to DSP-centric applications. Hardware development boards exist for most FPGA chips of different generations. They are constructed to test implementations of hardware models on a FPGA including surrounding hardware, because, in addition to the chip itself, there are different peripheral hardware devices available on a development board. The number and type of external hardware on a development board depends on the respective vendor and on the application for which this board is manufactured.

Available in most boards is some sort of on-board flash memory, several user programmable inputs/outputs, a clock circuitry and a communication protocol interface to interact with a FPGA. Hardware development boards include some sort of programming interface to a flash FPGA from a computer or from an internally available flash ROM card. Additional on-board hardware can be high-speed input/output connectors, special clock circuitry, DA/AD converters or high-speed communication protocol ports, a structural overview of a FPGA development board is depicted in Fig. 20.12. The development boards presented here are only a small selection of the vast range of different hardware development test boards and acts as an overview of possible configurations of a hardware system. The Nexys video trainer board is a FPGA development board that includes an on-board 24 bit DA/AD converter. It consists of an Artix-7 FPGA chip extended by multiple hardware components like an USB host controller or an Ethernet connection. It can be programmed via an USB connection and has several freely programmable switches and buttons. A development board of the Virtex-6 family is the *ML-605 evaluation board*, which is a development platform for high-speed communication and signal processing appliances built around a Virtex-6 chip. The on-board features include an PCIe controller, double data rate (DDR) RAM, a small display and several I/O proto-

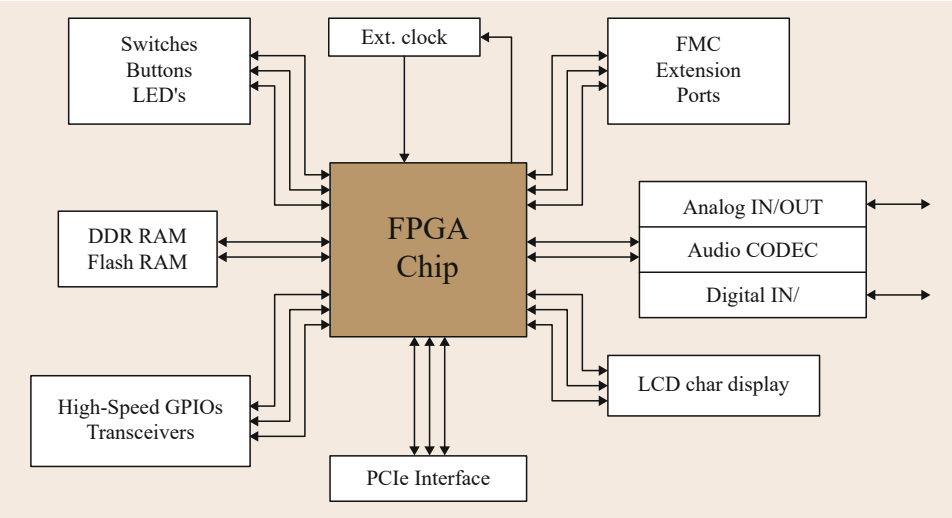

Fig. 20.12 Schematic overview of a FPGA development board

Table 20.6 Overview of several development boards

Name	FPGA device	On-board hardware	Interconnections
Nexys video	Artix-7	24 bit audio codec[a], DDR RAM	USB, ethernet, switches
ML-605	Virtex-6 XC6VLX240T	DDR RAM	FMC Interface, PCIe, ethernet

Stratix V ASD kit	2 Stratix V	DDR RAM	FMC interface, PCIe 3.0, USB

[a] codec = coder decoder

col ports. It can be extended by FPGA mezzanine card (FMC) daughter boards with other hardware devices, Table 20.6 summarizes features of several development boards.

20.7 Interfacing With a FPGA

The flexibility of FPGA devices is due to their free programmability and their flexible input/output capabilities realized through general purpose I/O ports. Depending on the architecture and the generation of the FPGA hardware, I/O ports are connected to the logic gates of the chip and can be accessed directly from a hardware design. They can either be routed to external devices or to other hardware blocks on a development board. In modern Xilinx devices the I/O ports are called *SelectIO*s and are configurable regarding their output voltage, slew rate and on-chip termination. The I/Os are divided into high-performance and high-range I/Os. The former can be used to interface with high-speed devices like memory or chip-to-chip connections; the latter facilitates a higher voltage range. Modern Xilinx devices facilitate interconnections that transmit data in the gigabytes per second range allowing for connections to PCIe 3.0 devices or 100 Gb LAN (local-area network) standards as well as many others. Other transceiver standards are realizable as well allowing connections to SPI (serial peripheral interface) buses, I2S (inter-IC sound) devices, or SATA (serial advanced technology attachment) connections.

20.7.1 LM4550-AC'97 CODEC

For DSP applications with an analog audio input or output an audio chip must be interfaced with the FPGA hardware. The Texas Instruments LM4550 chip provides an AC'97 protocol-compliant converter. In some development boards it is hardwired to programmable input/output ports of the FPGA and can thus be connected to FPGA logic resources using the serial AC'97 Rev. 2.1 communication protocol. Even though AC'97 protocol-compliant codecs are not state of the art anymore, as they have been replaced by newer protocols like Intel's HD Audio, they are still used in several newer development boards in the lower price segment.

The signals connected to a hardware model consist of:

- SDATA_IN : Signal from the microphone/line input of the converter
- BIT_CLK : Serial data clock
- SYNC : Synchronization bit to synchronize data frames
- SDATA_OUT : Output data sent to converter
- RESET : System-wide reset signal for cold and soft reset.

All signals are processed at a clock speed of 12 288 MHz by the master clock signal BIT_CLOCK. The SYNC signal subdivides the transmission protocol line into frames of 20.8 µs (20.8 µs = 1 /48 000 Hz) length with one tag slot of 16 bit length and 12 data slots of 20 bit length each. A decomposed serial data frame is depicted in Fig. 20.13.

Depending on the direction of the SDATA signal, slot numbers 1 and 2 contain command and status signals respectively. The following two slots contain PCM-coded data. Depending on the transmission mode and the implementation of the AC'97 protocol, the slots named RSV, which stands for reserved, contain PCM, status or control data.

As one can see, the AC'97 protocol makes use of a time-division-multiplex data transfer. The serialization of the parallel data is pipelined in the core module of the AC'97 interface design. The BIT_CLOCK signal is the master clock for the parallelization timing as well as the serialization of the data.

20.7.2 I2S Interface

Another interface protocol for communication between different hardware chips used in many signal processing appliances is the I2S interface protocol. Compared to the AC'97, the I2S protocol is more simplistic having a much smaller protocol overhead and thus is less demanding on hardware resources. Especially in newer audio chips or in in DIY minicomputers like the Raspberry Pi 2, it is used to transmit/receive pulse code modulation (PCM)-coded audio data. The I2S is a protocol specified by Philips semiconductors as depicted in Fig. 20.14.

Compared to the other serial protocols, I2S communication is performed in full duplex using a master/slave architecture. The master is either the data transmitter or the receiver. A schematic overview of a transmitter and receiver interaction is depicted in Fig. 20.14 in the upper left corner with the signal timing at the bottom.

At each device, a transceiver circuit is implemented to route and process the datastream from one device to the other device.

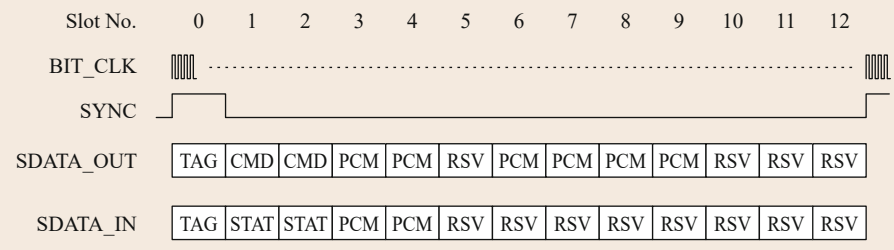

Fig. 20.13 AC'97 protocol signal overview

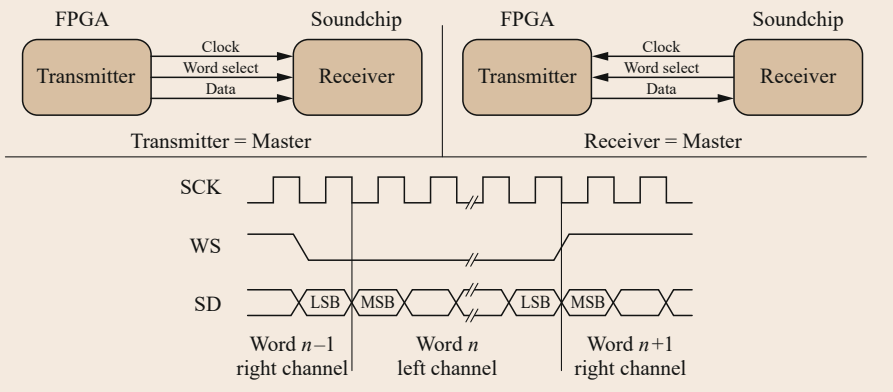

Fig. 20.14 I2S system configuration consisting of one transmitter and one receiver. The timing diagram illustrates the serial data transmission of a stereo signal

20.7.3 PCIe Interface

A commonly used high-speed input/output protocol, which is implemented in many modern FPGA boards in the high-performance range, is a peripheral component interface express (peripheral component interface express) interface. In a DSP-centric application design, the PCIe port can be used to transfer data between a hardware implementation of a DSP algorithm on a FPGA board (device) and a graphical user interface (GUI) running on a personal computer (host). In this section, an introduction to the basic functionalities of the PCIe protocol and a short overview of a example implementation, including a communication protocol, is given.

20.7.4 PCIe Fundamentals

In 2002, the PCI interest group, known as the PCI-Sig consortium, which consists of 900 hardware and software companies, published the first specifications of the PCIe protocol, as an extension to the already-established PCI and PCI-X protocols [20.33]. The basic protocol has undergone several revisions, at the point of writing it has version number 3.1 with 4.0 and 5.0 architectures already published [20.34]. Today, the PCIe interface is a de facto standard interface for high data throughput communication of peripheral devices, exchanging data with the central processing unit in personal computers [20.33]. One of the most notable differences of the PCIe interface compared to the older PCI and PCI-X protocols is the serial structure of the data transfer lanes, instead of the prior parallel structure. Another feature that discerns these protocols is the point-to-point communication of PCIe, enabling the bus to handle higher clock rates without protocol overhead of bus arbitration, found for instance in the original PCI protocol specification [20.35, pp. 134]. The maximum data transfer rates that can be achieved with a PCIe 3.0 interface are $\approx 16\,\mathrm{GB/s}$ [20.33]. In the presented models, the utilized PCIe interface is a version 2.1 revision with a 4x lane interface configuration. The maximal data rate including the 10 b/8 b protocol overhead is approximately $2\,\mathrm{Gb/s}$. Communication with the GUI running on the personal computer is achieved by implementing a Windows RAM driver, writing configuration data to the FPGA board and receiving sound data from the FPGA board.

20.7.5 PCIe Protocol Timing

The timing of the PCIe protocol depends on the type of PCIe connection type and the version. The bandwidth for the PCIe 2.0 implementation used in many development boards has a link speed of approximately $16\,\mathrm{GB/s}$ for a 16x connection. The Xilinx ML605 board for instance has a PCIe 2.0 8x link with a maximal transmission speed of $4\,\mathrm{GB/s}$. Because any real system has additional overhead added by the operating system driver and PCIe protocol overhead, the raw bit rate is mostly smaller. The communication protocol overhead and resulting effective bit rate has to be assessed upfront to decide if the data-rate is sufficient for the implemented hardware design.

20.7.6 Further FPGA Design Considerations

When implementing algorithms in hardware there are several guidelines that can be applied to help decide if a speedup is to be expected by using a programmable hardware platform like a FPGA. A number of practical principles developed for computational biology are published in [20.36]. They are aimed at describing general design patterns so they can be applied to DSP algorithms as well.

Two central questions regarding a hardware implementation of an algorithm are:

(*a*) Can the computations be expressed in a manner that is appropriate for FPGA hardware?
(*b*) Does the algorithm allow for the use of a suitable data type that leads to an optimized form of an algorithm?

Regarding point (a) there are several traits of a computational method that can facilitate speedups on FPGA hardware but the most important questions are: *Can my algorithm be parallelized*?, and *To what extend can it be parallelized*? If your answers are *Yes*! and *A lot*!, only then can you harness the full potential given by the massively parallel hardware facilities of FPGAs. Another question regarding point (a) is whether the algorithm can be expressed without too many conditional branches (for instance *if-else-case* instructions). Nested code cannot easily be transferred to FPGA hardware and it is important to assess if an algorithm can be simplified in this regard.

Regarding point (b), large speedups can be expected if the data can be represented with a data type that enables bit width reductions without losing accuracy. If for instance a fixed-point data type with a small bit width suffices for a certain operation there are data-type specific simplifications that can be used to speed up algebraic operations.

The flexible structure of FPGAs allows for arbitrarily arranged signals that are not bound to the 16/32/64 bit of half, single or double precision of most modern digital hardware that uses a floating-point representation. Another central advantage of FPGA hard-

ware over more closed hardware solutions is the complete control over every part of an implementation and the resulting possibilities of optimization at the core level of an algorithm. This can be of concern when a sample-accurate algorithm is sought after, and the exact predictability of the sample throughput of a system is important. Using timing simulations, a hardware implementation can be tracked with clock cycle accuracy and implemented on hardware, guaranteeing the same accuracy.

20.8 Real-Time DSP Applications

As mentioned in the introduction and the preceding sections, FPGAs have been shown to perform quite well for different kinds of DSP applications. A comprehensive overview of DSP methods on FPGAs in general can be found in [20.37] and in [20.38]. Both publications stress the advantages of FPGAs due to their flexible nature compared to other computing devices but also show the pitfalls when designing DSP applications for hardware. A rule of thumb for hardware implementations of algorithms is: The more an algorithm can be condensed to its core functionality, the more efficient a hardware model is and the faster and more effective it can perform its tasks in hardware implementations [20.39, pp. 20 ff].

When using FPGAs to accelerate numerical calculations, one form of optimizing the calculation towards speed can be achieved by parallelization of the underlying algorithm. This has been proven successful for a wide range of different applications, like real-time noise source identification [20.40], high speed direction-of-arrival algorithms [20.41] or delay-sum beam forming [20.42]. Other works using FPGAs for digital signal processing (DSP) applications are published by [20.43], where two-dimensional/three-dimensional (2-D/3-D) plane wave filters are realized by IIR/FIR filters, or the work of [20.44], who focuses on converting analog controllers to digital controllers using filter-design techniques. Similar to the mentioned work, there are several papers proposing methods of implementing DSP filter designs (IIR/FIR) on a FPGA chip [20.45, 46].

The parallel processing capabilities predestine the FPGA to be used in real-time applications [20.28], as shown for example for particle track recognition [20.47], high-speed cross-correlation [20.48] digital beam forming [20.49] among other publications. Real-time filter applications are shown in [20.50] or [20.51]. Other real-time applications are presented in [20.40, 52] or [20.53]. As was shown in the mentioned works, a considerable speedup could be achieved for numerical methods, some of which could be calculated in real time for the first time by fully utilizing the parallel processing capabilities of modern FPGA chips.

In addition to the mentioned papers, focusing on highly specialized topics of signal processing, there are several works using FPGAs to calculate various acoustical phenomena employing finite difference schemes. Among the earliest publications using a FPGA to solve a two-dimensional wave equation with a finite difference time domain (FDTD) method on a FPGA is the work by [20.54]. A physical model of a string implemented on a FPGA was proposed by [20.55]. Other notable publications regarding numerical calculation of the wave equation using finite difference methods are the works of *Erden Motuk*, for example [20.56] or [20.57]. Here, as well as in his thesis [20.58], Motuk utilizes a FDTD algorithm to solve the two-dimensional wave equation for membranes or plates. Other approaches focusing on synthesizing sound on a FPGA are published in [20.59] or [20.55]. A real-time implementation of finite difference models of acoustic instruments is presented in [20.60] and in more detail in [20.61].

20.9 Real-Time Filtering Applications

A central operation of digital signal processing is the application of some type of filter to some kind of signal. Being closely linked to a linear convolution, filtering techniques are applied in a variety of systems using differing design strategies. Applications that make use of a convolution operation can be found in image processing like blurring or enhancing a digital photo, high-frequency applications like signal reconstruction of noisy wireless data transmission, and filtering frequency content of audio signals in a recording studio. In systematic musicology, filtering operations can range from plain applications like amplifying a certain frequency band in a signal using a narrow-band notch filter, to more complex tasks like modeling the mammalian cochlea as a filter bank.

A vast amount of literature has been published regarding basic topics of filtering methods as well as on specialized topics focusing on hardware implementa-

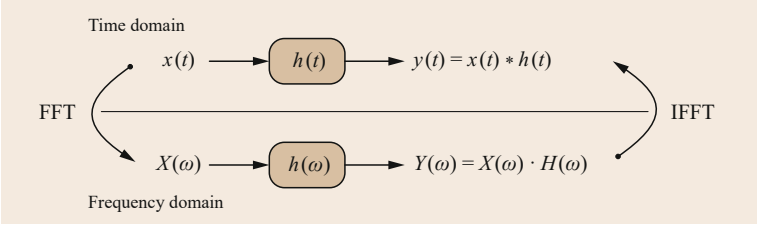

Fig. 20.15 The correspondence between time domain convolution and frequency domain multiplication

tion and acceleration of convolution algorithms. A landmark work, which is often regarded as the hour of birth of modern signal processing, was the rediscovery of the fast Fourier transform (FFT) published by Cooley and Tukey in 1965. The published work revolutionized many digital signal processing methods because of an equivalence, given by the convolution theorem [20.62], which states that a time-domain convolution of two signals can be performed as a multiplication in the frequency domain.

A basic assumption of digital signal processing is that it is possible to describe an analog system as a linear, time-invariant system (LTI system). If we have such an LTI system, the output ($y(t)$) of this system reacting to a certain input ($x(t)$) can be described completely by its impulse response ($h(t)$) in the time domain. In the frequency domain the system is characterized by its transfer function ($H(\omega)$).

Because of this, filtering (convolution) methods can be classified into two main groups, time-domain methods and frequency-domain methods. Modern FPGAs have been shown to perform very well for commonly applied filter designs in the time domain as well as in the frequency domain. In addition to that, the FPGAs' flexible structures and additional on-board DSP resources enable them to perform quite well even for more uncommon filtering approaches like wave digital filters (WDFs) [20.50, 63, 64] or number theoretic transforms (NTTs) [20.37, pp. 401 ff.]. This section tries to elucidate how a modern FPGA can be applied to filtering operations.

20.9.1 Filtering in the Time Domain

The system shown in the upper half of Fig. 20.15 depicts a time-domain convolution operation, where the output signal $y(t)$ is the input $x(t)$ weighted by the systems impulse response $h(t)$. In mathematical terms this is formally defined as

$$y(t) = x(t) * h(t) = \int_{-\infty}^{\infty} h(\tau)x(t-\tau)\delta\tau \; . \qquad (20.2)$$

In the digital domain we are concerned with discrete signals, thus the integral becomes a finite sum. Assumed we have a LTI system, the overall structure remains and can be written as

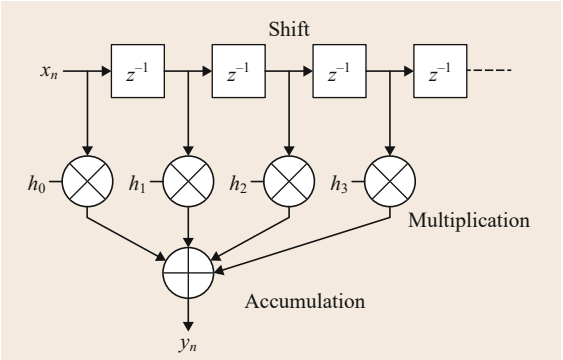

Fig. 20.16 FIR filter design using multipliers, one adder and discrete shifts (z^{-1})

$$y(n) = x(n) * h(n) = \sum_{k=0}^{L-1} h(k)\, x(n-k) \; . \qquad (20.3)$$

Equation 20.3 represents a convolution with a finite impulse response FIR filter of length L. Obviously, the only arithmetic functions needed to perform a convolution are a multiplier and an accumulator, summing the products, see Fig. 20.16 for a schematic block diagram. This procedure is known as multiply-and-accumulate (MAC), a term associated with filtering operations in general.

In addition to this class of filters there exists a second class of filters commonly applied in DSP: infinite impulse response (infinite impulse response) filters. For hardware implementations, both filter classes have certain advantages and disadvantages, which are summarized in Table 20.7.

A literature review on hardware implementations of filter designs shows that most designers prefer FIR filters over IIR filters because of their smaller susceptibility to rounding errors and numerical noise and their easily achievable linear phase. Both DSP blocks presented in Sect. 20.3 are optimized towards high-speed FIR filter designs and are highly adaptable to different filter sizes.

Table 20.7 Comparison of FIR and IIR filter design considerations

Property	FIR filters	IIR filters
Phase	Linear phase is realizable	Normally nonlinear phase
Stability	Nonrecursive FIRs are always stable	Unstable limit cycles are common
Rounding error	High resilience	Very sensitive to rounding errors and numerical noise
Filter size	Large–very large	Small
Coefficient calculation	Complex–very complex	Easy
High-speed designs	Easily realizable	Can be intricate
Pipelined design	Yes	Hard–impossible

FIR Filter Implementation on FPGAs

FIR filters can be implemented on FPGAs using some of the special logic blocks presented in Sect. 20.5. For filter designs, DSP slices can be used to perform additions and multiplications of a filter. To store the coefficients, an on-board RAM should be used. Another recommendation for high-speed filter design on FPGAs is the use of a systolic, i. e., pipelined, filter design, taking symmetry properties of FIR coefficients into account.

Figure 20.17 shows the symmetric characteristic of linear-phase FIR filters. This can be used to minimize

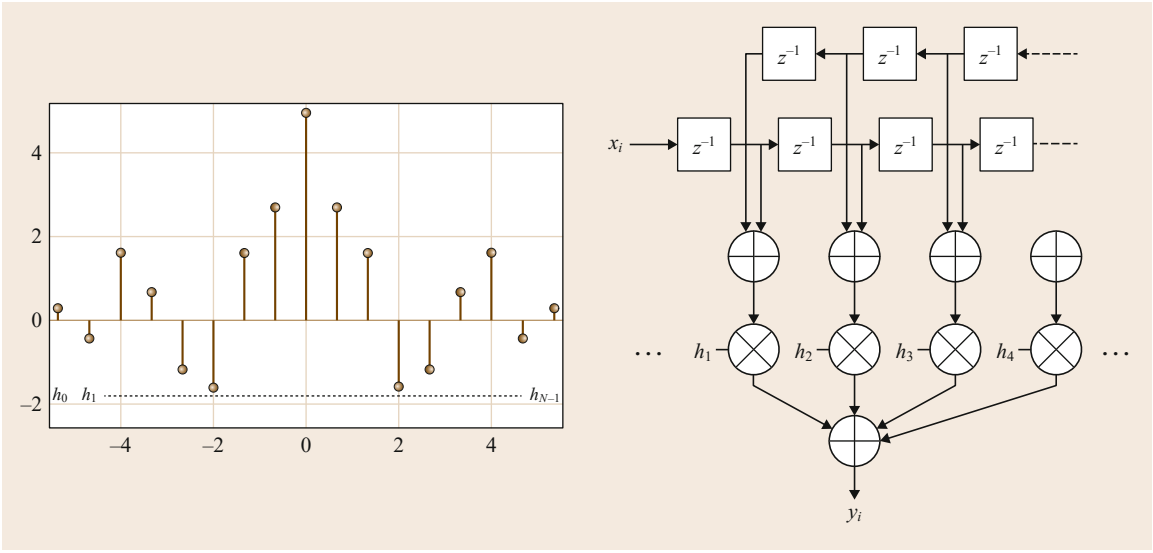

Fig. 20.17 FIR filter design with reduced multipliers making use of the symmetric coefficient structure

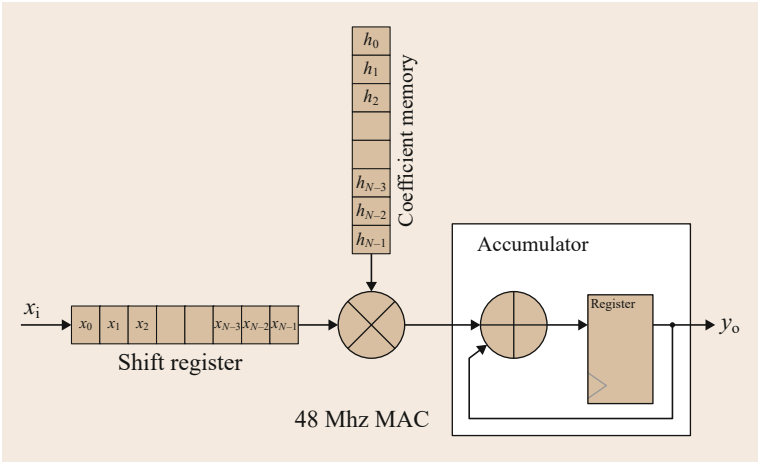

Fig. 20.18 FIR filter that operates at a multiple of the sample rate

the multiplication circuit usage. From the left side of Fig. 20.17, it should be obvious that the filter coefficients are odd symmetric, meaning that $h_0 = h_{N-1}$, $h_1 = h_{N-2}$ and so on. In a Virtex-6 FPGA, this can be realized by using the pre-adder of the DSP48e1 slice (Fig. 20.6). This minimizes the usage of multipliers from $N+1$ to $N/2+1$, with N being the filter order.

Another technique that can be applied to maximize data throughput, especially applicable for filters operating in the audio frequency range, is using a higher clock frequency for the arithmetic operations than the audio sample rate. This is known as oversampling. Take for example an audio signal that is digitized with a sample rate of 48 kHz, then we have a multiplication and accumulation circuit that operates at 48 MHz, which is achievable with most modern FPGAs, and we can process samples with a factor 1000. Figure 20.18 shows a schematic overview of such a system.

20.10 Real-Time Physical Modeling of Large-Scale Geometries

Physical modeling is an established method of simulating acoustic vibrations of musical instruments for sound synthesis purposes [20.65]. One of the large drawbacks of physical modeling methods is the correlation between model accuracy and computational cost. Over the last 30 years a multitude of advances in modeling techniques and in numerical methods in general have paved the way for accurate large-scale models of musical instruments.

Nonetheless, larger models of coupled geometries of musical instruments were not computable in real-time using standard hardware devices and even accelerators like GPGPUs seem to be unpractical for robust real-time synthesis. FPGAs on the other have been shown to be able to compute whole geometry real-time physical models of musical instruments, see for instance [20.60, 66–68] for models of coupled geometries, or [20.57] for a real-time plate physical model on a FPGA.

An introduction to physical modeling for sound synthesis is described in Chap. 19 of this handbook. Other comprehensive considerations regarding general methodologies and techniques can be found in [20.65, 69]. As shown in those works, physical modeling sound synthesis is a robust method for auralizing the vibrations of physically plausible models of musical instruments with high fidelity sound quality. In this section, a real-time implementation of a physical model of an acoustic instrument on a FPGA board is presented. Finite difference (FD) methods are used to discretize the model in the spatial and temporal domain. A focus is put on implementation specifics for FPGA hardware.

20.10.1 Finite Difference Equations of Vibrating Systems

The physical mechanisms that are involved in sound production and propagation in different parts of most musical instruments can be described by partial differential equations (PDEs), particularly the wave equation. Hence, musical instruments can be regarded as systems of coupled PDEs that obey the rules of Newtonian mechanics. As a consequence, all acoustic radiations can be explained by time-varying characteristics of the equations of motion and the interaction of the coupled PDEs. The continuous PDEs that govern Newton's equations of motion for the respective instrument part are discretized using finite difference (FD) operators in the spatial as well as the temporal domain. FD approximations can be derived by using the fundamental theorem of calculus, which states that the derivative of a variable function $u(x)$ along dimension x is defined by taking the limit of a *finite* difference Δx of the dependent variable Δu like

$$u_x = \lim_{\Delta x \to 0} \frac{\Delta u}{\Delta x} \tag{20.4}$$

with u_x indicating a first derivative by x. For nonzero but small Δx this expression can be utilized to approximate a differential as a difference

$$u_x \approx \delta_x u \,, \tag{20.5}$$

with δ_x indicating a centered first-order difference operator by x.

This generalized finite difference operator notation is applied throughout the remainder of this work. It is based on the notation used in works like [20.65, 70, 71].

A discrete shift operator acting on a one-dimensional (1-D) function $\mathbf{u}$ at position x is indicated by τ with

$$\begin{aligned} \tau_{x+}(u(t,x)) &= u(t, x+\Delta x) \\ \tau_{x-}(u(t,x)) &= u(t, x-\Delta x) \,. \end{aligned} \tag{20.6}$$

A difference approximation in the forward $(+)$ and backward $(-)$ direction at position x can be written as

$$\begin{aligned} \delta_{x+}\mathbf{u}|_x &= \frac{1}{\Delta x}(u(x+\Delta x) - u(x)) \\ &= \frac{1}{\Delta x}(\tau_{x+} - 1)\mathbf{u} \\ \delta_{x-}\mathbf{u}|_x &= \frac{1}{\Delta x}(u(x) - u(x-\Delta x)) \\ &= \frac{1}{\Delta x}(1 - \tau_{x-})\mathbf{u} \,. \end{aligned} \tag{20.7}$$

The same can be done in the temporal domain by defining the forward (+) and backward (−) approximation at time instant t as

$$\delta_{t+}\mathbf{u}|_t = \frac{1}{\Delta t}(u(t+\Delta t)-u(t)) = \frac{1}{\Delta t}(\tau_{t+}-1)\mathbf{u}$$
$$\delta_{t-}\mathbf{u}|_t = \frac{1}{\Delta t}(u(t)-u(t-\Delta t)) = \frac{1}{\Delta t}(1-\tau_{t-})\mathbf{u}\,. \tag{20.8}$$

An interesting feature of this operator notation is that higher-order approximations can be achieved by a convolution of lower-order operators. Using (20.7), a second-order centered finite difference operator can be computed by

$$\begin{aligned}\delta_{xx} &= \delta_{x-} * \delta_{x+}\\ &= \left[\frac{1}{\Delta x}(1-\tau_{-1})\right] * \left[\frac{1}{\Delta x}(\tau_{+}-1)\right]\\ &= \frac{1}{\Delta x^2}(\tau_{+}-1-1+\tau_{-})\\ &= \frac{1}{\Delta x^2}(\tau_{-}-2+\tau_{+})\end{aligned} \tag{20.9}$$

with the equivalence $\tau_+\,\tau_- = 1$.

Higher-order operators can be calculated similarly by

$$\delta_{4x} = \delta_{xx} * \delta_{xx}\,. \tag{20.10}$$

Time Integration

The temporal integration of the FD scheme for the presented FPGA implementation is realized with the Newton–Störmer–Verlet integration scheme [20.72]. This scheme was successfully utilized for nonreal-time FD models of a classical guitar [20.73], a violin [20.74], and real-time models like the model of a simplified banjo [20.67] and a whole geometry banjo [20.61]. The dependent variables of this scheme are the displacement u and the velocity v in solid bodies like strings, membranes and soundboards. When calculating air volumes the pressure p, and its first temporal derivative p_t are used. The PDEs used in this treatise conform to the Stäckel condition, meaning that they are separable, hence reducible to systems of coupled DEs of lower order. This can be achieved by introducing the intermediate variable $\mathbf{v}$; the global velocities. Using this it is possible to write the second-order wave equation as

$$\begin{aligned}\dot{\mathbf{v}} &= c^2\,\mathbf{u}_{xx}\\ \dot{\mathbf{u}} &= \mathbf{v}\end{aligned} \tag{20.11}$$

with the wave velocity in the medium c; a material-dependent constant in the linear case. Applying first-order FD operators to (20.12), the discrete scheme for the wave equation can be written as

$$\begin{aligned}\delta_{t+}\mathbf{v} &= c^2\,\delta_{xx}\mathbf{u}\\ \delta_{t+}\mathbf{u} &= \mathbf{v}\,.\end{aligned} \tag{20.12}$$

As is shown in [20.72, 75–77] this form of a simple Newton integrator is symplectic, meaning that the numerical flow is true to the physical flow of the solution. A necessary stability conditions of scheme (20.12) is the Courant–Friedrichs–Levy (CFL) condition [20.78]. For general dimension D it can be written as

$$\Delta t \sum_{i=1}^{D} \frac{c_i}{\Delta x_i} \le \lambda \tag{20.13}$$

with Δt, Δx the discrete temporal and spatial steps, c the velocity of propagation in the medium and λ the CFL number depending on the respective scheme. The basic FD scheme (20.12) for solving the wave equation without dispersion or dissipation has a CFL number $\lambda = 1$. This stability condition changes if damping or higher-order terms, which model stiffness, are included in the formulation. When this stability condition is satisfied, the basic Newton–Störmer–Verlet [20.79] scheme needs no further correction algorithm, unlike the Newton–Raphson alpha method [20.80] for instance, which adds artificial damping to the system to ensure stability.

20.10.2 Discrete FD Operators

An extension to the well-established FD operator notation, used at least since the early 20th century, is presented in this section. The operator notation allows us to abstract several mathematical operations into a simpler notation. In the following, this concept is extended to an even lower abstraction level by resolving the underlying mathematical operations to the specific operations depending on the data type and underlying hardware structure. Assuming a fixed-point data type, a centered finite difference operator can be expressed using

$$\hat{\delta}_x = T_\Delta[\hat{\epsilon}_{\Delta x+}, -\hat{\epsilon}_{\Delta x-}] \tag{20.14}$$

with $\hat{\epsilon}_{\Delta x+/\Delta x-}$ = a read operation from a register, a finite difference cell right (+) or left (-) of the actual cell and T_Δ a multiplicand that depends on the stride of the discrete grid in the spatial domain. A second-order centered FD operator in vector notation can be written as

$$\hat{\delta}_{xx} = T_\Delta[(\hat{\epsilon}_{\Delta x-}), (<1), (\hat{\epsilon}_{\Delta x+})] \tag{20.15}$$

with $T_\Delta = 1/\Delta x$ and (< 1) indicating a shift operation. This shift operation can be used to replace a multiplication by two in fixed-point arithmetic. A higher-order digital FD operator used for the fourth-order differential equation of the beam can be constructed by a convolution of two second-order digital FD operators

$$\hat{\delta}_{4x} = \hat{\delta}_{xx} * \hat{\delta}_{xx} \,. \tag{20.16}$$

This can be extended to higher-spatial-order difference operators leading to a specific numbers of digital operations for the respective operator given in Table 20.8.

Using the values given in Table 20.2, the used resources of a model must be approximated before implementation in hardware.

20.10.3 Finite Difference Physical Modeling on FPGAs

To gain benefit from the structure of FPGA hardware, the FD models introduced here are formulated in a maximal parallel way. As is shown in the derivation of FD methods, central parts of the core computations can be processed in parallel. This is achieved by dividing the spatial domain into parallel node points on a regular grid. The specific configuration of the discrete points of the respective domain enables a concurrent update of every node for every sampling time step. In addition to this parallel structure, the locality of the memory-access patterns are optimized by using spatially local block-RAM (BRAM) registers for every node point. This minimizes memory write/read overhead.

Scheme (20.12) can be split into sequential parts as well as parallel parts. The sequential parts are the calculation of the velocities and the deflections, which are interdependent and thus must be computed serially. On a given geometry, the update of the velocity and the deflection is computed for every discrete point at concurrent time instances. This means that the serial calculations of (20.12) can be done in parallel for every discrete node on the discrete geometry. Figure 20.19 shows an example of a parallel computation of three adjacent points on a string, at positions $k-1$, k and $k+1$ respectively.

Table 20.8 Digital operations for FD operators used in this work

Operator	Reg. Op.	Shift Op.	Mult.	Add./Sub.
$\hat{\delta}_x$	2	0	1	2
$\hat{\delta}_{xx}$	3	1	1	2
$\hat{\delta}_{4x}$	5	4	1	5
$\hat{\delta}_{2x2y}$	5	1	1	4
$\hat{\delta}_{\nabla^4}$	13	10	1	12
$\hat{\delta}_{2x2y2z}$	7	2	1	6

20.10.4 Serial-Parallel Implementation

When implementing more than one geometry model on a FPGA, or when a geometry is so large that it can't be implemented on one chip in parallel, it is possible to calculate parallel kernels shown in Fig. 20.19 several times. The maximum number of computable kernels depends on the sampling rate and on the clock rate of the FPGA design. The design in Fig. 20.19 is a segment of a 1-D string consisting of 10 parallel kernels. Figure 20.20 depicts an exemplary implementation of 10 parallel kernels getting evaluated eight successive times. In the *LOAD* block, all parallel kernels of slice 1 load the computed values of time step t, in the middle block the values for time step $t+1$ are being computed, in the *WRITE* block all computed values are written to the slice 1 memory position. This leads to the model of a string that consists of $8 \times 10 = 80$ grid points.

20.10.5 Model Routing on FPGA

For larger instrument designs consisting of several geometries it is a good design practice to subdivide the FD computations into several self-contained parts.

Using this strategy, it is possible to structure a model on a FPGA comparable to a design of several coupled IP cores. For a proto-lute made of one string coupled to a wooden box, one part could consist of the string calculations, the other could be the wooden box. Each of the two cores could be subdivided as well into smaller units, but their input and output signals would be defined signal ports using a specified data protocol.

By this it is possible to use and reuse parts of a design, which run correctly in a later design without a complete redesign.

As presented in [20.61] this structured layer approach can be used to realize full geometries of musical instruments. An exemplary part of the layer system is shown in Fig. 20.21. Therein several geometry parts are connected via defined output and input signals and can be controlled and modified by changing certain control parameters.

Interfacing With a Model

The interface layer (IL) is the topmost layer in the model. Here, all external data input and output is managed, decoded and routed. It is the interaction layer with all input and output devices, such as the PCIe interface,

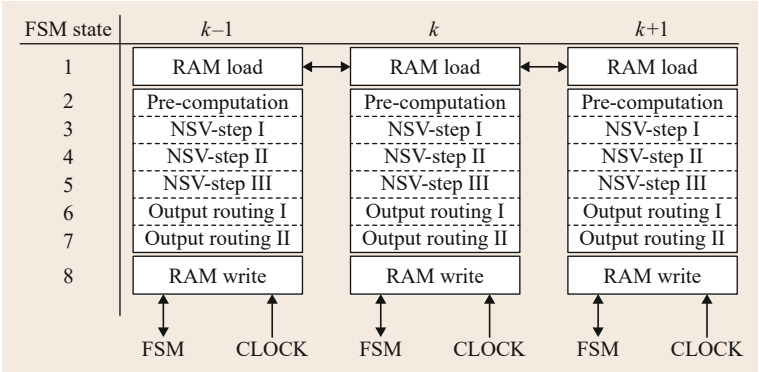

Fig. 20.19 Parallel implementation of sequential NSV-scheme parts

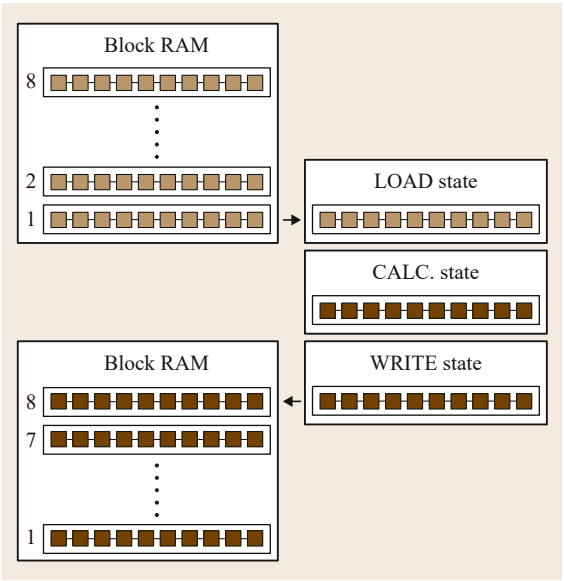

Fig. 20.20 Serial–parallel implementation of sequential NSV-scheme parts. Slices 1-8 consist of 10 parallel computation kernels each writing-to and reading-from their own memory address

a AC97 interface or a I2S interface for data transport. A block diagram of the IL is shown in Fig. 20.22.

Depending on the needs and given ports, either a PCIe, AC97 or the I2S interface can be used for communication and data transfer. In the IL, data from the respective transmitter is decoded and then routed to the instrument model, the model routing layer (MoR). In the output stage of the IL, the sound and status data is encoded depending on the respective receiver protocol.

20.10.6 Real-Time Physical Model of a Violin

In this section, an implementation of a violin on FPGA hardware is developed. It gives an overview of the mathematical models used for the singular parts as well as a detailed insight into characteristic implementation details. The real-time physical model of the violin consists of the frontplate and backplate of the violin. The enclosed air with two orifices, the wooden bridge, four strings and a model for the bow-string interaction complete the proposed model. The model can be controlled from a PC via a PCIe interface and interacted with by using a Leap motion controller.

20.10.7 Violin Research History

The *classical* violin is an instrument with a history in musicological research regarding the acoustic properties of the instrument as well as its organologic development. An introduction to the historic evolution of the modern violin is given for instance in [20.81]. A publication concerned with the early history of the violin can be found in [20.82]. A history starting from the time the modern violin was discernible as a distinct instrument and the development of the violin up to modern times is published in [20.83]. Early experimental studies on the acoustic properties of the violin were performed by Felix Savart [20.84] who focused his research on the vibrations of the front- and backplate and their different acoustic behavior, proposing that *good* violins have a special relation between their *eigenmodes*. He suggested that the sound post inside the violin stiffens the treble side of the violin, transforming the rocking motion of the bridge, which excites a dipole mode of the top plate into a monopole mode by this unilateral stiffening of the geometry [20.85, pp. 165–166]. His research led him to design a trapezoid-shaped violin. Following his publications there were several important publications regarding violin acoustics during the 19th century. One important work was published by Hermann von Helmholtz, who is credited with the first description of the stick-slip mechanism of the bow-string interaction. The theories of Helmholtz were further extended by Lord Rayleigh in [20.84]; findings

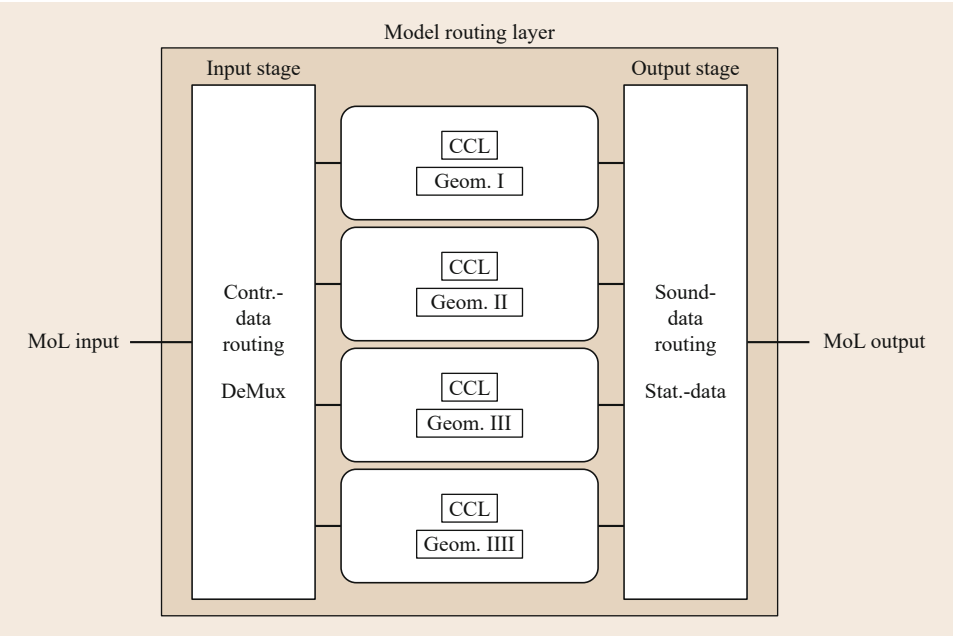

Fig. 20.21 Model routing layer overview

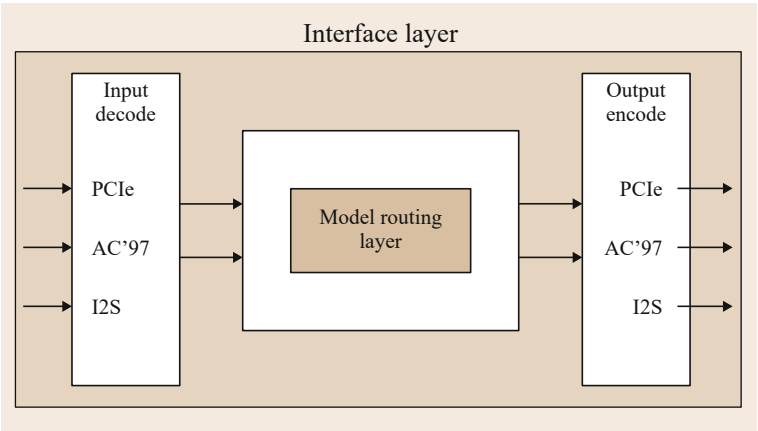

Fig. 20.22 Block diagram of the interface layer

were published by Lord Rayleigh and *Hermann von Helmholtz* [20.86]. At the beginning of the 20th century, Raman published several works concerned with violin acoustics and especially the bow-string interaction. An encompassing discussions about the structural mechanics and acoustic interactions of the violin can be found in [20.87].

Typical radiations of the f-holes and the interaction between lower body modes and the air volume are discussed in a technical manner for the whole class of the Hutchins–Schelleng violin octet in [20.88, 89], for a list of instruments from the Hutchins–Schelleng octet see Table 20.2 in [20.90, p. 325]. *C. Hutchins* followed the work of Savart and suggested that if the top plate *eigen*frequencies were slightly higher than the ones of the back plate, the violin sounds brighter; otherwise it sounds duller [20.91].

J.-L. Florens [20.92] presents a hardware design for interacting with a virtual model of a violin bow showing realistic simulation results. A virtual interaction model with digitized gesture data of bowing is presented in the work of *Matthias Demoucron* [20.93]. Based on this work *Esteban Maestre* [20.94] shows an implementation of a similar methodology with a high-level front end.

20.10.8 Violin String Model

The primary part of the violin's sound production mechanism are its four strings. Most modern violin strings

are made of a synthetic core wrapped with metal or some kind of alloy, like aluminum or titanium. The exact physical properties of those materials vary between string manufacturer and according to the desired sound characteristics.

The internal damping of modern violin strings is designed to facilitate the production of a stable Helmholtz motion under different playing conditions. Thus, most violin strings have a considerably higher internal damping compared to other string instrument strings. In comparison to a guitar string, this results in a less pronounced frequency content in the higher range of the spectrum. A thorough review on violin string research is published in [20.95].

In this treatise the strings are modeled as stiff strings with losses at the boundaries as well as internal damping. The motion is modeled for one transverse polarization leaving longitudinal and torsional effects out of the consideration, as shown in [20.96] longitudinal and torsional vibrations are measurable in cello and contrabass string vibration.

The equation of motion for the strings in one vertical polarization for $x \in 0, \ldots, L$ can be written as

$$\begin{aligned} \mathbf{u}_{tt} &= c^2\mathbf{u}_{xx} - B\mathbf{u}_{4x} - \beta\mathbf{u}_t + \alpha\mathbf{u}_{txx} \\ u(t,0) &= 0; \quad u(t,0)_x = 0 \\ u(t,L) &= 0; \quad u(t,L)_{xx} = 0 \end{aligned} \tag{20.17}$$

with $c = \sqrt{T/\mu}$, $T =$ tension and $\mu =$ linear mass density. The term $\beta\mathbf{u}_t$ is a viscous damping term, and the mixed derivative $\alpha\mathbf{u}_{xxt}$ is a phenomenologically justified damping term modeling the internal damping. A similar term was first proposed in [20.97] and extended to the form used here in [20.98]. The damping constants α and β are two heuristically approximated damping parameters. Due to the fact that all strings of the violin are metal strings with a considerable thickness they have a finite elasticity. This effect, the stiffness, is modeled by including a bar-like term $B\mathbf{u}_{4x}$. The factor B is defined as $B = ESK^2/\mu$, with Young's modulus E, cross-sectional area S and K the radius of gyration.

This adds a bar-like characteristic to the string and results in a stretching of partials, which is small in the case of thin strings [20.99]. Because we have a fourth-order term in the equation, we need four boundary conditions (BC): two at each side. On the side of the bridge ($x = 0$) we use clamped BC and fixed BC at the nut ($x = L$).

Separating (20.17) by introducing the velocity v yields

$$\begin{aligned} \mathbf{v}_t &= c^2\mathbf{u}_{xx} - \kappa^2\mathbf{u}_{4x} - \beta\mathbf{u}_t + \alpha\mathbf{u}_{txx} \\ \mathbf{u}_t &= \mathbf{v}\,. \end{aligned} \tag{20.18}$$

Discretized Equation

The separated and discretized scheme (20.18) can be written as

$$\begin{aligned} \hat{\delta}_{t+}\mathbf{v} &= (c^2\hat{\delta}_{xx} - \kappa^2\hat{\delta}_{4x} - \beta\hat{\delta}_{t-} + \alpha\hat{\delta}_{xxt-})\mathbf{u} \\ \hat{\delta}_{t+}\mathbf{u} &= \mathbf{v}\,. \end{aligned} \tag{20.19}$$

The hardware operations of the discrete difference operators can be added up to approximate the hardware utilization of one string. The multiplicands in front of the discrete difference operators can be combined with the multiplicand of the operator shown in (20.20). The requirements for one discrete point of the string are given in Table 20.3.

VHDL Model of the Strings

One string of the violin model is discretized with 80 points on the FPGA. Using the approach presented in Sect. 20.10.4, each string can be computed using 10 parallel computation kernels, where each of these kernels is computed eight times.

Summarizing the requirements for the strings, the values in Table 20.9 are multiplied by 40 (four strings with 10 kernels), which yields the values given in Table 20.10.

20.10.9 String–Bow Interaction

The excitation of the violin is implemented as a bow–string interaction model. The physical properties of the string–bow interaction are modeled based on a stick–slip interaction as presented in [20.100]. The system can be formulated using an iterative approach, modeling the forces acting at the contact point of bow and string. The fundamental idea behind the implemented

Table 20.9 Operator count for a damped one-dimensional string

Operation	Reg. Ops.	Shift	Mult.	Ad./Su.
$c^2\hat{\delta}_{xx}u$	3	1	1	2
$\kappa^2\hat{\delta}_{4x}u$	5	4	1	5
$\beta\hat{\delta}_{t-}u$	2	5[a]	1	8
$\alpha\hat{\delta}_{xx(t-)}u$	2	5[a]	1	8
Sum	12	15	4	23

[a] The damping parameters are approximated as shift operations

Operation	Reg. Ops.	Shift	Mult.	Ad./Su.
Sum:	480	600	120	920

stick–slip model, and most other friction models as published in [20.95], is the assumption that the bow sticks to the string, tearing the string in the direction of the bow motion. Hence, the contact-point velocity of the string equals the velocity of the bow during contact. If the net force of the string acting in the opposite direction is stronger than the force exerted by the bow, the string starts to slip off the bow. The force of the string can either be triggered by the deflection-dependent net force or by the pulses of the *Helmholtz* motion traveling on the string, catapulting the string off the bow. A schematic state diagram is given in Fig. 20.23.

The input signals starting the iteration are loaded at the beginning of the loop and the state changes depending on the truth-value of the respective conditions. This leads to an interactive playability of the model enabling a musician to expressively play the virtual violin. Several videos of this interaction model can be found at http://www.systematicmusicology.de. A flowchart of the excitation model is shown in Fig. 20.24.

String–Bow Model on a FPGA

What makes the string–bow model on a FPGA especially interesting is that the throughput of the systems has only a latency of several FPGA clock cycles. Therefore, a change in pressure or velocity of the bow is directly transmitted to the respective string that is selected. The selection of a string can be toggled by setting a *bow-contact* bit to **1**.

Figure 20.25 shows a schematic timing diagram of a bow contact on a selected string.

20.10.10 Bridge

The violin bridge has two feet, which transmit the vibrational energy of the string to the frontplate of the instrument. The geometry and physical properties of the violin bridge leads to distinct *eigen*vibrations, which adds a resonance peak in the radiated spectrum known as the *bridge hill*. In most violins it can be found around a frequency of ≈ 3 kHz [20.101].

Under realistic playing conditions, the bridge of the violin acts as a bidirectional transmitter of the acoustic vibrations between the strings and the frontplate. Its two feet exert a time-varying force on the frontplate and add a time-varying boundary condition for the strings. It is modeled as a two-dimensional plate with forces acting in the in-plane direction denoted as u and w, with u being perpendicular to the frontplate of the violin.

The differential equation for the respective directions x and y can be written as

$$\begin{aligned}\mathbf{u}_{tt} &= c^2(\mathbf{u}_{xx} + \nu_{1L}\mathbf{u}_{yy} + \nu_{2R}\mathbf{w}_{xy}) - \beta\mathbf{u}_t \\ \mathbf{w}_{tt} &= c^2(\mathbf{w}_{xx} + \nu_{1R}\mathbf{w}_{yy} + \nu_{2L}\mathbf{u}_{xy}) - \beta\mathbf{w}_t \end{aligned} \quad (20.20)$$

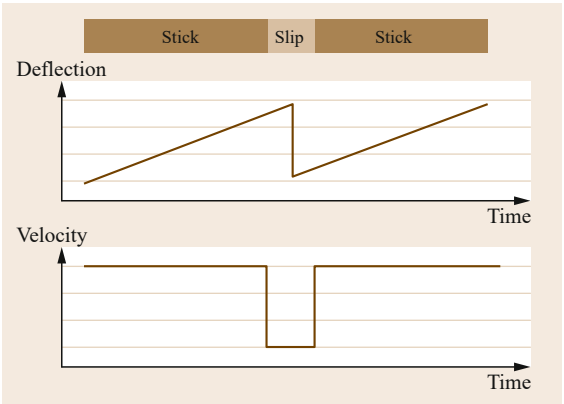

Fig. 20.23 A state representation of the bow model exciting the violin string

with material-dependent parameters ν_*, c^2 given below, and damping parameter β.

Discretized Equation

Using the discrete difference operator notation and separating them, Equations (20.20) can be rewritten as

$$\begin{aligned}\hat{\delta}_{t+}\mathbf{v}_x &= [c^2(\hat{\delta}_{xx} + \nu_{1L}\hat{\delta}_{yy}) - \beta\hat{\delta}_{t-}]\mathbf{u} \\ &\quad + \nu_{2R}\, c^2\, \hat{\delta}_{xy}\mathbf{w} \\ \hat{\delta}_{t+}\mathbf{u} &= \mathbf{v}_x \\ \hat{\delta}_{t+}\mathbf{v}_y &= [c^2(\hat{\delta}_{yy} + \nu_{1R}\hat{\delta}_{xx}) - \beta\hat{\delta}_{t-}]\mathbf{w} \\ &\quad + \nu_{2L}c^2\hat{\delta}_{xy}\mathbf{u} \\ \hat{\delta}_{t+}\mathbf{w} &= \mathbf{v}_y \end{aligned} \quad (20.21)$$

with v_y, v_x the velocities in the x and y directions respectively.

Coupling of the Strings to the Bridge

The coupling of the string vibration to the bridge can be formulated by taking the acting forces at the interaction point *ip* into consideration

$$F_{ip} = B\, u_{3x}^{\mathrm{str}} + T\, u_x^{\mathrm{str}} \quad (20.22)$$

with B the bending stiffness as defined before and T the tension of the string.

20.10.11 Top Plate/Back Plate

The body of the violin is made of wood. In most instruments, the frontplate of the violin is made of spruce whereas the backplate is made of maple. The frontplate and the backplate are held together by ribs around the rim of the instrument. In addition, the sound post connects both plates. The characteristic f-holes on the

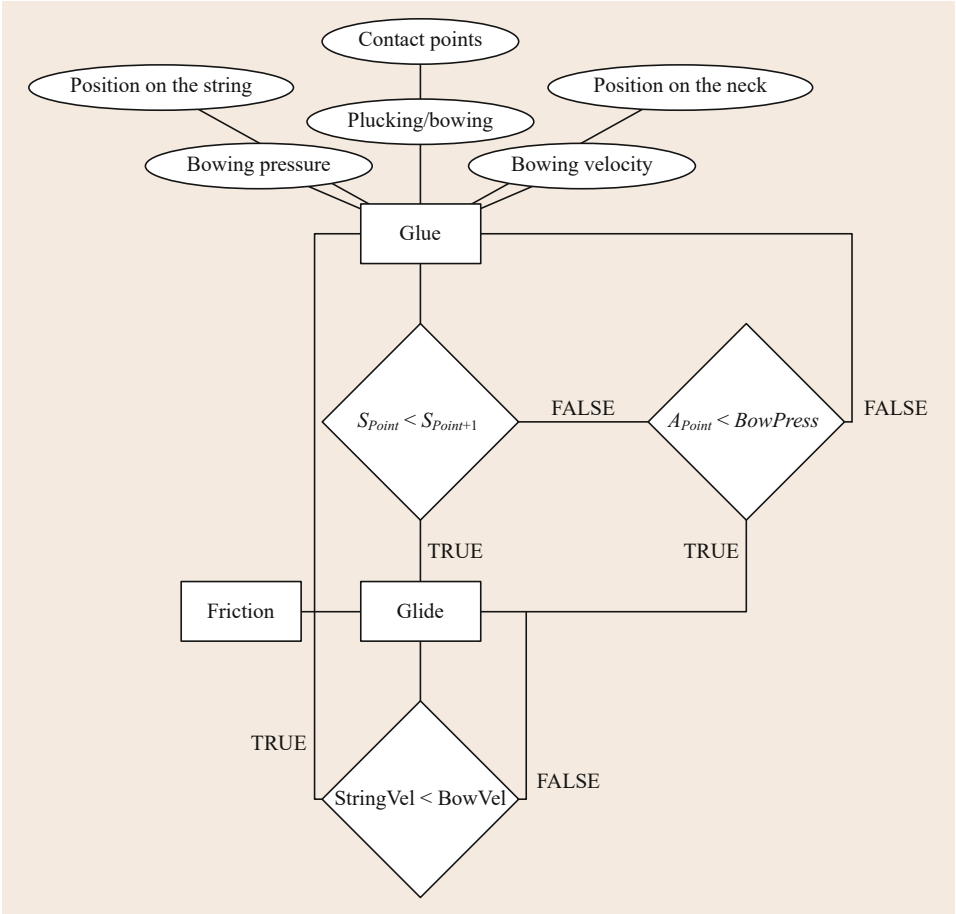

Fig. 20.24 A flow chart representation of the bow model exciting the violin string

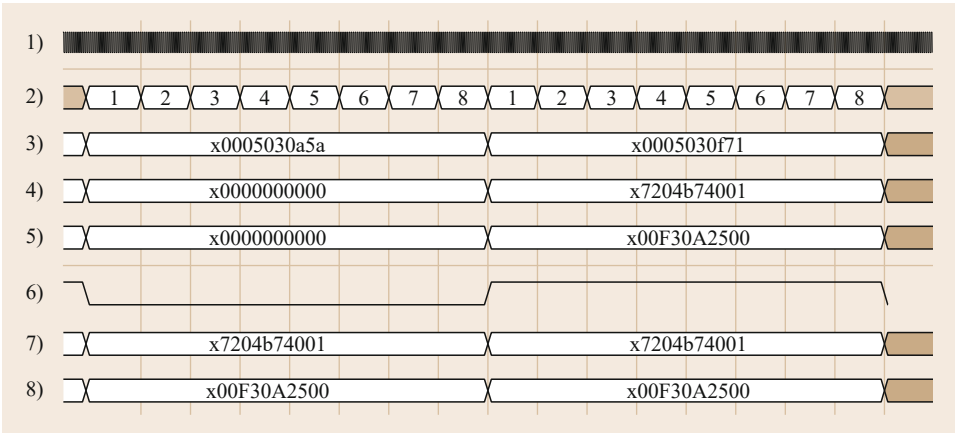

Fig. 20.25 A timing diagram of selected bow–string signals. When the *bow-contact* bit is set, the pressure and the velocity values of the bow interact with the string at the selected bowing point. 1) FPGA clock. 2) Serial/parallel string calculation state. 3) String deflection. 4) String–bow model contact pressure. 5) String–bow model contact velocity. 6) Bow contact. 7) Bow pressure. 8) Bow velocity

frontplate of the instrument give rise to a resonating enclosed air volume. Both plates are arched, which is commonly believed to increase the stiffness, which in turn changes the frequency of the plates without having to change the mass or the thickness of the plates. The arching of the plates can be modeled by using a PDE for a buckled plate.

The top plate and the backplate of the violin are modeled as orthotropic wood plates using the discrete version of a fourth-order differential equation.

This leads to the following PDE of a wooden plate including stiffness, damping and buckling

$$\mathbf{u}_{tt} = \tilde{c}^2[\mathbf{u}_{xx} + \mathbf{u}_{yy}] - \kappa \mathbf{u}_{\nabla^4} - \beta \mathbf{u}_t + \alpha \mathbf{u}_{xxt} - \mathbf{F}_{\text{ext}} \tag{20.23}$$

with $\tilde{c} = \sqrt{T(x,y)/\sigma}, T(x,y)$ the variable membrane tension, σ the area density, $\mathbf{u}$ the membrane displacement normal to the membrane plane and external forces $\mathbf{F}_{\text{ext}} = \mathbf{F}_{\text{air}} + \mathbf{F}_{\text{br}}$, where $\mathbf{F}_{\text{air}}$ and $\mathbf{F}_{\text{br}}$ are the forces exerted by the air volume and by the bridge respectively. Here, $\kappa = E h^2/12\,\rho(1-\nu^2)$ with Young's modulus E, h is the thickness, ρ is the density and ν is Poisson's ratio.

The biharmonic operator is defined as

$$\mathbf{u}_{\nabla^4} = (\mathbf{u}_{4x} + 2\mathbf{u}_{2x2y} + \mathbf{u}_{4y})\,. \tag{20.24}$$

Discretized Equation

The calculation of the plate deflection is partitioned into two substeps. First the bending moments M are calculated, with M the acceleration on the surface of the plate. The separated and discretized counterpart of (20.23) using a digital operator notation can be written as

$$\begin{aligned} \hat{\delta}_{t+}\mathbf{v} &= \left(c^{\hat{2}}\delta_{xxyy}c + \alpha\hat{\delta}_{xxyyt-} - \kappa\hat{\delta}_{\nabla^4} - \beta\hat{\delta}_{t-}\right)\mathbf{u} \\ &\quad + \mathbf{F}_{\text{ext}} \\ \hat{\delta}_{t+}\mathbf{u} &= \mathbf{v} \end{aligned} \tag{20.25}$$

with $\hat{\delta}_{\nabla^4}$ the discrete, digital biharmonic operator.

Coupling of the Bridge Feet and the Frontplate

The coupling between the bridge feet and the frontplate is modeled by constituting a spring with constant $k_{\text{br/fp}}$ between the bridge and the membrane leading to the coupled equation at the respective points.

$$u^p_{tt} = \frac{1}{m_{\text{fp}}}\mathbf{F}(u^b) - k_{\text{br/fp}}u^{\text{fp}} \tag{20.26}$$

$$u^m_{tt} = \frac{1}{m_{m_{\text{fp}}}}\mathbf{F}(u^m) - k_{\text{br/fp}}u^b\,, \tag{20.27}$$

with $\mathbf{F}$ the force function of the uncoupled part of the respective geometry and m_* the mass of the bridge (br) and the frontplate (fp) at the interaction area.

20.10.12 Model of the Air Cavity

An essential part of the violin sound is the presence of air inside the instrument's body. There are several important air modes of the instrument that can be found in the radiated spectrum of the instrument. The f-holes of the violin are modeled by the using Sommerfeld radiation conditions at the respective points [20.70, p. 50]. Using Helmholtz' equation for pressure $\mathbf{p}$ in air, the PDE can be written as

$$\mathbf{p}_{tt} = \frac{1}{K\rho}(\mathbf{p}_{xx} + \mathbf{p}_{yy} + \mathbf{p}_{zz}) - \beta\mathbf{p}_t \tag{20.28}$$

with pressure $\mathbf{p}$, air compressibility K, and density ρ, which are assumed constant inside the domain. Again, β is a heuristically approximated damping coefficient modeling the viscosity of air.

Coupling Between Air and the Body

The coupling between the air volume and the vibrating violin body is implemented by considering the continuity of normal velocity on the inside of the violin body leading to the conditions

$$\mathbf{p}_z(x,y,0,t) = \rho\mathbf{v}_t^{\text{frpl}}(x,y,t) \tag{20.29}$$

for the zero plane of the air volume in z direction and

$$\mathbf{p}_z(x,y,H,t) = -\rho\mathbf{v}_t^{\text{bpl}}(x,y,t) \tag{20.30}$$

for the air layer in contact with the backplate.

Discretized Equation

By setting $\mathbf{v} = \hat{\delta}_{t+}\mathbf{p}$ we can write the discretized and separated equation as

$$\begin{aligned} \hat{\delta}_{t+}\mathbf{v} &= \left(\frac{1}{K\rho}(\hat{\delta}_{xx} + \hat{\delta}_{yy} + \hat{\delta}_{zz}) - \beta\hat{\delta}_{t-}\right)\mathbf{p} \\ \hat{\delta}_{t+}\mathbf{p} &= \mathbf{v}\,. \end{aligned} \tag{20.31}$$

Note that $\mathbf{v}$ must not be confused with the particle velocity formulated in (20.11).

20.10.13 Application Example

In the following application example, the violin model presented in this section is running on a ML605 FPGA development board connected to a standard PC via the

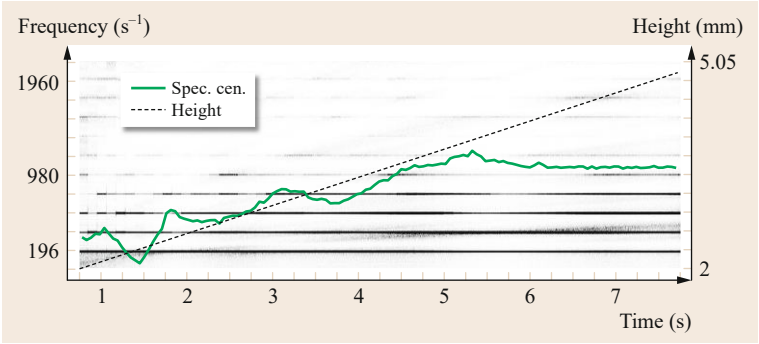

Fig. 20.26 Simulation output of increasing frontplate height in successive steps of 0.05 mm of a violin excited by a constant bowing force and velocity. In *black* and *white* is the spectrogram of the sound, in *green* the spectral centroid

PCIe bus. It is controlled by an application running in C# and C++. The model is excited with steady bow force and velocity, interacting with one single string. While a stable bowing sound of the violin is produced, the height of the frontplate is increased in 0.05 mm steps. The resulting sound is picked up at several positions in the air volume above the frontplate of the violin and transfered to the PC-host application via PCIe.

Figure 20.26 shows the influence of the changing frontplate thickness on the spectral centroid of the radiated sound. From psychoacoustic considerations it is known that the spectral centroid is a robust indicator for the perceived brightness of a sound.

As one can see from Fig. 20.26, the perceived brightness does not change linearly by increasing the thickness of the violin frontplate linearly but depends on the salient interaction between the string, bridge and frontplate.

This is one example of how a real-time FD model can be used by researchers or instrument makers who want to research the influence of a certain physical parameter on the resulting sound. This could enable users to tune an instrument to a desired sound characteristic and research the influence of fine structures on the resulting sound. Sounds and further application examples of the real-time violin model can be found at www.systematicmusicology.de.

20.11 Summary and Outlook

As shown in this chapter, FPGAs offer a vast amount of possible applications in the field of digital signal processing for research as well as for hardware prototyping. The raw processing power and flexible architecture enables them to perform highly specialized tasks using the inherently bit-parallel structure as well as the high clock speed of specialized logic blocks for sequential processing. But, as the saying goes, *with great power comes great responsibility*: handling large FPGA designs can become exceedingly difficult for a designer and places substantial demands on the design process and the appertaining tool chain. Nonetheless, as the design tools get more elaborate, automating and optimizing various steps of the development cycle, FPGA programming gets more and more accessible.

This is one of the future routes of FPGA development systems that two of the largest vendors are working on at the moment. In 2013, Altera has published a library making their FPGAs programmable using OpenCL code in C or C++. Xilinx devices can also be programmed from C or C++ using the high-level synthesis (HLS) tools introduced around 2013.

Simplifying the overall design process and thereby reducing the initial learning curve for hardware programming will surely be one of the central topics in future FPGA developments. On the hardware side there are several exciting developments in the field of microprocessor-FPGA interaction. The line of Xilinx and Altera chips that include an ARM processor is growing constantly and the purchase of Altera by Intel in 2015, as well as the cooperation between Xilinx and IBM announced in the same year, points to even more elaborate microprocessor-FPGA combinations, including server CPUs of the x86 family connected directly to FPGAs.

Altogether the recent developments indicate that FPGAs will play an important role in high-performance computing over the next decade and will also become more accessible to a larger audience due to simplifications in the design process.

The implementations and examples of signal processing applications in FPGAs presented in this chapter highlight how the flexibility of FPGAs can be used to simulate and model timing-critical problems in music

DSP applications. The main purpose of this chapter was the introduction of a platform capable of *real* real-time implementations of algorithms as well as the possibility to utilize special hardware traits to speed up timing-critical computations in acoustic research. In musical acoustics and especially in physical modeling applications there is an ever rising need for high(er)-performance computations to enable researchers as well as musicians to interact with highly accurate models in real time. Hence, extending the toolbox of a researcher to more specialized hardware platforms can open up new areas of research by facilitating the use of methods that were impractical previously due to throughput limitations of *standard* hardware.

Part C

Music Psy

Part C Music Psychology – Physiology

Ed. by Stefan Koelsch

There is no music without a brain. The brain is the biological substrate of music perception, creative processes, and of planning, executing, and monitoring the movements necessary to play music. For the investigation of the neural correlates of music, neurophysiological methods are used such as functional magnetic resonance imaging (fMRI) or electroencephalography (EEG). While listening to a musical piece, or while playing music, the brain dynamics of an individual is recorded, both in time and space. While the EEG mainly records neural activity in the neocortex, fMRI is able to measure neural activity both in the cortex and in subcortical structures located deep inside the brain, e.g., the thalamus, the amygdala, or the basal ganglia. EEG has a high temporal resolution (in the submillisecond range), enabling researchers to record brain activity with sampling rates necessary for the investigation of very fast perceptual or executive processes. fMRI, on the other hand, has a high spatial resolution (in the millimeter- or even submillimeter range), enabling researchers to differentiate brain regions, and thus the *where* of music processing in the brain.

EEG-recorded brain-electric potentials, also referred to as *event-related potentials* (ERPs), have been employed to investigate auditory-perceptual processes, auditory attention, auditory memory, musical syntax, musical meaning, and music-evoked emotions, as well as action-related processes during music production. For example, the so-called mismatch negativity (MMN) has been used to investigate auditory sensory memory, auditory grouping, and musical Gestalt. The so-called early right anterior negativity (ERAN), on the other hand, has been used to investigate the processing of musical syntax. It was shown that the ERAN is mainly generated in Broca's area, a region of the brain known to analyze the syntax of language – thus showing that both musical and linguistic syntax is processed in overlapping regions of the brain. On the other hand, studies with fMRI have provided detailed knowledge about brain structures that are involved in music processing. For example, fMRI studies have shown that beat perception involves not only the cerebellum, but also the basal ganglia, the premotor cortex, and the supplementary motor area.

However, understanding the functional neuroanatomy of music processing is challenging, e.g., because brain regions are usually active within networks, interacting strongly with each other, or even playing different roles during different tasks within different networks. How the interaction of many neurons leads to a sorting and organizing of musical content (which is then used to identify and recognize rhythms, melodies, or timbres) is not yet understood.

This section gives an overview of some different aspects and musical features investigated with neuroscientific methods (mainly EEG and fMRI), and modeling of neural networks in relation to perceptual tests. It gives insight into the state of the art in the field and discusses recent findings and trends.

In Chap. 21, *Simon Grondin*, *Emi Hasuo*, *Tsuyoshi Kuroda* and *Yoshitaka Nakajima* discuss auditory time perception, where perception based on the interval between two events is different from that of beats and a rhythm differentiating musical time. Also there is a difference in the perception of time in music and in language. The paper discusses the influence of pitch, intensity or musical markers in time perception. Furthermore, distinguishing the perception of musicians and nonmusicians gives further insight into the problem.

Elvira Brattico, *Chiara Olcese* and *Mari Tervaniemi* review the perception of musical sound in the brain in Chap. 22. They discuss the role of attention in the problem. Discussing fMRI and EEG investigations, different brain regions are identified for their contributiond to processing. In particular, experiments using the MMN and the ERAN are found to be helpful in recognizing ERPs that can give deeper insights into the attention problem of automatically or consciously perceived musical sounds or syntax.

Lola L. Cuddy reviews long-term memory in music in Chap. 23. This is discussed in terms of semantics and meaning, and episodic memory or procedural memory. Discussing neurophysiological evidence, Cuddy reports studies showing the preservation of musical memory in Alzheimer patients, and discusses potential use of these findings for therapy.

In Chap. 24, *Katrin Schulze*, *Victoria Williamson* and *Stefan Koelsch* discuss the relation between music and language in working memory. Based on fMRI and EEG studies, the paper discusses the role of Broca's region, the premotor cortex as well as other regions for working memory, and discusses which of these regions might differ between verbal and tonal working memory. They suggest an overlap between neural resources underlying working memory for tones and words, and put forward the hypothesis that sensorimotor codes (i. e., action-related processes) are fundamental for auditory working memory.

Marcus Pearce and *Martin Rohrmeier* discuss musical syntax in Chap. 25 in terms of its theoretical foundations. Based on Noam Chomsky's generative grammar, musical syntax is described as a set of hierarchically organized rules underlying the generation of a musical piece. The difference between finite-state and

context-free grammars is discussed, where the former assumes local dependencies among (adjacent) musical events, while the latter allows nonlocal dependencies between (nonadjacent) musical events.

Following these ideas, in Chap. 26 *Marcus Pearce* and *Martin Rohrmeier* continue to discuss musical syntax, now in terms of neural and perceptual models. The implementation of finite-context models as *n*-gram systems, compared to hidden-Markov models as finite-state models is discussed, next to neural networks. These findings are discussed with respect to perceptual as well as neurophysiological findings, methods and ideas.

In Chap. 27, *Tram Nguyen*, *Aaron Gibbings* and *Jessica Grahn* discuss musical rhythm and beat perception. Sensorimotor synchronization is discussed as the basic mechanism listeners use to perceive a beat or rhythm. The models and perception tests find differences between beat as a steady pulse, and rhythm as patterns of musical texture. This is also supported by fMRI, positron emission tomography (PET) or EEG experiments, but still research is ongoing and many questions remain open.

Chapter 28 by *Giacomo Novembre* and *Peter Keller* is devoted to music and action. It relates music perception to performance and reviews the perceptual data as well as the neuroimaging evidence. The relation between performance and social bonding is discussed. The role of beat perception on action is shown. The paper finds a coupling between the brain regions responsible for perception and performance.

Finally, Chap. 29 by *Tuomas Eerola* discusses music and emotion. He distinguishes between automatic emotions in response to music-making as a mapping of musical features and emotions an expectancy of musical events, which might be violated and cause emotions; and an entrainment between music and the subject, which leads to an emotional movement in the listener. He discusses measurement techniques for emotions and discusses future problems in this field.

21. Auditory Time Perception

Simon Grondin, Emi Hasuo, Tsuyoshi Kuroda, Yoshitaka Nakajima

In this chapter, we propose to review studies on the capability of making explicit judgments about the duration of auditory time intervals. After a brief look at the main methods used to study time perception, we then focus on factors affecting sensitivity to time (e.g., discrimination levels) including repetition of intervals and the duration range under investigation, as well as whether the interval is embedded in a music or in a speech sequence. Factors affecting the perceived duration of sounds and time intervals are then described using for example markers' length, space, pitch, and intensity. The last section of this chapter reviews the main theoretical perspectives in the field of temporal information processing, with an emphasis on the distinction between the traditional beat-based versus interval-based mechanisms.

One critical aspect of music perception and production is the capability of dealing with time. For instance, variations in time are minimal when several notes are played together, or almost, to form a chord or an arpeggio chord, whereas several notes are also sometimes delivered in very rapid succession to form an appoggiatura, or played successively but slightly more slowly in order to contribute to tempo.

In this chapter, we place emphasis on a description of empirical studies and theoretical issues related to the ability to estimate short time intervals. In other words, the content is dedicated to explicit judgments concerning duration. Phenomena like temporal displacement [21.1] will not be reviewed herein. Temporal displacement means there is no perfect correspondence between the physical arrival of stimuli and the perception of their simultaneity or successiveness. In addition, we will also not review the capacity of judging the order of arrival (temporal order judgments: TOJ) of stimuli. Note however that in their classical work, *Hirsh* and *Sherrick* [21.2] reported that the delay between sensory events for TOJ is approximately 20 ms. This delay is much longer than the delay (temporal separation) necessary to distinguish between simultaneity and successiveness. In the latter case, the delay depends on the sensory modality employed; typically 2–3 ms is needed in the auditory modality, and more in the visual and the tactile modality [21.3]. In the former case, TOJ, this delay is independent of the sensory modality. For the specific case of audition, the reader interested in the study of dichotic TOJ may consult a summary of threshold results in [21.4, Table 1].

21.1 Methods for Studying Interval Processing

There is a long history of research on psychological time and interval processing [21.5]. In order to understand the meaning of the results extracted from this literature, it is relevant to become familiar with some basic methods and terminology [21.6].

One fundamental distinction is related to the type of performance that is of interest. If someone is asked to tap twice with a finger and we have 3 s between the taps, it is likely that the main performance index will be how close to the target the finger production is. Maybe there will be an overestimation or an underestimation of time; it is the degree of deviation, also referred to as perceived duration in the next section, which is of interest. Suppose now that the 3 s tapping task is repeated several times. It may occur that the mean production is close to 3 s, but this does not mean that the timing system is excellent. The timekeeping system of a participant where each production lasts between 2.986 and 3.014 s is judged as better than the timekeeping system of someone whose productions are in the range 2.5 to 3.5 s. The mean productions (perceived duration) of the participants could be the same, but it is obvious that there is much more variability (less sensitivity) in the system of the second participant. In the next section, the dependent variable of interest is related to variability.

Another fundamental notion to learn is that the basic structure of an interval can vary. Essentially, one should distinguish a filled interval, where a continuous signal marks the beginning and end of the time period to be processed, from an empty interval, which is an empty period of time marked by two brief signals of or below 10 ms typically. Note that any of these signals can be issued from one sensory modality or another.

The methods described herein provide the possibility to obtain performance indexes related to both variability and perceived duration. These methods will not be described in detail, the aim of the presentation being to provide the reader with the main tools to approach the study of internal time. One basic method for investigating capabilities and mechanisms related to time perception is to present a participant with a signal (a stimulus) and to ask this person to estimate its duration verbally in chronometric units (seconds or minutes). This method is called verbal estimation. If intervals are not too long, an experimenter may rather choose to ask the participant to reproduce, usually with finger taps, the duration of these intervals. This method is referred to as time reproduction. There are different reproduction methods: two brief successive presses to mark the beginning and end of an interval, one continuous press to mark the entire interval, or a sensory signal that marks the beginning of an interval and a key press by the participant that marks the end. These variations may lead to slightly different results [21.7]. It is also possible to adopt a method where the experimenter verbally reports the target duration, in chronometric units, and the participants should reproduce this duration (time production), usually with finger taps. Note that the term production is sometimes used in the literature for indicating that, after the presentation of an interval or a series of intervals of equal duration, a participant has to produce a series of intervals of the same length with a series of successive finger taps. This may or may not involve a synchronization phase, i. e., a series of taps synchronized with the signals marking time, before tapping without these signals [21.8]. This interval production method proved to be very useful for distinguishing the respective proportion of variance belonging to the motor process involved in the tapping activity and the variance issuing specifically from the mechanism responsible for keeping track of time [21.9].

In addition to these methods (time estimation, reproduction, and production), there is a fourth one, interval comparison. There are several ways of presenting intervals to enable comparison. Many of the methods used for investigating human timing derive from classical psychophysics, and some from animal timing studies. Basically, a forced-choice procedure can be used where two successive intervals are presented and a participant is asked whether the second one is shorter or longer than the first one. In experimental designs where there are one standard and multiple comparison intervals, the standard is usually presented first. When the comparison interval is presented first, the discrimination level is lower [21.10]. There could be one presentation of a standard and of a comparison interval on each trial, or there could be multiple presentations of the same intervals. As we will see in Sect. 21.2.1, the number of intervals changes the discrimination level.

Amongst the other main comparison methods, there is one called single stimulus. With such a procedure, a response is required from a participant after each presentation of an interval. In one version of this method, the *bisection* task, the shortest and the longest (standards) of a series of intervals are presented several times, and in subsequent experimental trials, after each presentation of one of this series, a participant is asked to say if the presented interval is closer to the shortest or to the longest standard interval. Instead of presenting these standards, the experimenter could present several times the mid interval from a series, and then, in subsequent trials, ask if the presented interval from that

series is identical or different: this is a *generalization* task. Also, other studies on the sensitivity to time used a task where anisochrony is to be detected in a sequence of isochronous brief stimuli.

With many of these methods, it is possible to measure a difference threshold (or just noticeable difference, JND), which is the least two intervals need to be different to distinguish between them. The value of this threshold depends on the method and on the operational definition adopted for measuring it. Moreover, this value (threshold) is sometimes divided by the value of the duration under investigation: this ratio is the Weber fraction.

Finally, note that for measuring the perceived duration of a time interval, there is another method, called the method of adjustment, where a standard interval and a comparison interval are presented successively, and the participants are asked to adjust the duration of the comparison to make it subjectively equal to that of the standard [21.11].

21.2 Processing Time Intervals: Variability

In this section of the chapter, we will focus on different factors affecting the sensitivity to time. After a description of the impact of the number of intervals presented and of the duration range on the levels of duration discrimination, we will report how sensitive to time we are in the context of music and speech. The section ends with a comparison of audition with other sensory modalities for processing time intervals.

21.2.1 Number of Intervals and Duration Range

There are several factors that determine the level of sensitivity to temporal intervals. One of these factors is of particular interest for the present book: Increasing the number of intervals presented, i. e., inducing a pace [21.10, 12, 13]. Another factor of interest is related to the range of duration (tempo) under investigation.

When single intervals are presented, it is well established that the Weber fraction depends on the range of duration. In the auditory modality, this fraction is higher for very brief intervals (< 0.1 s) than for intervals from 0.1 to 2 s [21.14]. Such results are true for filled as well as for empty intervals [21.15, 16].

In a series of experiments where the threshold was estimated using an adaptive procedure with a convergence toward a 70.7% probability of correct detections, *Drake* and *Botte* [21.17] tested the influence of the number of intervals on sensitivity to time. In one experiment, they used two or more consecutive tones to mark one, two, four, or six successive intervals. They presented the standard interval(s), and then the comparison interval(s) (same number of intervals) which were shorter or longer. Participants had to indicate whether the standard or the comparison sequence was faster. Fors tandard intervals lasting 0.1 to 1 s, discrimination was better with two than with one interval, and with four than with two intervals; but it was not better with six than with four intervals. The tempo sensitivity (Weber fraction) in Drake and Botte was about 5% with a 100 ms standard, and slightly above 2% at 200 ms when a series of six intervals were presented. This means that listeners could detect a change in duration when this duration was changed by more than 5 ms for the 100 ms standard, and by more than 4 ms for the 200 ms standard. Note, however, that this value is partly related to the operational definition adopted for establishing the threshold.

Weber fractions for the discrimination of brief intervals marked by auditory stimuli presented in sequences ranged in other studies from 3 to 13% [21.18], and are often reported to be about 5−10% [21.19, 20]. In an interval discrimination study by *Hirsh* et al. [21.21] where participants were asked to detect anisochrony (the deviation of a tone) in sequences of tones, the Weber fractions were about 6−8%, 11−12%, and 20%, respectively, for standard intervals (interonset intervals) equal to 200, 100, and 50 ms. Higher Weber fractions (lower performances) with briefer intervals could be due to the fact that participants might have been unable to perceive some of the presented intervals correctly. Indeed, when participants are asked to report the number of sounds they perceive successively, these sounds must be separated by interonset intervals longer than about 100 ms for estimating the number correctly [21.22] (see also [21.23]). Nevertheless, the impairments of discrimination with shorter intervals, reported by Hirsh et al., are compatible with what we found for the discrimination of single intervals.

While it is well established that varying the number of presented intervals influences discrimination levels, it was only recently that researchers varied the number of intervals in each sequence, the first or the second, independently [21.10, 12, 13]. For instance, *Miller* and *McAuley* [21.13] showed that increasing the number of intervals in the second (comparison) sequence, but not the number of intervals in the first (standard)

sequence, improves time sensitivity. This finding has been shown for standard intervals ranging from 300 to 700 ms [21.12, 13].

One of the most complete studies on the influence of the number of intervals, standard or comparison, on temporal discrimination at different duration ranges was recently reported by *ten Hoopen* et al. [21.24]. In their first experiment, which included base durations of 100, 200, 400, and 800 ms, two sets of sequential sound patterns were presented: one sequence of 9 empty time intervals (standard) of equal duration (marked by 10 brief sounds). These standard intervals were followed in continuity by 1, 2, 3, 5, 7, or 9 comparison intervals and participants had to judge whether the tempo in the (total) sequence became faster or slower. The results revealed that sensitivity increased with an increase of the number of comparison intervals. In another part of this experiment, there was one last comparison interval immediately preceded by 1, 2, 3, 5, 7, or 9 standard intervals and participants had to judge whether the last sound of the total sequence came too early or too late. Sensitivity was not improved by an increasing number of preceding standards.

In ten Hoopen et al.'s second experiment, there were four sequential conditions: 9 leading standard intervals followed by 1, 2, ..., or 9 comparison intervals; 9 leading comparison intervals followed by 1, 2, ..., or 9 standard; 9 comparison intervals preceded by 1, 2, ..., or 9 standard, and 9 standard intervals preceded by 1, 2, ..., or 9 comparison intervals. The threshold was lower (higher sensitivity) when the increase in the number of intervals occurred before the tempo change rather than after. In their following experiment [21.24], the number of intervals was varied from 1, 2, 3, 4, to 5, yielding 25 standard/comparison pairings. The effect of the number of intervals before the tempo change was larger than that after the tempo change. The authors also noted that the thresholds were largest when the tempo changes occurred early, i. e., at the beginning of the sequence, and second largest when the change occurred at the very end of the sequence; the threshold was smaller when tempo changes occurred during the sequence. Finally, in their investigation, ten Hoopen et al. showed that adding one or two intervals improves performance but additional interval presentations provide negligible additional benefits.

The effect of the number of intervals is most often tested on brief intervals (< 1 s). Recently, it has been shown that the benefit of multiple interval presentations applies from 1 to 1.9 s, and is not limited to duration discrimination [21.25]. The effect applies with a duration reproduction task and a categorization task. What is more specifically interesting in this report is the fact that variability does not increase proportionally as a function of time (higher variability-to-time ratio with longer intervals), but this effect does occur similarly with single and multiple presentation conditions. These results are also consistent with others showing the violation of Weber's law [21.26]; for reviews, see [21.27] or [21.28].

Working with long intervals invariably raises the question of using counting or any other segmenting strategy to keep track of time. It is known that intervals do not have to be very long to gain benefit from a strategy where subintervals are used [21.29, 30]. For the reproductions of very long intervals (6–24 s), it is shown that both singing and counting reduce variability considerably, and keep the reproductions close to the target interval [21.31], see also [21.32]. Moreover, *Grondin* and *Killeen* [21.31] showed that with both strategies, singing and counting, musician participants remained much closer to the target intervals than nonmusicians. Also, the variability of the reproduced intervals is not only much lower for musicians, but the variability-to-duration ratio tends to keep decreasing as intervals get longer with musicians, but not with nonmusicians.

We have reviewed the literature where discrimination is improved when the number of presented time intervals is increased. However, it should be noted that discrimination between different temporal patterns can be both improved and impaired by the very fact that two or more intervals neighbor each other. *Sasaki* et al. [21.33] investigated how temporal patterns of two adjacent time intervals were discriminated from each other. For some patterns, the discrimination was more difficult than would have been predicted from a common duration discrimination experiment in which each time interval was isolated. This happened when the first time interval was varied from 60 to 100 ms, whereas the second time interval was varied from 120 to 80 ms, keeping the total duration of the adjacent intervals at 180 ms. This impairment can be related to the fact that two neighboring intervals were perceived as having very similar durations in these conditions (i. e., temporal assimilation occurred). We will return to this issue in Sect. 21.3.2, but the result indicates that different modes of processing may underlie the discrimination of single and of multiple empty intervals.

Indeed, multiple presentations of sounds could make listeners perceive a particular type of rhythm [21.35, 36]. Moreover, successive sounds could be sequentially grouped by their similarity or proximity [21.37]. It is beyond the purpose of this chapter to discuss the rhythmic and the sequential grouping, but duration discrimination is indeed modulated according to what type of grouping listeners perceive from the succession of sounds. *Trainor* and *Adams* [21.38]

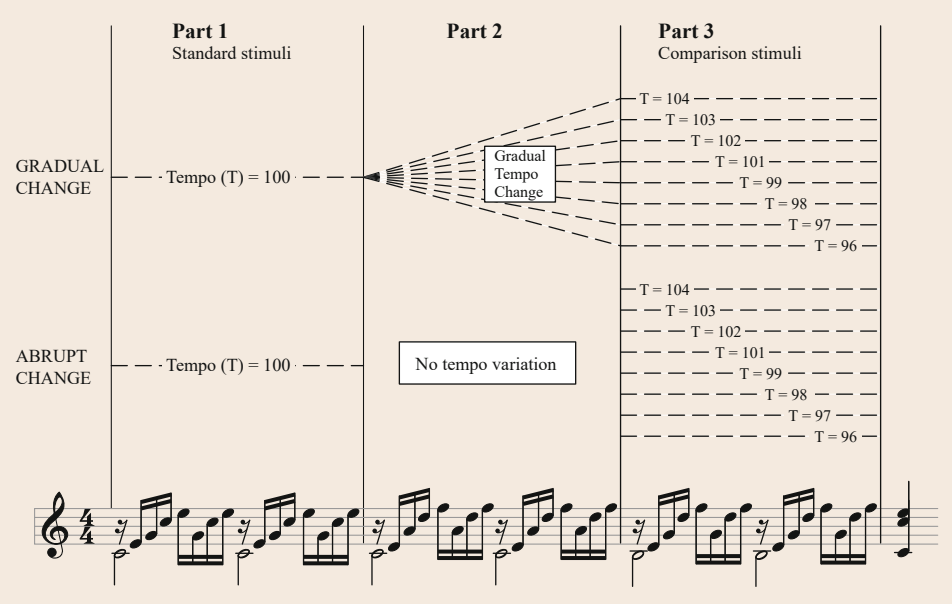

Fig. 21.1 Diagram of experimental conditions. Each excerpt consisted of three parts, with *Parts 1* and *3* being identical for the gradual- and abrupt-variation conditions. *Part 2* involved either a gradual change of musical tempo or an interruption. The excerpt was taken from Bach Prelude No. 1 (Vol. 1) in C Major for well-tempered clavier (after [21.34])

presented the repetition of sound triplets consisting of a 200 ms sound (short–S), a 200 ms sound (S), and a 600 ms sound (long–L), like SSLSSLSSL..., these sounds being separated by interstimulus intervals of 200 ms. The authors found that adult and infant participants were better at detecting an increase in the duration of intervals between SS or between SL compared to those between LS. According to previous studies involved in rhythm [21.39] (see also [21.40]), the pattern SSLSSLSSL... could be perceived as segmented into rhythmic groups of SSL, like [SSL][SSL][SSL]...; in other words, longer sounds are likely to mark the end of rhythmic groups. The SS and SL intervals were within the perceived groups of SSL, while the LS intervals did not belong to any perceived groups. A similar effect was reported by *Geiser* and *Gabrieli* [21.41] with different rhythmic patterns. The sequential grouping by frequency proximity [21.42] and by timbre or loudness similarity [21.43] could also result in a better discrimination of empty intervals within perceived groups than intervals between groups (but see [21.44–46] which failed to find any difference between these types of intervals).

21.2.2 Interval Discrimination in Music and Speech

In most psychophysical research on time-interval discrimination capacity, intervals are presented in well-controlled, but ecologically restricted conditions. In everyday life, however, changes in duration between events are embedded in much more complex contexts.

One of these complex contexts is music. Although temporal changes are essential for establishing the esthetic dimension of music, not much is known about precise sensitivity to slow changes in the context of musical detection. The capacity to detect tempo changes with clicks is about equal to a just noticeable difference of 4% [21.47], and in music, it seems to vary between 5 to 13%, depending on the base tempo under investigation [21.48].

However, in their experiment addressing this tempo change issue, *Grondin* and *Laforest* [21.34] reported a much higher sensitivity for the musical context. They used the method of constant stimuli, and two types of interstimuli intervals (ISI) were compared. As illustrated in Fig. 21.1, a standard musical excerpt was first presented, followed by a comparison excerpt. Compared to the standard, only the tempo (time between notes) was modified (accelerated or decelerated). The ISI conditions were an abrupt tempo change (empty ISI) or a gradual tempo change, i. e., a slow but continuous change of the tempo of the excerpt during the ISI. Sensitivity to tempo changes may indeed depend on the ability acquired through musical training to detect such changes. Therefore, this experiment also included in its design a comparison of performances by musicians and nonmusicians.

This experiment by Grondin and Laforest reveals the great sensitivity of all participants, even the nonmusicians, for discriminating tempi when interval discrimination is embedded within music. For both musician and nonmusician groups, the only difference between Parts 1 and 3 (Fig. 21.1) was the time between notes. There were about 150 ms between notes in the standard excerpt. The Weber fraction (variability/standard tempo) varied from 2.3 to 3.3% with the control group, and was below 1% with the musicians (Fig. 21.2). Within this duration range, sensitivity for discriminating intervals is usually reported to be lower than that. The difference between musicians and nonmusicians is not surprising considering that there seems to be fundamental differences between these groups for processing intervals [21.49]. What is remarkable here is the acute sensitivity of musicians, even when changes are gradual.

Note that the experiment revealed no bias toward easier perception for acceleration or for deceleration (no difference of the bisection point in the different conditions). This result was inconsistent with a portion of the literature on tempo discrimination [21.50, 51]. Greater sensitivity to acceleration or deceleration depends on base tempo [21.52], and the tempo adopted for the experiment by Grondin and Laforest [21.34] was probably too fast.

As for the discrimination of intervals in the context of speech, there are not that many reports describing this fundamental capability. *Quené* [21.53] systematically investigated this question in experiments where participants were presented with a standard sentence and a sentence in which the tempo was accelerated or decelerated. Quené reported just noticeable differences of about 5%, with sensitivity for accelerations being 1 to 2% higher (lower JND) than sensitivity for decelerations. This author also showed that participants' judgments were really based on tempo rather than on other acoustic properties. In Quené's investigation though, the difference between the standard and comparison intervals varied from 5 to 20%. In other words, the 5% reported value may be an overestimation of the real value, i. e., an underestimation of the real capacity to discriminate tempo in speech.

Kato et al. [21.54] also addressed the question of tempo sensitivity in speech but instead of using sentences, they used a series of four-syllable (mora) words, with each syllable consisting of a consonant and a vowel. In their study, the mean word duration was 713 ms, with modifications varying from 2.8 to 11.2%. When entire words were modified, Kato et al. reported a Weber fraction of 3.5%; this value was just above 5.1% when the vowel onsets were specifically modified. Note that Kato et al. also observed better discrimination for accelerations than for decelerations.

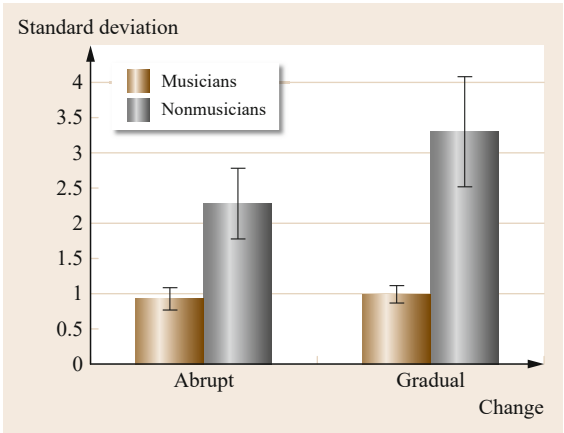

Fig. 21.2 Mean standard deviation for musicians and nonmusicians in abrupt- and gradual-change conditions (error bars correspond to the standard error) (after [21.34])

A recent experiment provided direct comparisons, with the same participants, of performance levels for sentences and tone conditions. *Grondin* et al. [21.55] conducted an experiment with French-speaking participants. In addition to delivering sentences in French, Slovenian (a foreign language participants did not understand) was also used because in French, semantic meaning may have attracted attentional resources. Moreover, during the experiment, certain grouping strategies were imposed on participants, the same in both languages. This temporal patterning of syllables was expected to provide rhythm, and sentences were selected accordingly. In each language, one sentence was divided rhythmically into 4 three-syllable fragments (3–3–3–3: *Il avait demandé à François de l'aider* and *Predite, popoldne, do nase, bicise*). The other sentence was divided into 3 four-syllable fragments (4–4–4: *Emmanuelle est repartie lundi matin* and *Solnce sije, kladvo bije, zgodnje ure*). There were two tone conditions. In one, there was a series of 11 identical empty intervals marked by 12 sounds; and in the other, there were 12 identical filled intervals, with 20 ms between intervals. There were also conditions where empty and filled intervals marked by tones were segmented into the 3–3–3–3 or the 4–4–4 structure.

As illustrated in Fig. 21.3, discrimination was excellent in all conditions, but remained much better in the tone conditions than in the speech conditions: Weber fractions below 2% with tones and around 4.5% in the speech conditions. Observing better discrimination with tones than with sentences reveals that extensive speech training does not improve sensitivity to time interval variations. The results rather indicate that the acoustical variations in speech reduce the discrimination of time interval variations. Keeping nontemporal

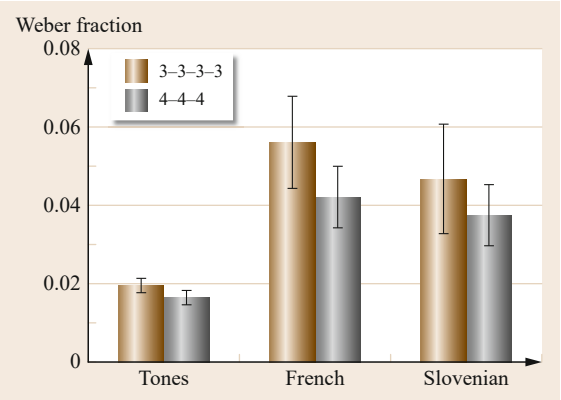

Fig. 21.3 Mean Weber fraction in each rhythm (3–3–3–3; 4–4–4) condition as a function of stimulus condition (tones, French, Slovenian) (after [21.55])

features simple and constant, as is the case with tones but not with speech stimuli, facilitates temporal discrimination. However, knowing or not the semantic meaning of a language does not seem to significantly affect tempo discrimination in a speech context.

This study also revealed that inducing internal subsequences within tone conditions, as opposed to using a series of equal intervals, does not lead to better discrimination. If anything, including rhythmic patterns in sequences of tones led to slightly lower discrimination levels. It is as if it is not possible to access a second level of rhythm for improving discrimination levels. Moreover, discrimination with filled intervals was at least as good as the one with empty intervals. This probably means that the high performance levels were linked to a repetition effect rather than to some rhythmic benefit. Finally, note that there was no significant difference between detecting acceleration versus deceleration.

21.2.3 Comparison of Audition with Other Sensory Modalities

The fact that audition basically constitutes the processing of successive sounds, and that this processing is continuously solicited by the need to understand speech and enjoy music, leads to the prediction that auditory signals must be more efficient for marking time, in a temporal processing task, than signals delivered from other sensory modalities.

There are many pieces of information in the literature for confirming that auditory temporal processing is better than visual or tactile temporal processing (for a review, see [21.56]). It is not the purpose of the present chapter to summarize this literature but the following information should draw a global picture about this issue. It is known for instance that participants are much better at discriminating intervals marked by auditory signals than by visual signals, and this finding applies to filled and empty intervals, and to intervals lasting 125 ms to 4 s [21.15]. In addition, the discrimination of empty intervals is easier with auditory signals than with tactile signals [21.57], and for brief empty intervals, discrimination is easier when signals are delivered from the same modality than from different (intermodal) modalities [21.57–59].

Recently, *Kuroda* et al. [21.60] presented two neighboring empty intervals delimited by three successive signals, each one being a sound (auditory–A) or a flash (visual–V). Participants judged whether the second interval, whose duration was systematically varied, was shorter or longer than the 500 ms first interval. Compared with VVV (three visual stimuli) and AAA (three auditory stimuli), discrimination was impaired for VAV (auditory stimulus between two visual stimuli) but not much for AVA (visual stimulus between two auditory stimuli), a finding consistent with what *Fraisse* [21.61] found with similar stimuli. The study by Kuroda et al. is also consistent with the idea of the superiority of audition (AAA) over vision (VVV) for processing temporal intervals.

Finally, just like there are benefits to expect from multiple presentations of intervals marked by auditory signals, increasing the number of intervals marked by flashes serves to improve performance [21.10], but this benefit may not apply with very brief intervals and may depend on the method adopted for presenting sequences of flashes [21.62].

21.3 Processing Time Intervals: Perceived Duration

Music is made up of multiple sounds of certain durations which are played successively. Perceiving the durations of these sounds and the time intervals created by these sounds is essential for enjoying music. It is said that perceived rhythm is closely related to the relationship between the onsets of successive sounds (e.g., [21.36, 63–65]). This is understandable considering that when an instrument that can produce long sounds, e.g., a violin, and an instrument that can only produce short sounds, e.g., a drum, play the same rhythm together, the sounds coincide somewhere around their onsets (e.g., [21.66], see also [21.67] for perceptual attack time

of musical tones). Accordingly, many of the rhythm perception studies have been conducted focusing on the timing of sound onsets (e.g., [21.68, 69]).

Interestingly, the perceived durations of sounds and time intervals are not always veridical to their physical durations. In this section, perceptual phenomena related to the perceived duration of sounds and time intervals will be explained.

21.3.1 Markers' Length

Sounds used in music, such as sounds of musical instruments and voice, have certain durations. The duration of musical sounds could vary depending on the instrument and the way the sound is played. Some sounds can be about tens or hundreds of milliseconds (e.g., [21.35, 36, 70]), while longer sounds can be more than a second (e.g., [21.36, 71]).

The duration of a sound can be considered as the duration of a filled interval. The perceived duration of a filled interval is said to be longer than that of an empty interval of the same physical duration [21.72–74]). In other words, the duration of a filled interval is overestimated compared to an empty interval. This phenomenon is sometimes called the filled duration illusion [21.73] or the sustained sound illusion [21.75], but note that in some cases, the filled interval which causes the filled duration illusion could refer to a time interval which is marked by two brief sounds like an empty interval but has one or more brief sounds inserted within this interval (e.g., [21.76, 77]). This illusion is a good example demonstrating that the perceived duration of a time interval is influenced by the structure of the interval.

Despite the simplicity of the stimuli, the filled duration illusion shows some complex aspects of time perception. For example, the amount of the illusion, i. e., the amount of overestimation of the filled interval compared to the empty interval, differed between studies. *Zwicker* [21.74] reported that the filled interval was perceived to be as long as an empty interval in which the physical duration was doubled (see also [21.78]). *Craig* [21.72] reported that a silent interval between two sustained sounds needs to be 657 ms longer than the first sound (i. e., a filled interval) to be perceived as having the same duration. *Wearden* et al. [21.73] reported that the perceived duration of an empty interval is only 55–65% of the perceived duration of a filled interval when their physical durations were the same. Moreover, there seemed to be individual differences in the occurrence of the filled duration illusion. In *Hasuo* et al. [21.79], where the subjective durations of empty and filled intervals of 20–180 ms were measured with the method of adjustment, the illusion occurred clearly for some participants but not for many others. Such individual differences were replicated in *Hasuo* et al. [21.80] with time intervals up to 520 ms. These authors also reported that the occurrence of the illusion is influenced by the experimental method.

One of the explanations for the overestimation of a filled interval compared to an empty interval assumes that there is more delay in perceiving the offset of a sound compared to the onset (e.g., [21.72, 81, 82]). In this case, the perceived duration of a filled interval will be longer than that of an empty interval because it will take longer to catch the end of the interval to be judged in the case of filled intervals (Fig. 21.4). Similar arguments were provided by *Fastl* and *Zwicker* [21.78], who schematized temporal changes of auditory-nerve excitation. In the internal-marker hypothesis of *Grondin* [21.15], it is not excluded that a part of the explanation is also located at the beginning of the timekeeping activity. Another explanation is based on the assumption that our internal pacemaker runs faster when there is sound compared to when there is silence (e.g., *Wearden* et al. [21.73] – see Sect. 21.4 for details about the internal-clock model). The same time interval will seem longer when the pacemaker runs faster. Similar explanation is sometimes applied to explain the difference in perceived duration between sensory modalities: when there is an auditory stimulus and a visual stimulus of the same physical duration, the perceived duration of the auditory stimulus will be longer than that of the visual stimulus (e.g., [21.83, 84]), and this phenomenon can be explained by assuming that the sound makes the pacemaker run faster than the light [21.84] (see also [21.56]). These explanations account for the overestimation of a filled interval relative to an empty interval, but given the complexity in the occurrence of the filled duration illusion, it seems difficult to come to a clear conclusion on which of these explanations is more plausible. Rather, it is more likely that the timekeeping process for these time intervals can be modulated depending on the listener and the experimental method [21.80].

Sound duration is not only important for the perception of the sound itself, but also for the perception of the time interval between sounds. *Woodrow* [21.85] showed that when there are two sounds marking a silent time interval of 500 ms between the offset of the first sound and onset of the second sound (offset-onset interval), lengthening either of the two sounds increases the perceived duration of this interval even though the physical duration of this interval was fixed. Similarly, *Grondin* et al. [21.86] showed that an intermodal offset-onset interval (250, 500, and 750 ms) is perceived to be longer when the first or the second marker is 100 ms rather than 5 ms. *Kuroda* et al. [21.60] showed a similar effect of

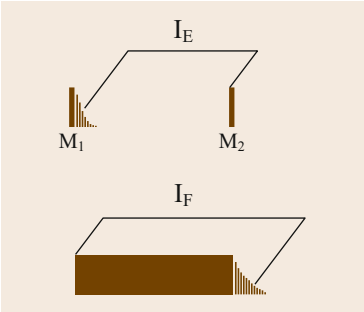

Fig. 21.4 From an internal-marker hypothesis' viewpoint, differences in perceived duration between a filled interval (I_F) and an empty interval (I_E) may depend on differences at the beginning and end of the marking activity. With an empty interval, an observer may wait for the end of the first marker (M_1) before starting to time, but would start timing a filled interval as soon as a signal is detected; and may stop timing as soon as the second marker (M_2) of an empty interval is detected, but would have to wait for the disappearance of the signal marking the time to stop the timekeeping of a filled interval

marker duration by changing the duration of the middle marker in a stimulus sequence of three successive inter- or intramodal markers. *Hasuo* et al. [21.87] observed the influences of sound marker duration, focusing on the time interval between the onsets of two successive sounds (onset-onset interval). Also in this case, the perceived duration of time intervals (120, 240, 360 ms) increased as the second marker lengthened from 20 to 100 ms [21.88]. Lengthening the first marker also increased the perceived duration of the time interval when the time interval was 240 ms or longer (in their Experiment 2), but this effect did not appear in their other experiments involving the duration of the first marker.

Interestingly, sound durations can influence the perceived duration of time intervals even in contexts related to music. *Hasuo* et al. [21.89] observed the effects of sound marker duration using a very simple rhythm pattern consisting of three successive sounds marking two neighboring time intervals by their onsets. In this case, similarly to *Hasuo* et al.'s [21.87] results, lengthening the second sound increased the perceived duration of the first time interval, and lengthening the third sound increased the perceived duration of the second time interval. In other words, a sound whose onset marked the end of the time interval to be judged increased the perceived duration of this interval. *Schubert* and *Fabian* [21.90] found similar effects of sound durations using a part of an actual music piece. They used the dotted rhythm in the opening two bars of Variation 7 of J. S. Bach's Goldberg Variation (BWV988). The rhythmic cell consisted of a dotted quaver (dotted eighth), a semiquaver (sixteenth), and a quaver (eighth), in this order, and the actual dottedness of the rhythm as well as the durations of the tones were varied. They found that shortening the last sound of the rhythmic cell (i. e., changing the quaver to a semiquaver and a semiquaver rest) caused the rhythm to be perceived as more dotted even when the actual dottedness was unaltered. This could be related to *Hasuo* et al.'s [21.89] results in the sense that shortening the sound which terminates the time interval makes the interval seem shorter; shortening the third sound of the rhythmic cell may have caused the second time interval between the second and the third sound to be perceived as shorter, which must have made the contrast between the first and the second time interval greater – making the perceived dottedness clearer.

21.3.2 Interactions Between Intervals

Music is made up of multiple sounds that are played successively. Thus, time intervals often appear in a context of many neighboring time intervals rather than in isolation. When there is more than one time interval, the perceived durations of these intervals can be influenced by one another; research indicates that the subjective duration of time intervals can be affected by preceding or following intervals (e.g., [21.91–94]).

The ratio between neighboring time intervals is important in music. In western music, simple integer ratios such as 1 : 1 or 2 : 1 often appear [21.35, 95], and even when the actual durations of neighboring time intervals deviate from such simple ratios, our perception can be shifted towards these simple ratios [21.68, 92, 96, 97]. One of the phenomena that could be related to the formation of the 1 : 1 perception is an illusion in time perception called *time shrinking* [21.98]. Time shrinking typically takes place in a temporal pattern consisting of three successive sounds marking two neighboring time intervals, T1 and T2, in this order (/T1/T2/; slashes denote short sound markers delimiting T1 and T2). When T1 is slightly shorter than T2, the perceived duration of T2 will be considerably shorter than when it is presented in isolation. A typical temporal condition in which time shrinking takes place is when T1 $\leq$ 200 ms, and maximum time shrinking occurs when T2–T1 is about 80 ms (see [21.77] for a review). Studies showed that time shrinking also appears with visual [21.99] and tactile [21.100, 101] stimuli, but in these cases, the time condition in which time shrinking occurs seems to be wider than in the auditory modality [21.99, 101]. When time shrinking occurs, the physically longer T2 will be shortened perceptually, thus being perceived as having a duration similar to T1. In other words, time shrinking can be considered to be a type of temporal as-

similation between two neighboring durations [21.102]. When T2 is lengthened further and exceeds the range in which time shrinking occurs, the underestimation of T2 disappears suddenly and an overestimation starts to appear [21.103]. In this case, the physically longer T2 will be even more different from T1 – this is probably a contrast between the two neighboring time intervals.

Time shrinking shows the influence of the preceding time interval (T1) on the perception of the following time interval (T2). A question may arise whether the perception of the preceding interval (T1) is influenced by the following interval (T2). Accordingly, *Miyauchi* and *Nakajima* [21.104] measured the subjective durations of both T1 and T2, and compared them to their subjective durations when the time intervals were presented in isolation. When T1 was slightly shorter than T2, T1 was overestimated, and T2 was underestimated; the perceived durations of T1 and T2 approached each other, indicating bilateral assimilation. Such assimilation took place when $-80 \leq$ T1–T2 ≤ 40 ms. The assimilation effect on T1 was much smaller, however, compared to time shrinking on T2. When the difference between T1 and T2 exceeded this range, the assimilation changed to contrast.

The assimilation and contrast between neighboring time intervals are important for the constitution of the 1 : 1 rhythmic category [21.77]. Because of the large effects of time shrinking, the temporal range of the 1 : 1 category is asymmetrical, especially for short durations (e.g., [21.89, 97]). In addition to the behavioral studies, there are electrophysiological studies by *Mitsudo* et al. [21.105, 106], who showed that the auditory temporal assimilation could be associated with brain activities that appeared after the presentation of T2 in the right prefrontal area.

When there are four or more successive sounds marking three or more neighboring time intervals, the perceived duration of the intervals can influence each other in complex ways [21.93].

Another duration illusion in a similar context occurs with filled time intervals. In this illusion, called the *time-stretching illusion*, a sine tone is perceived as longer when it is preceded by a noise than when presented in isolation [21.107]. This illusion also occurs with a band noise preceded by a wider band noise of the same spectral density [21.108]. According to Sasaki et al., the overestimation of the tone duration increases (1) as the noise intensity relative to the tone intensity is increased, (2) as the noise is closer to the tone in frequency, (3) as the tone duration is increased, and (4) as the noise duration is increased up to about 300 ms. However, Sasaki et al., as well as *Kuroda* and *Grondin* [21.109], also reported that some amount of overestimation remained even when the noise was weaker than the tone (see also [21.110]). Sasaki et al. and Carlyon et al. reported that the illusion disappeared when a gap of more than 20 ms was inserted between the two sounds. Finally, Kuroda and Grondin reported that the illusion did not occur when a tone was followed, instead of being preceded, by a noise.

21.3.3 Space, Pitch, and Intensity Effect

Duration processing is sometimes discussed in terms of the relation with space. This issue has attracted attention probably because space and time have to be integrated to perceive motion that is a fundamental feature of perceptual events. How space and time are integrated has been investigated since the early 20th century, and the pioneering works examined how time modulates spatial perception, instead of how space modulates duration perception, mainly with the visual and the tactile modality (see [21.111] for a review). These works reported the *tau effect* where time affects the perception of spatial distance. This phenomenon takes place, for example, with three successive brief flashes, A, B, and C, which are aligned at equal spatial intervals. Two spatial distances, A–B and B–C, are perceived as identical if these flashes are presented at equal time intervals. However, the A–B spatial distance is perceived as shorter than the B–C distance, despite the physical equality of these distances, if the A–B time interval is shorter than the B–C time interval; as well, the A–B spatial distance is perceived as longer than the B–C distance if the A–B time interval is longer than the B–C time interval. In other words, the ratio of two neighboring spatial distances is perceived as similar to that of the corresponding time intervals.

Since then, several studies demonstrated that the opposite effect, i. e., the effect of space on duration perception, could be observed with three visual flashes (e.g., [21.112, 113]). This phenomenon, called the *kappa* effect, was also tested with the auditory modality, whereas most of the studies adopted frequency (pitch) separation instead of spatial distance as an independent variable that would modulate duration perception. For example, *Shigeno* [21.114] used three successive sinusoidal sounds each lasting 200 ms. The initial and the last sounds were fixed at 1000 and 2500 Hz, respectively, while the middle sound's frequency was systematically varied. The relative durations of the first and the second interstimulus time intervals were systematically varied though the total duration was kept at 1000 ms. When the middle sound's frequency was closer to the last sound's frequency than to the initial sound's frequency, the first time interval was likely to be perceived as longer than the second one. Indeed, in this frequency condition, the middle

sound had to be presented before the physical bisection point so that participants perceived the two time intervals as equivalent. Using synthesized vowels /i/ and /e/ as the initial and the last, or the last and the initial sounds, respectively, Shigeno also found that the first time interval was likely to be perceived as longer than the second one when the formant frequencies (vowel quality) of the middle sound were closer to those of the last sound than to those of the initial sound (see also [21.115] using voiced stop consonants).

Note that *Cohen* et al. [21.116] were the ones who first tested the kappa effect with three successive sounds of different frequencies but failed to find clear evidence of the effect. However, they found another effect in the subsequent experiment where two continuous sounds (filled time intervals), instead of empty intervals, were consecutively presented. The first and the second sounds were at 1000 and 3000 Hz, 2000 and 4000 Hz, or 2500 and 2973 Hz, respectively. These sounds were also presented in the opposite order. The total duration of the two sounds was fixed at 1.5 s, while participants adjusted the relative durations of these sounds so that they perceived these durations as equivalent. Participants tended to adjust the first sound to be longer than the second one when the former sound was of lower frequency than the latter. In other words, when two sounds of different frequencies are consecutively presented, the sound of lower frequency is perceived as shorter. The effect was replicated by *Yoblick* and *Salvendy* [21.117].

Grondin and *Plourde* [21.118] examined whether the kappa effect would occur by spatial distance instead of frequency separation (see also [21.119]). Four 20 ms 1 kHz sinusoidal sounds were successively presented, delimiting three neighboring time intervals. The first three sounds were delivered from the same spatial location while the last one was delivered from a different location on a vertical plane. Both the first and the second time intervals were 75, 150, or 225 ms, while the last time interval, which was compared with the preceding ones by participants, was systematically varied. Increasing spatial distance between the two locations (from 1.1 to 2.2 m or from 2.2 to 4.4 m) resulted in an overestimation of the last time interval, except when the preceding intervals lasted 75 ms. This overestimation could be regarded as the occurrence of the kappa effect, but disappeared when participants knew where the sounds would be presented before each trial (one spatial condition per session) instead of when they were uncertain of the locations (all spatial conditions were mixed within one session).

The kappa effect is explained by the imputed-velocity model, positing the constancy of motion speed or velocity [21.77, 111]. According to this model, the kappa-effect (three-stimuli) pattern is perceived as consisting of a single object appearing three times, instead of three discrete objects appearing successively. This single object is perceived as passing through space with constant speed. Speed constancy is physically kept when three stimuli are presented at equal temporal intervals and at equal spatial distances, but not kept if the middle stimulus is made close to the initial or to the last one in space, when time intervals are kept equal. Because this speed inconstancy is re-adjusted by the perceptual system, the first time interval is perceived as shorter than the second one when the middle stimulus is close to the initial one; as well, the first time interval is perceived as longer than the second one when the middle stimulus is close to the last one. The single object, therefore, is perceived as moving between three spatial locations with constant speed.

Henry and *McAuley* [21.120] examined whether this model could apply to three successive sounds of different fundamental frequencies, ranging from 329.63 to 523.25 Hz. The key point of their experiments was the fact that the interonset interval between the initial and the last sounds were varied, this interval being 728, 1000, or 1600 ms. When the whole duration was shorter, pitch was perceived as changing faster during the stimulus pattern, thus strengthening the impression of motion. Indeed, the acceleration of the pitch velocity magnified the kappa effect. This is consistent with what was expected on the basis of the idea that the kappa effect is caused by the perception of motion implied by three successive signals. However, *Alards-Tomalin* et al. [21.121] demonstrated the occurrence of the kappa effect by the intensity separation (i. e., with three successive sounds of different intensities) but reported that the imputed-velocity model could not apply to this kappa effect. In their experiment, three additional sounds were presented before the kappa-effect (three-sound) pattern in order to extend the ascending or descending intensity change of the kappa-effect pattern. These additional sounds were expected to strengthen the impression of motion but indeed reduced, instead of magnifying, the kappa effect.

Note that the imputed-velocity model does not help to predict any spatial effects on the perception of single time intervals delimited by two signals. Indeed, the presentation of only two signals does not imply whether speed is constant or not. There are not many studies examining spatial effects on the perception of single time intervals, even with the visual [21.122–125] and the tactile modality [21.126–128]. However, *Roy* et al. [21.129] reported that single intervals lasting around 125 or 250 ms were perceived as shorter when they were marked by two sounds 3.3 m apart than when marked by two sounds 1.1 m apart from each other. In

other words, with single time intervals, longer spatial distance resulted in shorter perceived duration.

Since the frequency of two consecutive sounds affects their perceived duration as mentioned earlier (see also [21.130] with single intervals), it might be possible that sound intensity (loudness) also affects the perceived duration of filled time intervals. Several studies have investigated how intensity affects the perceived duration of single filled intervals but the results seemed inconsistent [21.131, 132]. However, *Matthews* et al. [21.133] indicated that perceived duration is affected by the relative intensity of signal and background sounds, instead of the absolute intensity of signals. In their experiment, a standard sound of 600 ms and a comparison sound of variable duration were successively presented. A background sound of about 42 (quiet) or 72 dBA (loud) was presented before the standard, between the standard and the comparison, and after the comparison. The standard and the comparison were at 46 and 68 dBA, or 68 and 46 dBA, respectively. In the quiet background, the probability that participants judged the comparison as longer than the standard was increased when the comparison intensity (68 dB) was higher than the standard one (46 dB) compared with when the comparison intensity (46 dB) was lower than the standard (68 dB). In the loud background, the probability of judging the comparison as longer was decreased when the comparison intensity was higher than the standard one compared with when the comparison intensity was lower than the standard. In other words, louder comparisons were perceived as longer when the standard and the comparison intensity was above the (quiet) background intensity but were perceived as shorter when the standard and the comparison intensity was below the (loud) background intensity.

21.4 Theoretical Perspectives

In the present portion of the chapter, the focus is given to a theoretical issue that is important to consider in the perspective of a handbook on music, and neuroscientific explanations are kept to a minimum. For a more complete view on the main theoretical proposals based on neuroscience, the reader is invited to consult some recent reviews [21.134–138].

One classical way of approaching the question of the mechanism(s) involved in temporal processing is to distinguish duration-based and beat-based timing [21.62, 139]. It is actually an interval-based mechanism that is proposed in the traditional internal (single, central) clock perspective originally proposed by *Creelman* [21.140] and *Treisman* [21.141]. This clock is described as a pacemaker emitting pulses whose accumulation in a counter determines the impression about time, more pulses accumulated resulting in longer perceived duration. Errors when estimating time intervals could be attributed to the properties of the pacemaker's rate of emission [21.27], and it is reasonable to posit that the counter is not error free [21.142]. Another source of errors in such a timing process is related to attention [21.143, 144]. A time interval is marked by one or more sensory signals, and fluctuations in attentional processes may change the beginning and end of a timekeeping period marked by the signals [21.145]. This fact is often referred to as a switch process. As well, if another task is to be performed in parallel during the timekeeping operation, the experience of time will be transformed. The attention devoted to a nontemporal task is not available for keeping track of time. When less attention is allocated to time, fewer pulses are accumulated and, consequently, time is perceived as being shorter [21.146, 147]. To explain this fact, *Zakay* and *Block* [21.148] posited that attention is under the control of a gate mechanism. Moreover, depending on the type of temporal tasks to be completed, memory and decisional processes are processing levels that are likely to be involved, and therefore, potential sources of errors. That is what is argued in the information processing version of the scalar expectancy theory [21.149].

Instead of a process based on a single interval presentation, sequences of sensory signals lead to a different level of discrimination, as we have seen earlier, and therefore, probably provide a different source of information on which temporal judgments can be made. This possibility is known as the beat-based hypothesis. Within such a view, the efficiency of timing is based on the expectation generated by the predictability of the arrival of the next signal (or stimulus). Indeed, this efficiency is based, according to *Jones* [21.150, 151] (see also [21.64]) on the synchronization (attunement) of some internal oscillatory activity with environmental stimuli having some coherence or predictability. In terms of Jones' *Dynamic attending theory*, this process is called a future-oriented attending mode.

The multiple presentations of intervals not only generate a beat but also provide an opportunity to stabilize the representation of an interval in memory, which should reduce variance in a duration discrimination process for instance. This perspective is known as the multiple-look model [21.17]. This model assumes that

increasing the number of standard intervals (models) presented improves the representation of this standard in memory. This model is supported by the data showing that increasing the number of standard presentations actually improves performance (up to a certain number of presentations), but not by the fact that the number of standard and the number of comparison intervals both influence performance, with more presentations in each case improving sensitivity to time [21.10, 12, 13].

Returning to the duration-based versus beat-based distinction, neuroscientific investigations now provide evidences that the role of the cerebellum, at least for the processing of subsecond intervals, differs according to the type of temporal processing required. Indeed, both mechanisms are likely available, but rely on distinct neural substrates [21.152, 153]. Moreover, there are probably important individual differences in the way these mechanisms are used. *Grahn* and *McAuley* [21.154] make a distinction between people on the basis of their way of extracting an implicit periodic beat. Indeed, their functional magnetic resonance imaging study helped to distinguish between *strong beat perceivers* and *weak beat perceivers*. When the two groups are compared, the former one has greater neural activity in the supplementary motor area (SMA), left premotor cortex, and left insula, but the neural activity is greater in the participants for the latter group in the right premotor cortex, the left posterior superior and left middle temporal gyri.

21.5 Conclusion

Experimental psychologists have been interested in testing a variety of auditory temporal experiences. The capacity to make an explicit judgment about the duration of sounds, or of an interval between sounds, has received a great deal of research attention. This capacity is crucial because the experience of audition, in speech or music for instance, is essentially temporal.

It is known that sensitivity to time is better in the auditory modality than in other modalities, and is increased when multiple, instead of single, intervals are presented. However, under specific conditions, the repetition of intervals may generate distortions like the impression that the last interval of a sequence is briefer (a time-shrinking effect). Having space between sound sources, or changing frequencies between successive sounds, also has an impact on perceived duration. It is also generally recognized that filled durations are perceived as longer than empty durations, but this effect depends on the method used and on individual differences.

Implicit judgments about time are traditionally reported to depend on an internal clock. This clock is usually described as a pacemaker-counter device, the experience of time relying on the accumulation by the second component of pulses emitted by the first component. Some recent findings in neuroscience reveal that there could be different systems for judging time, some people relying more spontaneously than others on the possibility of using a system based on the processing of beat.

22. Automatic Processing of Musical Sounds in the Human Brain

Elvira Brattico, Chiara Olcese, Mari Tervaniemi

This chapter introduces neurophysiological evidence on the dissociation between unconscious and conscious aspects of musical sound perception. The focus is on research conducted with the event-related potential (ERP) technique, which allows chronometric investigation of information-processing stages during music listening. Findings suggest that automatic processes are confined to the auditory cortex and might even involve the discrimination of deviations from simple musical scale rules. In turn, voluntary, cognitive processes, likely originating from the inferior prefrontal cortex, are necessary to understand more complex musical rules, such as tonality and harmony. The implications of understanding how and to what extent music is processed below the level of consciousness are discussed in rehabilitation and therapeutic settings.

22.1 Perceiving the Music Around Us: An Attentive or Automatic Process?

In psychology, perception of music is typically conceptualized as a conscious, attentive process. Auditory attention is what enables us to process sound information from the world and is also defined as a spotlight on sounds around us to make them stand out. When a sound or sound sequence stands out, we notice and process it. Attention can change rapidly, switching from one thing to another. For instance, attention can be steered by our intentions (*top–down*) or by features of sounds in the environment (*bottom–up*) [22.1]. Hence, outside the focus of attention, when our intentions are diverted elsewhere, we might be attracted by an object or a sound in the environment, which is then processed further and consciously. Outside the focus of attention, preattentive or automatic processes help us decide what to pay attention to and what to filter out [22.2].

Hillyard [22.3, p. 180] wrote:

> *A stimulus set preferentially admits all sensory input to an attended channel* [...] *for further perceptual analysis while blocking or attenuating input arriving over irrelevant channels* [...] *at an early stage of processing.*

According to early filter theories from which the statement by Hillyard was inspired [22.4, 5], after early sensory-memory stages, characterized by parallel and fast sensorial (nonintelligent) analysis of the different stimulus features, there are higher level stages of information processing leading to feature integration and conscious perception. These processes are controlled by top–down voluntary attention and they permit cognitive operations on sounds. Additional neural resources, particularly in the parietal lobe, midbrain and pulvinar, are allocated to selective stimuli of the environment, allowing only relevant information to be further processed by the cerebral cortex [22.6–9]. Subsequently, the neurophysiological signal from the auditory channel is amplified (*Posner* [22.9]; for brain-imaging evidence concerning the auditory system, see [22.10, 11]).

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_22

To study the chronometric succession of neural activity going from fast automatic to slow attentive processes, the most appropriate method is the event-related potential (ERP; also more generally, sometimes referred to as evoked response), which measures the neural responses to a stimulus or a mental act by averaging those portions of an electroencephalography (EEG) or magnetoencephalography (MEG) signal that are locked to each stimulus or act presentation (termed trial) in the experimental session. As compared with other brain research methods, such as functional magnetic resonance imaging (fMRI) or positron emission tomography (PET), that measure the slow metabolic changes in oxygenated hemoglobin and other molecule consumption deriving from neural activity, the ERP method allows one to study with millisecond accuracy the different stages of neural sound processing [22.6, 12, 13]. The ERP data, deficient in spatial resolution but refined in latency information, can then be combined with anatomical and functional knowledge to infer the localization of the recorded neural activity. ERP responses or components to sounds are typically measured as the voltage potential between a reference electrode and the electrode placed at the scalp vertex as early as within the first tens of milliseconds from sound onset.

With regard to neurocognitive processes involved in music listening, the intervention of voluntary attention allows the sophisticated analysis of music according to the high-level hierarchical rules of a musical system, such as those of Western tonal music [22.14, 15]. The attribution of meaning to musical sounds is also supposed to take place during the attentional stage of pitch processing [22.16]. However, while attentional processes are important to understand complex musical rules and likely to attribute musical meaning, the way they are studied with brain research methods, with attentive tasks on the sound stimuli of interest, can be regarded as artificial compared with the everyday experience of music listening [22.17]. Relevant to this, the most common way of consumption of music, amounting to about 76% of all music consumption, consists in hearing music in the background while attending to a primary activity [22.18]. Thus, in order to extract the neural processing specific to the encoding of musical pitch relations, allowing generalization to the most typical music consumption situation, it is preferable to adopt a paradigm in which subjects direct their attention away from the sounds. While this experimental procedure does not bear on all of the music consumption situations in which we find ourselves, it nonetheless includes most of them, at the same time permitting one to avoid contaminations from top–down processes related to attention.

22.2 The MMN as a Measure of Automatic Sound Processing in the Auditory Cortex

The mismatch negativity or MMN [22.19] is an ERP component, which permits one to probe auditory brain processes without the need of attentive listening. The MMN is measured with EEG as a negative wave over frontocentral scalp regions and a potential reversal at mastoidotemporal regions, peaking at around 100–200 ms in response to *deviant* sound stimuli inserted in a sequence of repetitive *standard* stimuli. The potential reversal at the mastoidal sites suggests the generation of the MMN in the bilateral auditory cortex, which is located in the supratemporal lobe. Typically, the MMN indexes the automatic change detection capacity in the auditory cortex and the auditory processing accuracy in the human brain.

The MMN is considered an automatic brain response since it is elicited even when the subject is focused on a primary (e.g., visual) task and not attending to the auditory stimulation. Furthermore, the MMN is observed even during sleep, in coma patients and in newborn infants, confirming its independence from neural processes related to awareness [22.20]. Nevertheless, many studies show that the attention-independent MMN recording can be used as a prediction of the individual discrimination accuracy in behavioral and sensory tasks that use different kinds of sounds and sound-features, such us simple isolated tones changing in pitch [22.21–23] and complex spectro-temporal patterns changing in their contour [22.24].

The MMN depends on the presence of a neural memory trace of a brief duration accurately representing each simple and complex feature of the standard stimulus, including its temporal aspects, and on a neurally distinct mechanism comparing the incoming stimulus with the stored trace [22.25]. Relative to this, *Tervaniemi* et al. [22.26] observed an MMN following the omission of the second tone of a tone pair only when the interstimulus interval was shorter than 200 ms [22.27, 28]. This finding demonstrated that the memory trace for the standard stimulus has a duration, called the temporal window of integration. The MMN is also described to reflect the cerebral cortex function of

predicting the upcoming events by continuously updating a model of the (auditory) environment [22.29–31]. This brain capacity of executing neural matches and mismatches between consecutive sounds at a preattentive level is a fundamental survival tool. It regulates adaptive behavior, allowing humans to detect potentially dangerous inputs.

Classically, the MMN is measured in experiments using the one-deviant *oddball* paradigm: each sequence of repetitive stimuli contains unexpected variations (10–20% occurrence) differing in only one physical feature from the *standard*. The eliciting changes in the auditory input include frequency, pitch, intensity, duration, spatial location and rhythm, as well as more complex features, such as the presence of one phoneme instead of another or an unexpected auditory pattern violating a rule of the auditory sequence. More recently, a *multifeature* paradigm has been introduced, consisting of several deviant sounds deviating from the standard in one feature each (50% occurrence) in the same sound sequence [22.32]. This allows the recording of several MMNs for different auditory features in less than 15 min. The *musical multifeature* paradigm was adapted from the *multifeature* one to mimic a musical context, by integrating the feature changes in 4-tone patterns selected from the pitches of the chromatic scale and modulated into different keys and modes [22.2]. Also a *melody multifeature* paradigm, with changes in melodic contour, key, timbre, rhythm, and tuning has been implemented [22.33, 34]. These fast multifeature paradigms permit one to study automatic musical processing skills even in children and clinical populations, using experiments that are not uncomfortable in terms of duration [22.35–37].

By performing experiments with different stimulation intervals, it has been estimated that the memory system indexed by the MMN lasts almost 10 s [22.38, 39]. This has traditionally been the duration of the long-term auditory sensory memory [22.40]. Furthermore, the so-called *backward-masking* effect has to be considered: *Winkler* and *Näätänen* [22.41] observed that the MMN is elicited only when the *intertone interval* between the first and second tone of a pair is long enough (150–400 ms). The MMNs seem to also reflect the long-term memory, for example in the case of mother-tongue phonemes or musical scale sounds (as will be described in the following sections). Therefore, the MMN is not only a measure of auditory discrimination accuracy but also an index to investigate the higher level mechanisms of neuroplasticity [22.42]. In fact, based on MMN evidence, new views of the human auditory system have been developed: instead of one-way flow of information from short-term memory storage towards long-term memory, we now consider the memory system to also include information flow from the long-term memory towards short-term subsystems [22.43].

22.3 Neural Generators of the MMN

The neural activity underlining the MMN depends on different generators located in different brain areas. They integrate their activity to create a network that works to detect violations and evaluate unexpected stimuli. The MMN generators have been studied by fMRI [22.44–51], PET [22.52–55], and optical imaging (OI [22.56, 57]) methods. The first phase of the MMN mechanism, the detection of a change in the auditory space, originates in the superior temporal gyrus, namely in the nonprimary auditory cortex. Indeed, the auditory cortex is the area mainly involved in the MMN and it is fundamental to creating the short-term memory trace underlying it, as well as to estimating the degree of its violation by the incoming sound [22.58].

The second phase of the MMN consists in the orientation of attention toward sound deviants automatically processed in the auditory cortex [22.59, 60]. The inferior frontal cortex (mainly in the right hemisphere) is the neural generator of the second MMN phase. The frontal activation is delayed with respect to the auditory-cortex processing [22.61], supporting the hypothesis that the auditory cortex change-detection process activates the frontal attention-orientation mechanism [22.20, 25, 62, 63].

The MMN elicited by variations of pure sinusoidal tones originates in the auditory cortex, where different feature changes, such us frequency, intensity, and duration are processed in distinct areas [22.2, 64]; this is analogous to data from MEG in *Levänen* et al. [22.65, 66]. The generation sources of MMNm (magnetic mismatch negativity) responses to a change in different features of complex sound information were found to be differently located. This suggests that distinct supratemporal neuronal populations exist, each involved in the processing of a specific sound change and probably located in different portions of the auditory cortex [22.67]. *Tervaniemi* et al. [22.68] investigated the location and activation of phonetic versus musical sound processing. They presented the subjects with sequences of frequent and infrequent phonemes (/e/ and /o/) or chords (A major and A minor) and observed that the MMN in the right hemi-

sphere was stronger when elicited by an infrequent chord change than by a phoneme change, while it did not significantly differ within the left hemisphere. Furthermore, the MMNm sources for a phoneme or a chord change were found to be differently located in spatially distinct cortical areas, with the phoneme processing areas superior to those for the chord change in both hemispheres. In a subsequent fMRI study, pseudowords and musical sounds were found to activate distinct parts of the auditory as well as thalamic areas [22.69]. Thus, in healthy adult listeners, auditory areas seem to have a highly specialized structure to encode sounds of different complexity and informational content.

22.4 The MMN for Studying Automatic Processing of Simple Musical Rules

Using the MMN one can study whether the auditory cortex can process a violation of a rule-based sound sequence even outside of attentional focus. For instance, *Tervaniemi* et al. found that a significant MMN is elicited by an ascending tone or a repeating tone randomly presented in descending tone sequences [22.70]. It was concluded that not only physical stimulus properties, but also its abstract features are encoded in a sensory memory trace and automatically compared at a preattentive level [22.71, 72]. The MMN elicited by rule violations was defined as an abstract-feature MMN indicating how physical and abstract deviations are encoded even preattentively from the standard stimulation [22.71, 73–78].

In a more musical context, a local rule of Western tonal music is represented by the chromatic scale, which identifies the 12 pitches of the scale as the basic elements for composing a musical piece. As *Levitin* and *Tirovolas* [22.79] remarked, *composers sometimes reward and sometimes violate listener expectations [22.80, p. 216] but do so within this system of legal tones for their culture's music*. *Brattico* et al. [22.81] showed that a violation of the rules of the chromatic scale elicits an MMN in the auditory cortex at the preattentive level. In this case, the prediction for the incoming sound is based not on a repetitive sound heard before but on the relations between sounds, which are governed by the musical scale [22.81]. The ERPs were measured in participants with minimal musical education while they were presented with unfamiliar melodies, containing out-of-tune or out-of-key violations in a passive condition (reading a book) or an attentive condition (they rated the congruity or incongruity of the melodies). An early frontal MMN-like negativity was elicited in response to both pitch violations, but it was stronger for the out-of-tune than for the out-of-key pitches, independently of the subjects' attention. These results showed that the musical scale features are automatically processed and compared with the representations for the musical scale pitches already at the level of the auditory cortex (although a second generator was also noticed in the inferior prefrontal cortex). These findings evidence *intelligent* cognitive processes related to (simple) musical rule extraction already at the preattentive level [22.81, 82].

Furthermore, two important dichotomies governing Western music – major versus minor and consonance versus dissonance – have also been studied using MMN. *Brattico* et al. [22.83] found that two-tone intervals characterized by a simple frequency ratio (such as consonant intervals: octave, major fifth) are more easily discriminated than intervals characterized by complex frequency ratios (such as dissonant intervals: minor sevenths, minor second). She and her colleagues also showed with magnetoencephalographic recordings that in professional musicians or students from music academies (as opposed to nonmusicians) the magnetic MMN (MMNm) originated from the bilateral auditory cortex and was enhanced specifically in response to nonconventional chords, such as dissonant or mistuned chords. In contrast, their MMNm did not significantly differ from that of nonmusicians in response to minor chords, which are more frequently encountered in Western tonal music. The study pointed at a chord-selective neuroplasticity of the auditory cortex dependent on the exposure to a musical culture. *Virtala* et al. [22.84] further tested the MMN of healthy nonmusicians exposed to four different chords, major, dissonant, minor and inverted major, composed of the same tones and transposed to 12 different levels but with a different tone order. The minor and dissonant chords among major chords elicited an MMN while the inverted major chord did not. This finding, thoroughly investigated also in newborn infants, adolescents, and adult musicians [22.85–87] suggests that the knowledge of traditional music categories is implicitly learned from exposure to a musical culture and consequently preattentively encoded from an early age. The MMN enhancement in musicians demonstrates that explicit training in music might further facilitate and strengthen these processes.

22.5 ERAN as an Index of Semiautomatic Processing of Musical Rules

The violation of the less-local, hierarchical rule of harmony, dictating how chords should succeed each other (for instance, that a musical piece is always ended by a tonic chord preceded by a dominant chord), elicits a different brain response, the early right anterior negativity (ERAN) originating selectively from distinct anatomical regions of the frontal lobe, namely the inferior frontal gyrus (BA44; Brodmann area 44) and the ventral premotor cortex [22.88]. In *Brattico* et al. [22.81] the MMN to the violation of the musical scale was comparable in attended and unattended conditions, showing the automaticity of the neural process of neural representation of that basic musical rule and of the discrimination of its violation. In contrast, the ERAN process, underlying the neural representation of chord succession rules, is only partially automatic, since it is typically elicited when subjects pay attention to deviant timbres inserted in the musical sequences. Moreover, while in *Koelsch* et al. [22.89] an ERAN was elicited even when subjects were distracted from the sound stimulation by a primary task unrelated to the sounds, there was no ERAN to the chords in the middle of the cadence but only to the final ones, which are more salient. Similarly, in *Loui* et al. [22.90] the ERAN was larger when subjects were paying attention to the sounds as opposed to when they were distracted by a reading comprehension task. The formal knowledge of music enhances the neural representations of musical rules as indexed by the enhancement of the ERAN in musicians as opposed to nonmusicians [22.91]. In relation to this, when musical expertise is complex, such as in the case of Finnish folk musicians trained to perform pieces of various musical cultures, sometimes not even containing chords typical of Western tonal harmony (such as the Neapolitan chord not much used in Finnish folk music), the ERAN response is affected and diverges from that of typical listeners [22.92].

22.6 Environmental Exposure Modulates the Automatic Neural Representations of Musical Sounds

The brain modifies its neural activity to adapt to the environmental demands [22.93]. This process is most visible during childhood and adolescence, when it intermingles with developmental processes such as neuronal apoptosis, mielinization and overall body growth, but it exists to a certain extent even in adulthood. For instance, the exposure to repetitive sounds modifies plastically the auditory-cortex representations in order to implement their autonomic processing, saving neural resources, and to quickly discriminate the deviant incoming sound events. The MMN indexes this plastic process in the auditory domain. For instance, an enhanced MMN was elicited in response to infrequent voices familiar to the subjects (a close relative or a long-term friend of each subject recorded their utterance of the vowel *a*) as compared to infrequent unfamiliar ones [22.94], or to an infrequent tongue-clucking sound versus a similar but unfamiliar sound [22.95].

The MMN sensibility to familiar sounds might also imply that musicians, exposed everyday to musical sounds and sequences, would show a larger MMN response to any musical sound than nonmusicians, and particularly to those musical sounds to which they are most accustomed. This would indicate that the musicians' auditory cortex has an increased preattentive ability to discriminate violations of musical sound features and perhaps even of musical rules (which could be viewed as instances of sound sequence features). This hypothesis was confirmed by data from various studies [22.29, 96–98]. In particular, *Koelsch* et al. [22.96] presented major chords and single tones to both professional violinists and nonmusicians, in both passive and active conditions. Slightly mistuned chords elicited an MMN only in professional musicians, but not in nonmusicians. In contrast, the musicians and nonmusicians did not differ in their MMN elicited by sinusoidal tones. These results indicate that the sensory memory function can be trained and modulated, however, this modulation being specific to musical sounds.

This neural sensitivity to encode particular music features in a highly specialized manner has prompted research in which musicians with different practice history are compared. Such an approach is also motivated by the fact that musicians' perceptual and motor skills depend highly on the level of expertise as well as on the instrument, practice strategies, and musical genre. The *musical multifeature* paradigm defined by *Vuust* et al. [22.2] allowed one to study systematically and in a time-efficient manner the influence of a specific musical training on musicians' skills. In this paradigm, six types of acoustic changes relevant for different musical genres (pitch, mistuning, intensity, timbre, sound-source location, and rhythm) were presented in the same sound sequence including 4-tone

patterns resembling Alberti's bass. A pitch slide typical for improvisational (jazz) music (less present in classical music) was inserted in order to compare the neural responses of musicians with those of other musicians playing different musical genres [22.99]. The MMN was measured in three groups of musicians playing classical, jazz, or rock/pop music; also a group of nonmusicians was included. The jazz musicians had the larger MMN amplitude across the six different features, indicating a greater overall sensitivity to sound feature violations, but particularly to pitch-related feature deviants, such as the pitch slide. These data suggest that not only the musical training, but also the characteristics of the genre of music played by musicians might increase and influence their auditory cortex preattentive skills [22.99]. However, one has to keep in mind that the advanced sound discrimination skills of musicians might reflect either an innate prerequisite or an effect of music practice. In fact, superior performance in musicality tests is also reflected as enhanced MMN responses [22.21, 100]. Thus, longitudinal studies using the MMN need to be conducted in order to determine the sources of individual abilities in music perceptual skills.

Recently, Tervaniemi's group obtained pioneering evidence on the effects of music training in sound discrimination accuracy [22.101] in a semilongitudinal setting with the majority of the children involved in the study being followed up on many times over several years. In their study, children aged 7–13 years were presented with a multifeature paradigm (with deviances in pitch, perceived location, intensity, and duration; additionally a gap was placed within the sounds) and with a major–minor chord paradigm. Half of them were actively involved in musical training and received individual teaching in an instrument as well as lessons on music theory on a weekly basis, while half were active in other hobbies but not in any music-related ones. When the recordings were conducted for the first time at the onset of the musical training at the age of 7 years, the groups did not differ in any MMN parameters in the multifeature or chord paradigms. However, during the accumulated training in music until the age of 13, the MMN grew faster in the musically active children than in the musically inactive children. This observation was specific to the chord paradigm; in the multifeature paradigm, a similar statistically nonsignificant trend was observed for the location deviance alone. This result extends to childhood previous observations made with adult musicians [22.33, 99, 102] according to which music training can selectively modulate sound discrimination of those sound features and sound types that are most common in a certain musical culture and/or most salient in a particular instrumental practice, without being generalized to all sounds and sound types.

The selectivity of auditory-cortex discrimination skills does not, however, exclude the possibility of a cross-modal transfer of those skills to other domains. It has been found that musicians have superior automatic discrimination skills for acoustic features of language sounds, as a consequence of musical training, as the features involved are those spectral (pitch) features relevant also in music [22.103]; even the brainstem frequency-following response that indexes neuronal phase locking to the F0 acoustic cue – of a pitch note or a phoneme – is enhanced in musicians compared to nonmusicians [22.104, 105]. This spectral sound discrimination superiority dependent on musical training and thus on a *highly trained auditory system* has also been noticed in the discrimination of speech sounds, namely vowels and temporal variations of consonant-vowel syllables [22.106], although whether this is strictly a result of musical training or of inborn musicality skills [22.107] remains to be determined in future investigations.

22.7 Disrupted Automatic Discrimination of Musical Sounds

In the population, it is not uncommon to find individuals with self-reported or objectively suboptimal abilities for musical perception. Peretz et al. identified these individuals as congenital amusics or tone-deaf by means of a listening test, the Montreal battery for evaluation of amusia [22.108], combined with other perceptual and cognitive tests that isolate the music deficit from any other behavioral or cognitive difficulty. Scoring below two standard deviations from the mean obtained with the normal population is the commonly used criterion for a diagnosis of congenital amusia. The percentage of amusics among the general population has been estimated to be around 4, hence similar to other developmental disorders, such as dyslexia.

Neurophysiological and structural evidence shows that congenital amusic individuals have an abnormal connectivity between the superior temporal gyrus and the inferior prefrontal cortex, namely between the two brain regions that allow the processing of musical rules and their violations [22.109]. The first study reporting related functional brain evidence was by *Peretz* et al. [22.110]. In that study, eight amusic individuals

and ten controls were measured with the ERP technique while they listened to patterns of five repeated tones, in which the fourth tone was replaced 30% of the time, displaced either upward or downward by a quartertone to 3 semitones. In an attentive condition, the most evident ERP components reflecting the conscious detection of a sound change are typically the N200 and the P300. In amusic individuals the N200–P300 complex was enhanced for large pitch changes, whereas for quartertone and semitone changes the P300 was significantly reduced, as compared with controls (for whom the N200 was not even visible). Remarkably, the N100, an earlier obligatory ERP component reflecting initial sensory encoding of any incoming sound, did not distinguish the two experimental groups, confirming that the origin of the neural deficit for music perception can be traced down to the later, conscious stages of auditory processing [22.110, 111]. Seemingly discrepant results were obtained by *Albouy* et al. [22.109] in an MEG study using a working memory task where nine amusic individuals and nine control subjects were asked to detect if two 1.5 sec melodies of six tones, separated by a 2 sec silent interval, were the same or different. The change, presented in half of the melodies, could appear in the second to fifth tone of the second melody. The N100 response to the first tone in the melodies was similar in amusic and normal individuals, replicating previous findings, whereas the N100 response to the subsequent changed tones was diminished in amusic individuals as compared with controls (with a later enhanced response in amusic individuals, due to a delayed N100 latency). The authors claimed that they traced the music-specific problem down to the level of the auditory cortex. However, the neural generator of the N100 was identified in the inferior frontal gyrus, and indeed the neural response was obtained in a task involving conscious and effortful retrieval from working memory of musical material. Behavioral data obtained in the same study (replicating other findings: e.g., *Tillmann* et al. [22.112]) confirms a specific working memory deficit for pitch in amusic individuals, which is reflected in the N100 response and hints at a later stage of processing than the auditory-cortex one indexed by these findings.

The possibility that preattentive auditory-cortex skills might be preserved in amusia was further explored in a study by *Peretz* et al. [22.113]. They found even more surprising evidence about the dissociation between preattentive skills of amusic individuals and their conscious perception of musical pitch. Amusic individuals showed an early negative ERP response (MMN or N200) to mistuned pitches, which were at a quartertone interval from the preceding sound, when those pitches were inserted in unfamiliar tonal melodies, but not to out-of-key pitches. In contrast, amusics did not show the later positive ERP response (P600) to mistuned or out-of-key pitches, which were observed in controls, suggesting the presence in amusic individuals of a neural dysfunction for cognitively extracting and becoming aware of the musical violation, in spite of their preattentive ability to discriminate it. The authors commented on the findings as follows [22.113]:

> *This early neural information, typically computed in the right auditory cortex* [...] *appears, however, insufficient to make contact or to build schemas about musical keys for conscious detection of violations in the right inferior frontal region.*

The neurophysiological studies evidencing residual neural reactions to wrong pitch in congenital amusia have encouraged attempts for rehabilitation towards compensating the neurogenetic vulnerability. For instance, Peretz's group investigated 10–13-year-old children with a marked deficit in perceiving small pitch intervals (but with normal general intelligence [22.114]). The children were asked to listen to music for at least 30 min per day during a period of 4 weeks. Such passive music intervention, though, did not have any effect on the neural or behavioral correlates of the defective pitch processing in amusic children, leading the researchers to conclude that *musical deprivation in childhood does not seem to be the cause of congenital amusia* [22.114]. However, the authors left open the question as to whether active and motivational musical training would produce any positive rehabilitative effects on amusic children.

Recently, altered musical sound processing has also been studied in cochlear implant (CI) users. A CI is a device comprising a microphone, a speech processor and a transmitter coil, for conversion of acoustic signals into electric pulses. The CI is implanted above the basilar membrane of the inner ear in patients suffering from severe and profound hearing loss, allowing them to substantially increase speech intelligibility, especially if implanted early in life, but with limited improvements in regard to music perception, particularly in the domains of timbre and pitch [22.115, 116]. Using the fast *multifeature* paradigm *Torppa* et al. [22.36] showed the presence of an MMN to sound features in prelingually deaf children with a CI, which was diminished as compared with control children but only in timbre, sound duration, and gap. Diminished MMN amplitudes to timbre and pitch deviants inserted in a *musical multifeature* paradigm were also obtained with postlingually deaf CI adults [22.117], and even with 14-year-old CI adolescents who had been prelingually deaf [22.37].

Remarkably, in the latter experiment the CI adolescents followed an intensive active ear-training program lasting two weeks, and this short-term intensive program was sufficient to modify the neural responses to rhythm deviants, showing the potentiality of a musical rehabilitation program for young CI users.

22.8 Conclusions

The findings presented above highlight the role of preattentive neural mechanisms in music perception, as indexed by the MMN. Indeed, a study with stroke patients showed that the increase in the magnetic MMN to pitch changes correlated with the recovery of cognitive functions, such as behavioral improvement in the story recall and mental subtraction tasks [22.51]. This and other evidence presented also in the above text depicts preattentive auditory skills as prerequisites for more complex operations, which require cognitive functions.

The MMN literature reviewed, nevertheless, also evidenced dissociation between unconscious and conscious aspects of musical sound perception, suggesting that voluntary, cognitive processes, likely originating from the inferior prefrontal cortex, are necessary to understand more complex musical rules, such as tonality and harmony. This neural dissociation points at the presence of subliminal sound events never reaching the level of awareness which results in a behavioral music-specific deficit, but at the same time represent a hope for rehabilitation (such as for amusic individuals and CI users). In the auditory domain, then, the concept of unconscious by *Jung* still holds and describes our phenomena well [22.118, p. 964]:

> *The unconscious contains all those psychic events which, because of the lack of the necessary intensity of their functioning, are unable to pass the threshold which divides the conscious from the unconscious; so that they remain in effect below the surface of the conscious, and flit by in subliminal phantom forms.*

Subliminal effects of music on cognitive activities or even emotional responses in another modality have been proved, and the general mood state of subjects can be improved without realizing it while being exposed to relaxing music in the background without paying attention to it [22.119, 120]. Hence, understanding how and to what extent music is processed below the level of consciousness has potential implications not only for applications of music in rehabilitation of perceptual and cognitive functions but also in therapeutic settings or for our wellbeing in everyday life.

23. Long-Term Memory for Music

Lola L. Cuddy

This chapter begins with a brief overview of traditional approaches to long-term memory in general. It highlights the memory system known as semantic memory, and then in subsequent sections explores the proposal that a purely musical semantic memory may be identified and is isolable from semantic memory in other, nonmusical, domains. Finally, neuropsychological evidence for the selective sparing of the musical semantic memory system in dementia is reviewed.

23.1 Long-Term Memory and the Semantic System

Research in long-term memory has led to a theoretical description of memory organization according to three interdependent systems – semantic, episodic, and procedural memory systems [23.1]. The concept of *semantic memory* was famously introduced to psychology by *Tulving* [23.2] as follows:

> *A mental thesaurus, organized knowledge a person possesses about words and other verbal symbols, their meaning and referents, about relations among them, and about rules, formulas and algorithms for the manipulation of these symbols, concepts, and relations.*

It was to be distinguished from the type of memory typically studied in laboratories of the time, namely, *episodic memory* [23.2, 3]. Episodic memories are memories for specific events or life-time situations, tagged with reference to specific temporal-spatial locations. Recalling that California is a state of the U.S. requires semantic memory, whereas recalling whether you have ever been in California requires episodic memory. Recalling a list of unrelated words in a memory experiment involves episodic memory – that is, the meanings of the words are already known and represented in semantic memory, but the participant in the experiment must remember that a given word was presented at a certain place and time in a word list spoken by a specific individual. Autobiographical memories – self-referential life-time memories – are a type of episodic memory that may contain semantic features. Semantic and episodic memories have been studied traditionally in the verbal and visual domains.

The third system, *procedural memory*, is skill memory – the performance in multiple domains of particular types of action such as riding a bike, reading, tying one's shoes, or, perhaps, singing a tune. It is thought that procedural memory is below the level of conscious awareness, because it is easy to produce these actions, though difficult to explain how and where they were learned. Thus, procedural memories do not require conscious control or attention. They are acquired through repetition of a complex activity and so become automatic.

Another distinction arising from theories of memory organization is that of explicit and implicit memory. Whereas *explicit memory* involves conscious recollections of events, *implicit memory* involves the effect of prior learning on performance without conscious awareness of effect. Procedural memory, with its characteristic definition of unconscious processing, has been identified with implicit memory. By contrast, semantic and episodic memories have been identified with explicit, conscious, memory. However, implicit memory is not always related to procedural memory. Both semantic and episodic memories have implicit features, a point which has implications for describing the contents of musical semantic memory, as discussed below.

23.2 Semantic Memory for Music

This section deals with the issue whether there is a musical semantic memory that is behaviorally, and possibly neurally, distinct from verbal semantic memory. It addresses the questions how such a memory might be described and defined. It is a matter of debate whether musical semantic memory is contained within a general verbal semantic system or is itself a separate entity.

Slevc and *Patel* [23.4] argue that it is not possible to disclose the semantic meaning of music specifically. According to *Patel* [23.5], the range of musical semantics is rather limited, because music, unlike words, does not have semantic referents that link to meaningful concepts. Such a perspective implies that musical semantic memory may be loosely tied to a general semantic memory, but lacks the resources to organize a vast semantic network of its own.

It is true that musical knowledge may be tied to linguistic elements – such as song lyrics, titles, music-theoretic, and cultural concepts. *Steinbeis* and *Koelsch* [23.6] have demonstrated that the emotions expressed by single musical features activate the processing of related emotional words. It is also plausible, to borrow an example from *Patel* [23.5], to conclude that it takes little effort to decide whether Beethoven's *Appassionata* connotes *explosive fury* or *passive contemplation*. However, word-associations to music are extramusical and failure to retrieve these linguistic descriptors need not signal failure of the musical semantic memory system.

Apart from extramusical referents, however, musical meaning *can emerge from the interpretation of intramusical structural relations* contained in the music itself [23.7, pp. 170–171]. For *Omar* et al. [23.8, p. 468]), semantic musical memory is a *self-contained, abstract, purely musical* [...] nonreferential system *meaningful on its own terms* containing knowledge of familiar tunes, instrumental timbres, symbols (notation), rules of musical structure, and emotion. For *Platel* et al. [23.9, p. 245]:

> *Semantic memory allows us to identify or to have a strong feeling of knowing for familiar songs or melodies* [...] *Musical semantic memory may represent a musical lexicon, separate of a verbal lexicon, even though strong links certainly exist between them.*

The musical lexicon has been formally described as a component of a modular music recognition system [23.10] (see also [23.11, 12]).

> *The musical lexicon is presently best understood as a perceptual representational system for isolated tunes, much in the same way as the mental word lexicon represents isolated words.* [23.13, p. 257]

This perspective on musical semantic memory emphasizes the point that the musical lexicon enables a strong sense of familiarity for a previously encountered tune interacting with, but relatively independently of, verbal associations with the tune.

In accord with this notion, neuroimaging studies have proposed distinct neural networks for musical and verbal semantic memory. For example, *Groussard* et al. [23.14] reported an fMRI study comparing activation for verbal and musical semantic representations. Within the left temporal cortex, musical material mainly activated the superior temporal gyrus and verbal material mainly activated the middle and inferior gyri.

The contents of musical semantic memory are acquired and processed implicitly – that is without conscious effort and awareness. In an extensive and important critical review, *Rohrmeier* and *Rebuschat* [23.15] discuss evidence that implicit musical knowledge is formed through mere exposure to musical structures without explicit instruction about the rules for building such structures. See for example, the studies on implicit knowledge of musical regularities and the results of artificial grammar learning studies (reviewed in [23.15, 16]). Knowledge of the principles governing tonality is implicit knowledge. This knowledge, implicitly acquired, may be tapped by semantic and episodic memory.

Formal music training is not required to recognize familiar tunes, generate musical expectancies and respond to the emotional properties – arousal and valence – of music [23.17]. *Krumhansl* [23.18] proposed that statistically frequent patterns in music are guides to understanding the organizing principles of hierarchical tonal structure in music. *Krumhansl* and *Cuddy* [23.19] note that these principles are implicitly picked up by preschool-age children, though they cannot describe this knowledge. The process of acquisition may be similar to that of natural language acquisition [23.20].

Moreover, when presented with musical excerpts that do not correspond to Western musical tonality, adult listeners implicitly re-orient to the unfamiliar pitch hierarchies of cross-cultural musical systems. Their pitch judgments correspond to the statistical distributions of tones (for the music of North India, see [23.21], for the music of Bali [23.22], for Korean court music [23.23]).

23.3 Evidence from Neuropsychology

There are many underlying causes of amnesia and memory loss – for example, stroke, tumor, psychiatric depression, vitamin deficiency, and neurodegenerative disease. Patients with brain damage following stroke have provided evidence for an isolated musical semantic memory or musical lexicon that is selectively lost or alternatively spared. *Peretz* and *Coltheart* [23.10] summarize case reports in which brain-damaged nonmusicians have lost the ability to recognize tunes while maintaining the ability to recognize words, including the lyrics that accompany the tunes. Similarly, the patient KB, who became amusic and aprosodic following right-hemisphere stroke, was unable to recognize instrumental tunes despite preserved cognitive abilities [23.24] (see also [23.25]). KB was able to recognize lyrics of popular tunes, when spoken, but unable to produce a single response to the request to sing the tune that would normally accompany the spoken lyrics. The reverse situation, loss of ability to recognize words but preserved ability to recognize tunes, is found more rarely, but was reported for three brain-damaged patients who were afflicted with word deafness yet able to recognize music [23.10]. However, selective preservation of musical memory is more commonly and strikingly found among the dementias.

Evidence from dementias studies: Alzheimer Disease (AD): Of the cases of neurodegenerative disease leading to dementia, Alzheimer's disease (AD) is the most prevalent accounting for about 2/3 of cases of dementia. The course of AD is relentlessly progressive through mild, moderate, and severe stages. There is no known cure. It primarily affects cholinergic transmissions to all cortical areas; some may be affected at differential rates but eventually all become impaired. The diagnosis is confirmed only by postmortem findings of characteristic plaques and tangles in brain tissue.

Participants in early studies of sparing in AD were representative of a selected population – professional or skilled musicians (pianists, violinists, a trombonist; for a detailed summary table of references, see [23.8, Table 1]; also see [23.26, Table 1]). Performance sparing for these individuals might be seen as evidence of preserved procedural, not semantic, musical memory.

Our first study was a case study [23.27] of an 84-year-old woman (EN), a former music lover, but not a professional musician, EN was severely demented; she was unable to carry on an intelligible conversation and did not recognize family members. Yet, as the family members reported to us, she still enjoyed and remembered music. We did not attempt imaging because of the difficulty of explaining the procedure to EN and our wish to avoid creating obvious distress. However, a postmortem examination two years following our testing sessions revealed neuropathological changes that confirmed relatively advanced AD – moderately severe atrophy of medial temporal lobe (MTL) structures and expansion of temporal horns of lateral ventricles. Immunostaining of representative sections showed significant neuronal loss and reactive gliosis in MTL together with the presence of moderate to numerous diffuse and neuritic amyloid plaques and prominent neurofibrillary degeneration (Braak Stage V of VI: [23.28]).

We had administered three tests in which we assessed EN's familiarity with melodies and one in which we had assessed her ability to detect a pitch distortion in familiar melodies. The test employed was the Distorted Tunes Test (DTT) constructed by *Dennis Drayna* [23.29] as an update of a test intended to identify tune-deafness [23.30]. Twenty-six short melodies were presented of which 17 were distorted by pitch errors. Pitch errors changed two to nine notes generally within one or two semitones of the correct note. The distortion maintained the contour (ups and downs in pitch) and rhythm of the familiar melody but the distortions violated the tonal structure of the melody. An online version of the DTT is available where the melodies may be heard [23.31].

Familiarity was assumed if EN sang along correctly with a short test tune and continued to sing after the tune stopped. *Unfamiliarity* was assumed if she sat with a blank stare and made no effort to sing along with the test tune. Evidence of correct detection of a pitch distortion was grimacing, frowning, and other facial signs of displeasure. No such displeasure was taken to indicate that she found the tune to be correctly played.

EN's test results provided encouraging support for the possibility that sparing of musical memory may be detected in dementia and may be reliably and quantitatively assessed through behavioral observation. Allowing assessment by behavioral observation corroborated with an independent judge, we found that EN's scores were high and typically in the control range. We noted dramatic contrast between EN's response to music and her mental status. We also noted that evidence of sparing would not have been recovered with conventional assessment – conventional assessment requiring verbal communication would suggest severe musical difficulties.

Subsequent work [23.32] followed the case study with an assessment of 50 AD persons at various stages of the disease. Their performance on six tests was compared with a larger sample of healthy young and older adults and showed intact recognition of familiar melodies along with preserved ability to detect pitch

distortions in the mild and moderate stages. Difficulties with detecting grammatical distortions in spoken song lyrics were evident even at the mild stage of AD.

Among some AD persons there is also sparing of ability to detect tonal violations even with unfamiliar melodies [23.33]. Where this is found, it may be said to reveal a preservation of implicit tonal knowledge. It implies that the detection of a distortion is not merely a process of matching a heard melody with a stored template of a melody and detecting a mismatch. It implies that there is an ability to detect a deviation from the tonal system of pitches, an ability that reflects musical knowledge of the Western tonal-hierarchical system of pitch organization.

A recent study by *Kerer* et al. [23.26] assessed 10 participants with MCI and 10 with early stage AD and compared their results with 28 cognitively normal older adults. They tested identification of familiar musical melodies and recognition of a pitch distortion in the melodies. Pitch distortions were introduced by rules similar to those followed in the DTT described above. Compared to healthy controls, their patient sample was poorer on verbal tasks such as naming the titles of the melodies, thus exhibiting a failure of the word-association system. However, patients were superior to controls on detecting a pitch distortion in familiar melodies and also in a timbre task, which was to decide whether melodies were normally played by instruments or presented vocally. The authors attribute the latter findings to a specialized memory for music.

In tandem with the above studies from our laboratory, we have also reported that recognition memory is compromised, not preserved, both in healthy aging, and dementia, as well as in mild cognitive impairment (suspected prodromal to AD) [23.34, 35]. The paradigm for assessing recognition memory involves presenting a playlist of melodies to a participant followed by a test list in which the playlist is interleaved with new melodies. The participant must judge which melodies in the test list occurred in the playlist and which did not. Young adults find the test quite easy, but older adults, even cognitively healthy older adults, do not. The problem for older adults and AD adults is that it is difficult to distinguish melodies heard on the playlist (where the participant must remember the episode of hearing the melodies in a certain place at a certain time) from melodies heard before outside the laboratory. The kind of memory being tested in a recognition memory paradigm may be characterized as episodic memory, and its failure in AD may be partly attributable to aging, rather than the disease.

Other studies with the recognition paradigm have obtained similar results [23.36, 37]. Halpern and O'Connor used an explicit and an implicit memory task. Whether test instructions were explicit (yes/no responses to a previously heard playlist of melodies mingled with new melodies) or implicit (pleasantness) ratings for the melodies, AD participants show poorer performance than healthy controls. An exception to this finding is a study by *Quoniam* et al. [23.38] who reported a positive affective bias (liking) for previously heard melodies in AD. Their results are puzzling, however, in that healthy controls showed little effect of repetition on likingness with the AD group surpassing the controls; the finding deserves to be replicated.

Evidence from other neuropsychological sources: A number of researchers have studied a somewhat rarer form of dementia, known as fronto-temporal dementia and its temporal variant semantic dementia. Frontotemporal dementia involves damage to the brain's frontal and temporal lobes and affects planning and judgment, emotions, speaking and understanding speech, walking and other basic movements. Both frontotemporal degeneration (FTD) and Alzheimer's disease (AD) are characterized by atrophy of the brain, and a gradual, progressive loss of brain function. However, FTD is primarily a disease of behavior and language dysfunction, while the hallmark of Alzheimer's disease is loss of memory, especially episodic memory. FTD patients exhibit behavioral and personality changes but retain features of memory such as keeping track of day-to-day events, and orientation to space and time. AD patients display increasing memory deficits, but typically retain socially appropriate behavior in the early (mild to moderate) stages. Some FTD patients may have language dysfunction only as revealed in the two types of progressive aphasia: semantic dementia and progressive nonfluent aphasia. The language decline seen in AD patients is of a milder nature [23.39].

Semantic dementia (SD) is associated with predominantly temporal lobe atrophy (left greater than right). The hallmark of the aphasia in semantic dementia is difficulty generating or recognizing familiar words. Patients exhibit language difficulties, not in producing speech but with a loss of the meaning or semantics of words, faces, and objects. Although semantic memory impairment occurs in AD, AD is almost always accompanied by severe impairment of episodic memory, and eventually disruption of many other cognitive domains, including visuospatial and frontal executive function [23.40, 41].

A few studies have assessed long-term musical memory in FTD and SD; some have drawn comparisons with AD cases [23.42–45]. In general, SD participants showed deficits in familiarity decisions, especially where naming of tunes is involved. *Hailstone* et al. [23.46] present a case study of SD with convincing evidence that musical knowledge was relatively

preserved. In the study by *Hsieh* et al. [23.42] variability in SD results was high and three of the 13 SD patients performed in the normal range on their tune familiarity test. AD patients, as might be expected from the AD findings cited earlier above, did not differ significantly from controls.

Weinstein et al. [23.47] report a case study of profound impairment in SD – a computer programmer in his early 60s who had also been a semiprofessional harpsichordist. The man was able to perform both familiar and previously unfamiliar Baroque pieces with accuracy and musicality. Of particular importance was the presence in his performances of novel, additional, notes that were style-appropriate embellishments. He also introduced a stylistically appropriate retard in the final, compared with the initial, presentation of a theme. The authors suggest that their case study may reflect the preservation of the abstract concept of musical style in SD; that is, preservation was not limited to the habitual striking of keys and was not solely procedural. They propose the hypothesis that:

> *knowledge represented in semantic memory is partly modular, dissociating long-term representations of object and word concepts from meaningful knowledge in other domains, such as music.* [23.47, p.250]

A case of musical sparing despite profound semantic and episodic impairment following herpes encephalitis was presented by *Finke* et al. [23.48]. Their patient was a a 69-year-old professional cellist (PM) who, despite his severe memory impairment, performed normally on a battery of musical tests, including discriminability of famous from nonfamous pieces, and learning complex new musical material as revealed by an incidental memory task. *Finke* et al. [23.48, p. 592] note that for PM: *learning and memory of complex musical information constitutes an island of intact cognition within a severe amnesic syndrome* and suggest this information involves a brain network independent of other types of (nonmusical) episodic and semantic memory.

23.4 Concluding Comments

Neuropsychological studies of neuropathology have yielded valuable behavioral/cognitive evidence supporting the notion of a musical semantic system that may be dissociated from semantic memories in other domains. This musical system may be preferentially spared in the face of loss of cognitive abilities. What my colleagues and I [23.27] once felt was a puzzle to decipher – whether there was loss or sparing of the musical system in AD – is resolved by considering that loss was found where musical episodic memories were tested, preservation when musical semantic memory was tested. Here it is doubtless relevant that *Platel* et al. [23.9] have uncovered separate neural substrates for musical episodic and musical semantic memories.

This chapter therefore proposes that a *musical semantic memory* can be dissociated from the *traditional*, or nonmusical, *semantic memory*. From patient studies, results indicate that musical semantic memory may be further characterized in three ways. First, musical semantic memory contains or accesses implicit tonal knowledge allowing the detection of tonal irregularities or violations. Second, memories may be acquired independently of performance. The patient studied by *Finke* et al. [23.48], reported above, was capable of learning music composed, but not practiced, after the onset of his encephalitis. Third, musical semantic memories may activate other personal, autobiographical memories in both AD [23.49–51] and brain-damaged patients [23.52]. The music may never have been performed by the patient but was experienced under memorable circumstances. Hence an associative link was established between a musical semantic memory and a life-time episode.

For future research what is needed is a standardized battery of musical tests that includes both musical episodic, musical semantic, and musical procedural tasks. Comparison of research results, including neuroimaging, would then be facilitated. More attention should be paid to the implicit features of musical knowledge, as outlined by *Rohrmeier* and *Rebuschat* [23.15].

Behavioral findings of spared long-term musical memory in neurodegenerative disease have important implications for palliative care while the cure remains elusive. Care givers can rely on the emotional associations with familiar music to promote a reduction of patient anxiety and agitation.

Acknowledgments. Lola L. Cuddy's research was supported by a Discovery Grant from NSERC (RGPIN/333), the GRAMMY foundation, and the Alzheimer Society of Canada. Ritu Sikka provided invaluable assistance in the preparation of this chapter.

24. Auditory Working Memory

Katrin Schulze, Stefan Koelsch, Victoria Williamson

This chapter reviews behavioral and neuroimaging findings on:

1. The comparison between verbal and tonal working memory (WM)
2. The impact of musical training
3. The role of sound mimicry for auditory memory
4. The influence of long-term memory (LTM) on auditory WM performance, i. e., the effect of strategy use on auditory WM.

Whereas the core structures, namely Broca's area, the premotor cortex, and the inferior parietal lobule, show a substantial overlap, results in musicians suggest that there are also different subcomponents involved during verbal and tonal WM. If confirmed, these results indicate that musicians develop either independent tonal and phonological loops or unique processing strategies that allow novel interactive use of the WM systems. We furthermore present and discuss data that provide substantial support for the hypothesis that motor-related processes assist auditory WM, and as a result we propose a strong link between sound mimicry and auditory WM.

24.1 The Baddeley and Hitch WM Model: Theoretical Considerations and Empirical Support

Working memory (WM) describes a brain system that is thought to be responsible for the temporary storage and simultaneous manipulation of information [24.1–4]. This system underpins higher cognitive functions like planning, problem solving, comprehension and reasoning, and is critical for understanding or appreciating speech and music.

There are many theories and models of short-term memory (STM) or WM (for an overview see [24.5–11]). Our chapter, however, is theoretically embedded in the highly influential *Baddeley* and *Hitch* [24.3] WM model due to the fact that studies that have examined WM for music and language have overwhelmingly focused on this framework [24.3, 12–18]. In addition, although parts of this model are still debated, no other verbal memory model is as well investigated, developed, or corroborated by research results [24.4].

There is little consensus in the literature regarding use of the terms STM and WM [24.19]. In some publications the term STM is used to describe the temporary storage of information, while WM refers to the maintenance and manipulation of information [24.6, 19]. Often, however, it is difficult to know whether a task needs further processing and/or manipulation in addition to the passive storage of information, e.g., if one tone has to be compared with several tones played in a sequence. Therefore, in this chapter no distinction is made between STM and WM; we refer only to WM. In

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_24

addition, the term *auditory WM* will be used to describe WM processes for stimuli that were presented auditorily. Finally, it should be noted that whereas verbal WM has been investigated using both recall and recognition tasks, WM for tonal material has primarily been studied within recognition paradigms (but see [24.18] for a recall task for musical stimuli).

As mentioned, the present review is based on the *Baddeley* and *Hitch* WM model, the first version of which was described almost 40 years ago [24.3]. This initial WM model was developed from earlier frameworks such as the *Atkinson* and *Shiffrin* model [24.20], which assumed that:

1. Successful conversion to long-term storage required information to be held in the short-term store.
2. The short-term store was essential for access to long-term memory (LTM).
3. The short-term store was a seat of intellectual ability.

These assumptions were challenged by evidence that long-term memory (LTM) was dissociable from STM, as seen in neurological patients [24.21], and that complex encoding strategies, as opposed to simple rehearsal, predicted recall success [24.22].

Baddeley and *Hitch* [24.3] conducted their own series of dual task studies where they demonstrated that people could manage a concurrent task while holding items in memory for later recall with just a small decrement in processing speed, something that should not have been possible according to previous memory models. The concept of a unitary, passive short-term store was consigned to history and replaced with the WM model, which separated out attentional control from storage processes in memory. The original WM model proposed an attentional control system (the *central executive*) that operated in conjunction with two subsidiary systems: the visuospatial sketchpad and the phonological loop. Each of the subsidiary systems contained tightly coupled storage and rehearsal elements.

The central executive component was underresearched for many years, leaving the *homunculus* of the WM system poorly understood. After a decade, *Baddeley* [24.23] drew on a new theory proposed by *Norman* and *Shallice* [24.24] to suggest that the executive comprised a supervisory attentional system that allocated limited resources between the storage systems depending on task demands. More recent studies have confirmed the central executive's role in complex processes such as focusing and dividing attention, and task switching [24.6]. The true extent of the central executive's role in higher cognition however remains a highly contentious issue [24.25].

The *phonological loop* represents speech-based or verbal materials in WM. The loop comprises a short-term store and an articulatory rehearsal mechanism, both of which are described in more detail below. Theory regarding the development of the phonological loop framework was directly informed by behavioral research, which demonstrated that:

1. Storage within the loop is phonological as opposed to visual (the phonological similarity effect [24.26]).
2. Spoken material gains obligatory access to the storage component (the articulatory suppression effect [24.27]).
3. Subvocal rehearsal is likely to occur in real time (the word length effect [24.28]).

The *visuospatial sketchpad* is responsible for processing and storing both visual and spatial information. There is a degree of dissociation between visual and spatial memory within this WM component as evidenced from findings of behavioral dual task paradigms, [24.29] and the neuroimaging literature [24.30].

The *episodic buffer* was introduced as a fourth component to the WM model to acknowledge the mutual interaction between LTM and WM [24.31]. As a limited capacity system, the episodic buffer is thought to:

1. Bind information from the subsidiary systems
2. Store information in a multimodal code
3. Enable the interaction of resources between the WM and LTM systems [24.6, 32].

24.2 WM: Behavioral Data

24.2.1 Verbal Information

Baddeley and *Hitch's* [24.3] multicomponent WM model predicts that verbal information is processed by the phonological loop. As described above, this component can be further subdivided into (i) the *phonological store*, a passive storage component and (ii) the *articulatory loop*, an active rehearsal mechanism. The store can maintain speech-based information only for a few seconds [24.2, 5]. If longer maintenance is required,

then the articulatory loop can rehearse the information, a process comparable to subvocal speech [24.1].

The phonological loop component of the WM model continues to provide a parsimonious account of a number of verbal memory phenomena. Firstly, the phonological similarity effect describes how memory span is lower for lists of visually presented acoustically similar verbal items compared to lists of dissimilar sounding verbal items (B, V, P, T, G versus X, R, J, Y, S). Furthermore, errors made in this task are typically phonological rather than visual (i. e., recalling a C instead of a T). As a result of this finding, *Conrad* [24.33] argued that short-term storage of verbal materials must rely on recoding visual letters into subvocal auditory codes. (Note that such subvocal processing presumably involves sensorimotor-related codes, i. e., codes related to vocalization. This issue will become important when we discuss the *tonal loop*.) This argument has remained a principle of the WM model ever since. Phonological similarity is disruptive to memory as the phonological codes become confused either during the storage or retrieval phases of recall [24.34, 35].

A second, well-established finding in verbal memory research is that maintenance and rehearsal of stored material in the articulatory loop can be interrupted by articulatory suppression [24.1, 2], and overt or covert movement of the articulators including the jaw, tongue and throat musculature [24.28, 34, 36–39]. According to theory, articulatory suppression gains obligatory control over at least part of the articulatory loop within WM, which then reduces the overall functionality of the phonological loop by preventing the basic recoding of visually presented materials into (sensorimotor-related) phonological codes and/or disrupting the rehearsal process [24.27, 40].

Finally, the word length effect demonstrates that subvocal rehearsal within the articulatory loop is likely to occur in real time. People achieve greater memory spans [24.28] and superior recognition accuracy [24.36] for lists of short words compared to lists of long words. Although the word length effect has proved to be one of the most contentious aspects of the WM model [24.41], both the effects of articulatory suppression and of word length suggest that verbal material is maintained within WM in a manner comparable to subvocal speech [24.1, 2, 6].

24.2.2 Tonal Information

Because the *Baddeley* and *Hitch* WM model [24.1, 3] was developed to explain mainly verbal and visual-spatial information, the framework does not specify whether nonphonological information is processed by the phonological loop, or whether, in addition to the phonological loop, different subsystems exist for other materials such as tones [24.12, 15]. We have seen above that verbal material is maintained in WM by internal articulatory rehearsal; can tonal pitch also be maintained in this way?

Studies have found that internal rehearsal improved WM performance for tones [24.14–16]. Other studies, however, report that internal rehearsal only leads to a small improvement of WM performance or no improvement at all [24.42–44]. These conflicting results could be explained by the fact that the experimental stimuli used across these studies differed to the degree to which participants can imitate them. Studies that found a small or no beneficial effect of internal rehearsal used auditory stimuli that were difficult to sing or repeat, because:

1. The pitches of the tones did not correspond to the Western chromatic scale [24.43, 44].
2. The pitch difference between the tones was smaller than one semitone [24.43, 44].
3. Chords were used, which consisted of several simultaneously played sine wave tones [24.42].

By comparison, studies that found a benefit of rehearsal used auditory stimuli with (i) pitches that corresponded to the Western chromatic scale [24.15, 16] and/or (ii) pitch differences larger than one semitone [24.14–16], and are thus easy to sing/repeat. Overall therefore, the data support the assumption that internal rehearsal mechanisms underlie WM for tones.

24.2.3 Comparison Between Verbal and Tonal WM

The majority of auditory WM studies to date have used verbal materials (phonemes, syllables, and words) to explore both storage and rehearsal processes. By contrast, research on WM for pitch, or research comparing verbal and tonal WM, is rather scant and to date provides an inconsistent picture.

Deutsch [24.45] was among the first to conduct an auditory WM experiment and reported that intervening tones interfered more strongly with memory for a single tone compared to intervening phonemes. Deutsch interpreted this result as evidence for a specialized tonal WM system, at least when it comes to the storage of single tones. Furthermore, *Salame* and *Baddeley* [24.46] observed that vocal music interfered more with verbal WM than instrumental music, again supporting the assumption of two independent WM systems for verbal and tonal stimuli.

Semal et al. [24.47], however, criticized the lack of control of the pitch relations between the standard tones

and the intervening verbal material in *Deutsch*'s [24.45] study, and argued that this could explain the missing interference between the to-be-remembered tones and the intervening verbal material. In their experiment, pitch similarity of the intervening stimuli, which were either words or tones, modified WM performance to a greater degree than the nature of their modality, suggesting that pitch for both verbal and tonal material was processed in the same WM system. This result was replicated by *Ueda* [24.48] using different stimuli. Furthermore, *Chan* et al. [24.49] showed that better verbal WM performance was associated with musical training, a result also pointing towards overlapping mechanisms underlying verbal and tonal WM.

Few behavioral studies have attempted to compare WM storage using sequences of verbal and tonal materials. Whilst it seems difficult to recreate classic WM storage effects such as phonological similarity in the musical domain, some studies have drawn close parallels in order to compare verbal and tonal WM. *Williamson* et al. [24.18] argued that the phonological similarity effect was based on acoustic confusion at the point of memory storage, an effect that could be represented in music by pitch proximity [24.47]. In *Williamson* et al. [24.18] nonmusician participants recalled sequences of phonologically similar (B, D, G) or dissimilar (M, Q, R) letters and pitch proximal (C4, D4, E4) or distant tones (C4, G4, B4), the notes being balanced according to theory of tonal hierarchy [24.50]. The results replicated the traditional phonological similarity effect with verbal items and saw in parallel a smaller effect of pitch proximity with tonal stimuli. Participants were pretested for their ability to perceive the difference between the tones, meaning that acoustic confusion within memory storage was the most likely explanation for the observed effect. This study supports the theory that storage of both verbal and tonal material in WM is based on acoustic representations of sound. Whilst this finding argues for similar processing constraints in verbal and tonal WM storage it does not, in of itself, support storage system overlap; the principles of storage may be similar for verbal and tonal materials but storage could still be separable, based on the individual codes of speech (phonological store) and tones (tonal store) [24.51].

Studies of rehearsal activity in WM for verbal and tonal material more clearly show support for overlap than is necessarily justified for storage processes. *Schendel* and *Palmer* [24.16] demonstrated that when musicians carry out music suppression (singing *la*) there was decreased recognition accuracy for both digit and tone sequences, in the same manner as with verbal suppression (producing the word *the*), indicating that musical or verbal suppression does not selectively impair verbal or tonal WM. (To our knowledge, there is lack of studies investigating effects of nonphonological sensorimotor suppression, such as moving the fingers of the left hand in string players during a pitch WM task.) *Williamson* [24.52] required nonmusician participants to carry out whispered articulatory suppression while encoding and recalling sequences of letters and tones. She reported that both verbal and tonal WM tasks showed a decrement under articulatory suppression, a finding that could not be accounted for by the dual-task nature of the experiment. This result suggests that subvocal rehearsal of verbal and tonal material may take place in a similar way within the articulatory loop.

24.3 Neural Correlates Underlying WM

24.3.1 Verbal Information

As with behavioral work, most neuroimaging studies that have explored the functional neuroarchitecture underlying auditory WM utilize verbal material. The internal rehearsal of verbal material has been found to be supported by a functional network comprised mainly of Broca's area and premotor areas (as well as the supplementary motor area (SMA) and pre-SMA) [24.53–57]. In addition, data indicates that both the insular cortex [24.54, 58, 59] and the cerebellum [24.57, 60, 61] are involved during the internal rehearsal of verbal information.

The crucial role of Broca's area and the premotor cortex for internal rehearsal has been corroborated by numerous studies (for an overview see [24.1]). Findings regarding the phonological store, however, are much less conclusive. It has been suggested that parietal areas, particularly the inferior parietal lobule [24.53, 54, 56, 60–64], but also the superior parietal lobule [24.53, 60], serve as the underlying neural correlate of the phonological store. However, pinpointing the phonological store in the parietal lobe is controversial. Firstly, neural activity in the parietal lobe has been associated with attention, and therefore activation in this area might also reflect increased engagement of attentional resources [24.65, 66]. Secondly, the coordinates of the reported activation during tasks requiring storage of verbal material differ greatly between studies [24.4]. And finally, passive listening does not activate the infe-

rior parietal lobule (IPL) [24.4, 67], a finding predicted by the WM model [24.3, 4] if this structure is involved in automatically storing incoming auditory information.

As a consequence of these theoretical and empirical inconsistencies, area Spt (Sylvian-parietal-temporal, i. e., left posterior planum temporale), has been suggested as an alternative neural structure underlying the temporary storage of verbal information during WM tasks [24.4] based on the following observations. First, activation in the left Spt was (i) enhanced during the delay period of a WM task [24.13, 68] and (ii) not influenced by the modality of the presented stimuli (auditory or visual [24.68]). In addition, area Spt is involved during the perception and production of speech. Based on these findings it has been suggested that area Spt acts as an auditory-motor interface for WM [24.4, 13, 68], meaning that perception, production and WM are more closely linked than previously believed. This proposition is corroborated by the dual-stream model of speech processing [24.69–72]. This model assumes a ventral stream that supports speech comprehension via lexical access and a left dominant dorsal stream comprising also area Spt, which enables humans to map perceived speech signals onto articulatory representations, and therefore supports sensory–motor integration.

24.3.2 Tonal Information

Far fewer neuroimaging studies have investigated WM for tones than have investigated the phonological loop. *Gaab* et al. [24.73] showed the involvement of the supramarginal gyrus (SMG), the intraparietal sulcus (IPS), the planum temporale, premotor regions encroaching on Broca's area, and cerebellar regions during a pitch memory task in participants that were not selected for musical expertise. The neural network observed in this study is surprisingly similar to the network supporting the phonological loop described above. Another group had previously observed activation of a similar network during a WM task for tones, including the inferior frontal and insular cortex, the planum temporale, and the SMG [24.74].

24.3.3 Comparison Between Verbal and Tonal WM

To our knowledge, only three neuroimaging studies have compared the neuroarchitecture of auditory WM for sequential tonal and verbal material [24.13, 14, 17]. In a functional magnetic resonance imaging (fMRI) experiment, *Hickok* et al. [24.13] studied nonmusicians and compared the neural correlates underlying verbal and tonal WM. The authors presented piano melodies during a tonal condition and pseudoword sentences during a verbal condition. The internal rehearsal of the verbal and tonal materials involved activation of area Spt and premotor regions encroaching on Broca's area [24.13]. A similar functional network was uncovered in a WM recognition study by *Koelsch* et al. [24.14] in which neural similarities between WM for verbal (syllables) and tonal (pitch) material were explored, again in nonmusicians. The functional network observed during verbal rehearsal included the premotor cortex, the anterior insula, the SMG/IPS, the planum temporale, the inferior frontal gyrus, pre-SMA and the cerebellum. Importantly, internal rehearsal of the tonal stimuli relied on a virtually identical network to that activated during verbal rehearsal.

In a follow-up study, *Schulze* et al. [24.17] employed a recognition task to compare the neuroarchitecture supporting the internal rehearsal of verbal and tonal WM. In a replication of the above-described experiment [24.14], both verbal and tonal WM tasks activated structures previously reported during either verbal [24.1, 53, 54, 56] or tonal [24.13, 73, 74] WM processes in nonmusicians, namely Broca's area, the left premotor cortex, (pre-)SMA, left insular cortex, and left IPL. This finding corroborates data from previous experiments, which have reported considerable overlap of the functional networks subserving verbal and tonal WM [24.13, 14]. Importantly, all these core structures activated during tonal WM were also activated during verbal WM in nonmusicians. By contrast, verbal but not tonal WM relied on additional structures, including the right ventrolateral premotor cortex, right IPL, right cerebellum and the left mid-dorsolateral prefrontal cortex (mid-DLPFC). These structures have previously been associated with verbal WM tasks [24.1, 75, 76]. This activation difference between verbal and tonal WM was also expressed in the behavioral data: nonmusicians showed superior performance during verbal than during tonal WM.

In summary, the few neuroimaging studies that have directly compared the structures underlying verbal and tonal WM [24.13, 14, 17] have obtained data from nonmusicians that point towards a considerable overlap of neural resources underlying WM for verbal and tonal material. This common (core) network is mainly left-lateralized and includes fronto-parietal structures, that is premotor cortex, Broca's area, and in two of the three studies also the IPL [24.14, 17] and the cerebellum [24.14, 17], as well as the planum temporale/area Spt [24.13, 14]. (*Schulze* et al. [24.17] did not scan continuously like in the other fMRI studies [24.13, 14], but employed a sparse-temporal sampling scanning technique. Thus, participants did not have to separate scanner noise from the information they had to rehearse, possibly leading to less (or no) activation of

area Spt. Another possibility is that the sparse temporal scanning method was not sensitive enough to capture the involvement of area Spt.)

24.3.4 Comparison Between Nonmusicians and Musicians

Speech is a fundamental human skill typically acquired during early childhood. Thus, while both musicians and nonmusicians are trained in processing and producing speech, nonmusicians' expertise in the music domain is comparatively far less developed. This begs the question of whether tonal WM would be different in musicians compared to nonmusicians, where a group difference in verbal WM would not be predicted. In support of this hypothesis *Williamson* et al. [24.18] found that nonmusicians showed effects of both phonological similarity and pitch proximity, whereas musicians showed the former but not the latter. It was suggested that musicians, thanks to their specialized training, develop systems and/or strategies for storing tones that negate the impact of pitch proximity. Nonmusicians, on the other hand, are more likely to store a basic acoustic representation of the tonal sounds that they hear, which are then more vulnerable to the impact of pitch proximity.

Schulze et al. [24.17] directly studied the neural underpinnings of verbal and tonal WM in highly trained musicians to see how they compared to the established WM network in nonmusicians. The aim was to determine if musicians had developed a specialized or alternative system for processing tones. Many of the structures (Broca's area, left premotor cortex, left insular cortex, (pre-)SMA, and left IPL) that were activated more strongly in nonmusicians during verbal WM showed an increased involvement in musicians compared to nonmusicians during tonal WM. That is, the functional network that supported verbal WM in nonmusicians was also used by musicians for tonal WM tasks. In addition, unlike nonmusicians, musicians recruited a number of structures exclusively for either verbal or tonal WM: the left cuneus, the right globus pallidus, the right caudate nucleus, and the left cerebellum supported WM for tonal material; the right insular cortex was exclusively involved in processing verbal information.

On top of these differences, activation distinctions between verbal and tonal WM tasks were reported for a number of structures in musicians, thus supporting the existence of two WM systems, potentially a phonological loop maintaining and processing phonological information and a tonal loop maintaining and processing tonal information. Both WM systems showed a considerable overlap in activation because the same WM core structures were activated. Differences, however, were also observed for both systems in that they relied on different neural subcomponents. Importantly, it is not possible to explain the observed functional differences between the verbal and tonal WM tasks in musicians by citing performance differences between both tasks, because several brain structures were recruited selectively for verbal or tonal WM [24.17, 77]. Instead, musical expertise might facilitate the development of a more extended network underlying tonal WM, which shows similarities to the functional network supporting verbal WM, but also substantial differences.

24.4 Sensorimotor Codes – Auditory WM and the Motor System

To acknowledge the interconnection of verbal WM with speech perception and production, the underlying representations of verbal WM have been named sensorimotor codes [24.78]. In the following we explain and discuss results that indicate internal WM rehearsal for verbal material shares characteristics with speech production.

The word length effect and the articulatory suppression effect, which were described above, support the assumption that verbal WM is similar to subvocal speech (for an overview see [24.1]). In addition, the phonological loop has been conceptualized as a memory system that involves internal articulatory speech actions implemented by motor-related areas such as Broca's area, premotor and insular cortices [24.1, 58], SMA [24.53, 54, 57], and the cerebellum [24.1, 57, 60]. As discussed above, results suggest that tonal WM can be improved by internal rehearsal only if participants are able to imitate and repeat these auditory stimuli [24.14–16, 42–44]. WM thus seems more closely linked to production (i. e., action-related) processes than previously believed. This assumption has been supported by data that compares the neural correlates of verbal and tonal WM between musicians and nonmusicians described above [24.17]. The better performance of nonmusicians for verbal compared to the tonal WM tasks, and the superior performance of musicians compared to nonmusicians for tonal WM tasks, was primarily associated with activation differences in neural structures that have been described to support planning, programming, executing and controlling actions, like Broca's area, premotor cortex, (pre-)SMA,

left insular cortex, intraparietal sulcus and IPL, and the cerebellum.

Initially we interpreted these observed behavioral and neurophysiological differences between verbal and tonal WM in nonmusicians as a consequence of the extensive production and rehearsal of verbal material in their daily life, which for nonmusicians is not the case, or is to a lesser degree, for musical material. An alternative but related interpretation is that musical training could lead to a long-term learning of associations between pitch information and motor actions [24.79–83]. As a result of this process, musicians could have developed more elaborate sensorimotor codes supporting the internal rehearsal of tones compared to nonmusicians. Such codes probably include, e.g., finger representations, and codes of finger movements, in piano and string players.

To our knowledge no studies have investigated whether the ability to repeat an auditory stimulus might facilitate its internal rehearsal and therefore increase auditory WM capacity, but there is some indication that mimicry is important for auditory WM [24.84–86]. For example, WM processes for timbres, which are difficult or impossible to mimic, differ from those for tones and words, which are easy to mimic: Whereas WM for timbre seems to rely on a passive sensory trace, WM for verbal and tonal stimuli appears to be maintained by active internal rehearsal processes [24.85]. Furthermore, distractors that share features with hard-to-mimic auditory stimuli are likely to overwrite and degrade their memory trace [24.87, 88].

Interestingly, monkeys, who are not vocal learners and therefore cannot learn to mimic unfamiliar auditory stimuli, seem to rely only on a *passive form of auditory STM* (the authors [24.89] referred to a passive form of STM to explicitly distinguish it from WM, therefore this term has also been used here. Otherwise, as explained in the introduction, in the present chapter no distinction has been made between STM and WM): *Scott* et al. [24.89] used a small set of sounds from different categories (pure tones, environmental sounds, monkey calls, etc.) and observed that monkeys performed very poorly on an auditory serial delayed match-to-sample task. The authors observed an *overwriting* effect for auditory stimuli (including monkey vocalizations) that was far greater compared to that in the visual domain, indicating that the observed performance in monkeys depended on the passive form of STM and not on WM. Interestingly, when humans are tested on auditory stimuli that they cannot mimic, they too seem to rely on passive auditory STM [24.87, 88].

The idea that auditory WM relies on the assistance of the motor system is further supported by patient studies. Speech disorders such as speech apraxia, a disorder of speech planning and programming [24.90], are associated with decreased performance in a verbal WM task [24.91]. Another piece of evidence comes from the investigation of the three-generational KE family, half of whom suffer from a speech and language disorder caused by a mutation of the FOXP2 gene [24.92, 93]. Although the speech impairments of the affected KE (aKE) family members are widespread, their core deficit is in executing orofacial, especially articulatory, sequences. The structural and functional cortical abnormalities in the aKE also include the inferior frontal (Broca's) area and ventral premotor cortices [24.92, 94–96]. The first study to compare WM in aKE and controls used a test [24.97] based on the Baddeley and Hitch WM model and analyzed the different components of WM separately – the central executive, the phonological loop, and the visuospatial sketchpad [24.98]. Compared to controls (the control group was matched to the aKE for age and performance IQ), the aKE performed only worse for the tasks related to the phonological loop. Importantly, the aKE members were also impaired in the recognition-based subtest of the phonological loop *word list matching*, in which repetition (i. e., motor output) of speech-based material is not required. Results thus suggest that the aKE, who show both structural and functional abnormalities in Broca's area, a structure underlying phonological and auditory WM (see above), could be specifically impaired in phonological WM but not other domains of WM. This indicates an association between the speech difficulties of the aKE members and their representations underlying internal rehearsal of speech-based material in phonological WM [24.98].

Interestingly, just as with auditory WM, auditory LTM appears to require the assistance of the (oro)motor system. *Schulze* et al. [24.99] tested whether a sound that can be neither mimicked nor labeled can be stored as a long-lasting representation for subsequent recognition by comparing participants' ability to recognize different auditory stimuli that varied widely in the degree to which they could be reproduced or labeled (words, pseudowords, nonverbal sounds, and reversed words, i. e., words played backwards, were presented auditorily). Participants listened to a list of 10 stimuli once for familiarization (study list), and then, after a 5 min interval filled with a counting task to block WM, were presented with these 10 items from the study list again in random order intermixed with 10 new items (recognition list), and had to make an old-new judgment for each of these items. The results were clear; participants showed recognition difficulty only for the reversed words, which were hard either to mimic or to label with an associate. Importantly, a control experiment demonstrated that recognition difficulty was

not due to a perceptual failure. The participants' poor memory performance of the reversed words supports the proposal that a sound's pronounceability – its potential to activate subvocally the speech production system, potentially via an auditory mirror-neuron system [24.100, 101] – may be essential for generating a long-lasting representation of that sound.

In summary, sensorimotor processes are thought to be involved in the rehearsal and representation of information in auditory, verbal and tonal WM [24.13, 14, 17, 102, 103] and thus may play in important role during the representation and manipulation of auditory information. These action-related sensorimotor codes are assumed to rely on motor knowledge – how to produce the auditory stimulus (e.g., syllable, tone). The dual-stream model of speech processing [24.69, 71, 72] suggests that sensory–motor integration, i. e., mapping the perceived speech signals onto articulatory representations is one of the functions of the dorsal path of the auditory system. Results indicate that the superior longitudinal as well as the arcuate fasciculi [24.104] form the dorsal stream. Speech production requires motor speech representations as well as representations of sensory speech targets to compare between predicted and actual consequences of motor speech acts [24.70]. Sensorimotor integration also seems to play a role during singing [24.105, 106]. Therefore, we propose that internal rehearsal associated with auditory WM relies on sensorimotor representations, which also underlie singing and speaking.

24.5 The Influence of LTM on Auditory WM Performance

WM is a limited-capacity system in terms of how much information can be stored and for how long [24.1, 28, 107]. However, the use of a strategy based on information stored in LTM can improve WM performance, for example by chunking the to-be-remembered information [24.108, 109]. During chunking, items are organized into one unit or chunk [24.107], resulting in stronger associations between items within one chunk than between chunks [24.110]. This process is thought to be supported by the episodic buffer, which enables features from different sources to be bound [24.6]. Previously, the neural correlates underlying such strategy-based memorization were explored for the visual–spatial or verbal domain [24.111–114], but it was largely unknown whether a similar functional network was also involved during the strategy-based WM for tones.

By using structured (all tones belonged to one tonality) and unstructured (atonal) five-tone sequences, *Schulze* et al. [24.115] investigated: (i) whether musical structure influences performance on a nonverbal auditory WM task, and if so, (ii) how this is reflected in the brain of nonmusicians and musicians. Musicians, but not nonmusicians, performed better for the structured than for the unstructured sequences, indicating that musicians' knowledge about musical regularities helped them to maintain the structured sequences in WM [24.116–119]. In terms of brain responses, musicians showed stronger involvement of a lateral (pre)frontal–parietal network during the memorization of the structured sequences, including the right inferior precentral sulcus and the premotor cortex, as well as the left IPS. A similar network has been described previously to support strategy-based WM processing for visual and auditory–verbal stimuli [24.111, 113, 114]. The combined results point towards a modality-independent (pre)frontal–parietal network subserving strategy-based WM. A follow-up behavioral study by *Schulze* et al. [24.120] has confirmed the facilitating effect of tonality (structure) on tonal WM performance in both musicians and nonmusicians, but only during memory maintenance (forward task) and not complex memory manipulation (backward task).

24.6 Summary and Conclusion

This chapter reviewed and discussed research results demonstrating behavioral, structural, and functional differences and similarities between verbal and tonal WM. Whereas the core structures, namely Broca's area, premotor cortex, and IPL, show a substantial overlap, results in musicians suggest that there are also different subcomponents involved during verbal and tonal WM tasks. If confirmed, these results indicate that musicians develop either independent tonal and phonological loops or unique processing strategies that allow novel interactive use of the WM systems. In addition we discussed behavioral and neuroimaging results that provide substantial support for a strong link between sound mimicry and auditory

WM. Sensorimotor processes are thought to be involved in the rehearsal and representation of information in auditory WM. These action-related sensorimotor codes are assumed to rely on motor knowledge – how to produce the auditory stimulus (e.g., syllable, tone).
