25. Musical Syntax I: Theoretical Perspectives

Martin Rohrmeier, Marcus Pearce

The understanding of musical syntax is a topic of fundamental importance for systematic musicology and lies at the core intersection of music theory and analysis, music psychology, and computational modeling. This chapter discusses the notion of musical syntax and its potential foundations based on notions such as sequence grammaticality, expressive unboundedness, generative capacity, sequence compression and stability. Subsequently, it discusses problems concerning the choice of musical building blocks to be modeled as well as the underlying principles of sequential structure building. The remainder of the chapter reviews the main theoretical proposals that can be characterized under different mechanisms of structure building, in particular approaches using finite-context or finite-state models as well as tree-based models of context-free complexity (including the Generative Theory of Tonal Music) and beyond. The chapter concludes with a discussion of the main issues and questions driving current research and a preparation for the subsequent empirical chapter *Musical Syntax II*.

> *The idea that there is a grammar of music is probably as old as the idea of a grammar itself. Mark Steedman* [25.1, p. 1]

25.1 Outline

What distinguishes music from other sounds? One answer is to be found in the manner in which the elements are organized and related within a structural framework and, most importantly, the apprehension of this structure by a listener, so that the sound is *experienced as music* by that listener. Therefore, discovering the principles of musical structure building is one of the central questions for theoretical and empirical music research. Despite the strong historical (and methodological) divide between music-theoretical, computational, and psychological/neuroscientific approaches, questions about musical structure and the perception of it facilitate a close link across traditional divisions between disciplines [25.2]. Note that we use the term *computational* to describe a theory that is expressed in computational terms, whether or not it is actually implemented as a computer program.

Exploring the principles of musical structure building naturally requires us to distinguish between the goal of uncovering rules governing the structure of music (an

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_25

external goal) and the cognitive principles of the perception and production of these structures (an internal psychological goal). Yet both aspects form two sides of the same coin: the capacities and limitations of human perception and cognitive processes influence the possible structures that composers can use (for a similar argument about language, the reader is directed to [25.3]) and, together with other constraints (e.g., those imposed by cultural factors or the physical properties of instruments, constraints of the hands or the body, constraints of the performance and so on [25.4]) give rise to the musical structures that we find in music. In turn, musical structure is acquired implicitly by listeners from mere exposure and musical interaction and represented internally [25.5, 6] and, ultimately, reproduced in compositional practice (since composers are listeners before they become composers). However, there can be no learning without a hypothesis space and therefore theoretical models of musical structure, especially those grounded in computational modeling, provide a useful approach to understanding the hypothesis space that human learners are faced with when they acquire the syntactic structure of a musical style.

Finding a formal characterization of musical structure brings traditional music theory in close connection with computational modeling since the search for an optimal structural description (that relates to structures as *heard*) strongly implies *modeling* the internal structure of the music (whether it is a single composition, a part thereof, or a corpus). Since music is an inherently psychological phenomenon, we often use psychological understanding to guide the development of structural models of music, just as we use structural models of music to guide the development and testing of psychological theories of the perception of musical structure.

The disciplines involved in research on musical syntax range from musicology and music theory, through computational modeling, to psychology and neurobiology. Although the disciplinary perspectives are distinct (e.g., it is possible to develop a structural theory that is optimal according to some criterion, such as simplicity, but not according to the criterion of matching human perception and cognition), in this contribution, we focus on a converging picture that emerges when musical syntax is examined by triangulating between theory, computational modeling, and cognitive research. Here we focus on theoretical approaches to musical syntax while empirical research using computational models, psychological experimentation, and neuroimaging are covered in the companion chapter, *Musical Syntax II*.

25.2 Theories of Musical Syntax

25.2.1 The Concept of Musical Syntax

Berwick et al. [25.7, p. 89] give a brief account of syntax as:

> *the rules for arranging items (sounds, words, word parts, phrases) into their possible permissible combinations in a language.*

In human language the set of items (alphabet of symbols) may be words and morphosyntactic units, in birdsong they may be pitches, slides and other sounds. In music the symbols may be melodic notes, chords, voice-leading patterns or relationships between voices, timbral qualities and so on. Many music-theoretical approaches constitute informal, verbal accounts of syntactic models of music. Although the use of strict and well-defined formalisms is not (yet) common in music theory, there are some accounts that employ the notion of syntax in music theory. For instance, *Aldwell* and *Schachter* write the following in order to characterize *harmonic syntax* [25.8, p. 139]:

> *One way that music resembles language is that the order of things is crucial in both.* I went to the concert *is an English sentence, whereas* I concert went the to *is not. Similarly, I-VII6-I6-II6-V7-I* [...] *is a coherent progression of chords, whereas I-I6-VII6-II6-I-V7* [...] *is not, as you can hear if you play through the two examples. In the study of language, the word* syntax *is used to refer to the arrangement of words to form sentences; word order is a very important component of syntax. In studying music, we can use the term* harmonic syntax *to refer to the arrangement of chords to form progressions; the order of chords within these progressions is at least as important as the order of words in language. (Other components of harmonic syntax are the position of chords within phrases, the preparation and resolution of dissonances, and the relation of chord progressions to melody and bass lines.)*

A syntactic theory might be applied to any aspect of musical structure – melody, harmony, rhythm, metre, grouping structure, form, or even aspects such as timbre and dynamics. In practice, syntactic approaches have typically been applied to *what* happens in a musical sequence – e.g., predicting (combinations of) pitches and chords – rather than *when* it happens. Conversely,

theories of rhythm and metre often do not take an explicitly syntactic approach. By analogy, metrical and rhythmic features of language are often studied from the perspective of phonology rather than syntax. A well-formed harmonic sequence, for instance, may be assigned to metrical structure in a regular or irregular way. It is important to note that despite the predominance of Western music in theoretical and cognitive research [25.9], the general notion of musical syntax is *not* limited to Western tonal music – and there are approaches addressing non-Western music [25.10–12]. Different aspects of musical structure may be more or less important in different musical styles and cultures.

Several models for musical syntax have been proposed based on different levels of structural representation (melodic structure, harmony and chords, bass lines, outer voices, voice-leading, other types of categorized sound, polyphonic pitch structure and so on). Here, we reserve the term *syntax* for approaches presenting a formal system characterizing the sequential structure of such building blocks, in contrast to the more general term *musical structure* which captures the rich interaction of different musical features such as rhythm, metre, timbre, counterpoint, dynamics, phrasing, instrumentation, agogics, and so on. The precise identity of these building blocks is one of the central ongoing research questions in musical syntax.

The general term *musical structure* refers to the way in which one or more pieces of music may be represented in terms of their constituent parts, potentially reflecting a wide range of different musical features including rhythm, metre, timbre, counterpoint, dynamics, phrasing, instrumentation, agogics, and so on.

Musical syntax is a formal characterization of the principles governing permissible sequential structure in music. It characterizes sequences of musical events generated from a *lexicon of building blocks* and a set of *rules* governing how the building blocks are combined.

The *lexicon* (the set of building blocks) may consist of single events or patterns (schemata) of notes, glissandi, rests, chords, voice-leading patterns, timbres, or other noises. The *rules* may constitute any formal system that characterizes how sequences may (and may not) be formed by combining elements from the lexicon.

25.2.2 Foundations of Musical Syntax

Why do we need a syntax of music? When characterizing musical structure, and the cognitive representation and processing of that structure, several issues arise which motivate the development of a formal syntactical understanding of music. These include distinguishing regular and irregular musical structures (i. e., making grammaticality judgements), the fact that the space of possible musical compositions is theoretically infinite (or unbounded), the idea that we want to be able to describe structural relationships within musical sequences (i. e., focus on strong generative capacity compared to weak generative capacity). Syntax is also relevant to tasks such as compression, identifying the stability of events at different levels within music, and measuring musical similarity. We investigate these issues further in the following sections.

Grammaticality

One core foundation for the concept of musical syntax is the notion of regularity, permissibility, well-formedness or grammaticality, i. e., the characterization of structures that are regular or irregular with respect to a particular system (representing, for example, a musical style). If such a distinction were irrelevant, the characterization of musical syntax would be unnecessary since every sequence would be equally plausible. However, musical styles and idioms are implicitly characterized by regular and irregular sequences. Although categorical grammaticality decisions are often made, the distinction may be one of degree (compare [25.13–15], in linguistics). For instance, not every chord sequence or every musical form is regular in the 18th century Classical idiom [25.16]. Another example illustrates a regular and irregular common-practice harmonic sequence (Fig. 25.1 adapted from [25.17]). Musical regularity can be characterized empirically through (computational or hand-conducted) corpus analysis, which can provide information about frequent and less frequent regular patterns and indirectly about irregularity by the discovery of absent and low-probability patterns (although absence does not necessarily constitute evidence for ungrammaticality). Grammaticality can also be experimentally established through psychological experiments. Furthermore, introspective analyses by individual experts may be regarded as single-participant experiments, with some extrapolation to wider groups (whether expert or otherwise) assumed. In this context it is essential to understand the importance of negative evidence in the form of explicit instruction about implausible or irregular structures (note that this is different from the absence of positive evidence). While some regularities and rules may be inferred from positive data alone (i. e., the presence of well-formed structures), it is negative evidence that makes the strongest conclusions possible with regard to range, scope of generalization, and mutual interaction of grammatical systems. There is continuing debate about whether and how people might receive negative evidence in the development of language, but this topic has received little attention in the domain of music.

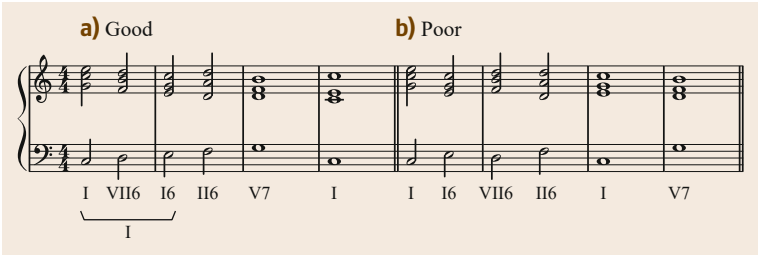

Fig. 25.1a,b The contrast between a good **(a)** and a poor **(b)** harmonic progression as discussed by *Aldwell* and *Schachter* [25.8, p. 140]. **(b)** is poor because the dependencies between the chords are disrupted – for instance, the II6 chord is not functionally well connected to its context (even though it features good voice-leading). Further note that in the analysis of the good example, the authors propose a hierarchical analysis of I VII6 I6 as a prolongation of a single I harmony

Unboundedness

The set of possible musical structures is unbounded – music, in Humboldt's famous words, makes infinite use of finite means. It is simple to demonstrate the unboundedness of musical structures: for every sequence we can imagine a longer one or a variation of it that inserts another element (tone, chord, etc.) into the sequence; we can further imagine a composition that never ends (such as ideal airport music). Hence, it is impossible to construct an exhaustive list of all musical sequences. Therefore, the only way to characterize musical structure is by employing a finite set of building blocks and recursive (or iterative) rules to generate grammatical sequences based on the recombination of building blocks using the rules. Generative grammars [25.18, 19] are *one kind* of formalism that embodies this principle, often used in theoretical approaches to the syntax of music (and other auditory sequences such as language or birdsong). Note that in this context the term *generative* does not refer to (human) music generation but to the description and analysis of a set of sequences by formal rules that are capable of generating them by a well-defined formal mechanism (such as a formal grammar).

Weak and Strong Generative Capacity

A syntactic model of a set of (musical) sequences may focus on the description of the surface sequences in order to reproduce exactly those sequences. For a given language (i. e., a set of strings), such a characterization may be accurate in terms of coverage (i. e., they can generate the set of strings). This is referred to as *weak generative capacity*. However, for most languages there is an infinite number of formal models that adequately describe the language, many of which are highly implausible. For this reason it is desirable that a syntactic theory matches theoretical insights as well as cognitively relevant (or adequate) structures, provides useful and testable generalizations, and achieves optimal compression (see below). This broader concept is known as *strong generative capacity*.

Compression

Characterizing a set of (musical) sequences using a generative theory allows us to capture a potentially infinite set of sequences using a finite set of rules. In this sense, we can think of generative theories in terms of the extent to which they enable compression through efficient representations of a set of sequences. Highly efficient, sparse encoding of the environment constitutes a core principle of cognitive systems [25.20, 21], and there is a close relationship between prediction and compression because we only need to store the information that is not predictable using a model [25.22]. Research in music information retrieval [25.23] and music psychology [25.24] has used general-purpose compression algorithms as models of musical complexity. A model that better captures structural regularities with general coverage in a given musical idiom is expected to be capable of more accurate prediction and, therefore, compression. Conversely, we can use compressibility (of unseen data to ensure generalizability) as a measure of the power and efficiency of a generative theory (and the latent structure that it postulates). However, a more complex model will itself consume more space, meaning that increased level of compression of the data must exceed the increased size of the model in order to be efficient. In this respect, approaches following the paradigms of minimum description length (MDL; [25.25]) and Bayesian model comparison provide closely related methods [25.22, Chap. 28] for comparing different candidate models taking into account differences in their complexity and the numbers of free parameters and so on [25.26, 27]. See *Mavromatis* [25.28] for an example of these principles applied to music.

Compression-based evaluation of a model of musical syntax is independent from other questions such as

grammaticality or weak/strong generative capacity. In particular, the criterion of optimal compression makes it possible to evaluate and compare syntactic models independently of the grammaticality distinction as well as independently of tests (such as pumping lemmata) that require grammaticality distinctions over sequences that are extremely improbable and do not generalize over corpora (such as *n*-th level center embeddings). In this context, compression provides a better way to provide a foundation for strong generative capacity and also assess the cognitive relevance of a proposed syntactic account of a (musical) language.

Stability, Similarity, and Semantics as Underpinnings of Syntax

There are several other ways to motivate syntactic structure in music. One of these is the proposal that we need an account of syntactic structure in music to be able to predict the relative stability of musical events. Many music theorists observe that in harmonic, melodic or voice-leading sequences, some events may be considered ornamental or accidental whereas others are structurally fundamental [25.8, 29, 30]. If this notion of relative structural stability – not to be confused with tonal stability and the tonal hierarchy [25.31] – is extended to a fully recursive structure (i. e., not just to individual notes or chords but also to motifs, phrases, and other larger scale components of musical form), it can be accounted for using a hierarchical syntactic formalism. Whether or not this type of structure is in turn coextensive with the above forms of establishing hierarchical structure remains a question open for further theoretical investigation.

Another, related avenue for establishing hierarchical structure is similarity. From a theoretical and psychological perspective musical similarity may be construed in terms of operations of omission or insertion of events with respect to a common core structure (for instance, differences between different cover versions of a song). In this context, it is important that such operations respect (hierarchical) structural boundaries of constituents (e.g., a tonic expansion) rather than comparisons between unstructured surface sequences. For example, *De Haas* et al. [25.32] implemented a similarity measure that is closely related to structural stability in terms of the largest common embeddable subtree between two compositions. This approach outperformed *edit distance* (a structure-free surface comparison between sequences) in predicting harmonic similarity between music sharing similar melodies. Similarity is also closely related to the concept of compression since we can train a syntactic model on one piece of music and use that model to predict another piece of music – greater degrees of predictability (and hence compressibility) indicate greater degrees of structural overlap between the pieces [25.21, 23].

Finally, semantics may constrain syntactic structures, particularly in linguistics. Whereas linguistic syntactic structures to a large extent serve the temporalization/linearization of semantic structure (in terms of form/meaning pairs), there is no immediate analogy in music. Although music may express meaning in terms of illocutionary acts like warnings, or aggression, or in terms of symbolic associations, it is agreed that music, in general, lacks complex, explicit propositional semantic forms ([25.33] and its discussion [25.33–36]). However, the patterns of relative stability outlined above (which are themselves related to syntactic structure) lead to perception and experience of tension and release by the listener, which can be viewed as a kind of semantic interpretation [25.37–40]. However, further research is required to examine these potential relationships between syntax and semantics in music.

25.3 Models of Musical Syntax

A model of musical syntax consists of two core components: first, a choice of the underlying representation for musical building blocks and how they relate to the musical surface; second, a formalism used to generate musical structure based on the set of building blocks.

25.3.1 Building Blocks

The choice of building block is fundamental for the syntactic model. In contrast to language, where the set of morphosyntactic features is largely accepted, syntactic models of music have made different choices of building block. This entails modeling musical structure at different levels of representation (or abstraction), such as: harmony and chord sequence, bass line, melodic line (diastematics), outer voices and voice-leading, or polyphonic pitch structure. Every choice involves selecting a distinction between structural and nonstructural items *with respect to the underlying model*. For instance, a model of harmonic syntax may regard different surface and melodic realizations of a chord sequence as equivalent; similarly, a theory of voice-leading would regard certain note repetitions, trills, or ornaments as nonstructural. Given the divergence of representations, styles, and level of abstraction adopted by different approaches in the literature, there is no consensus at

present how (and based on which principles) a *fundamental domain* of building blocks for a musical syntax could be established independently of the modeling goals.

We should mention here that some very interesting work has been done on representational spaces for various aspects of musical elements including, most notably, pitch spaces [25.37, 41–48] and metrical structure [25.49]. These theories define how these aspects of music may be expressed in algebraic ways and potentially represented by cognitive systems [25.50], but since they characterize the formal space of musical objects rather than explicitly specifying how sequences of elements may be combined, we do not consider them as theories of syntax proper.

25.3.2 Structure Building

Traditionally there have been a number of theoretical attempts to characterize the sequential structure of elements in a sequence, ranging from Markov models to context-free languages and corresponding probabilistic models. Many theories of structure have used explicit types of formal languages in the Chomsky hierarchy and its extensions [25.51]. Characterizations with models of different complexity involve a trade-off between the expressive (and compressive) power of the representation and corresponding processing requirements.

The languages generated by each class of grammar form proper subsets of the languages generated by classes of grammar higher up in the hierarchy. However, as we move up the hierarchy, the complexity of recognition and parsing increases in tandem with the increased expressive power of each class of grammar. In particular, while context-free grammars (and those higher in the hierarchy) are capable of capturing phenomena, such as embedded structure, which cannot be captured by finite-state grammars, they also bring with them many problems of intractability and undecidability, especially in the context of grammar induction [25.52].

It is fundamental to note that the Chomsky hierarchy and its extensions [25.51] constitute just *one way* of characterizing (musical) sequential structure. They are in no particular way primary or more natural than other approaches that characterize classes of infinite sets of strings, except in historical terms. There are many ways to characterize sequential structure, as any handbook of formal languages demonstrates (e.g., Handbook formal languages, [25.53]). Furthermore, computational models are, fundamentally, in no respect distinct from hand-crafted models by theorists in terms of their expressive power [25.5, 54, 55].

25.4 Syntactic Models of Different Complexity

25.4.1 Finite-Context Models

There is an interesting subclass of grammar contained within the class of finite-state grammars which are known as *finite context* grammars [25.56, 57]. In finite context automata, the next state is completely determined by testing a finite portion of length $n-1$ of the end of the already processed portion of the input sequence [25.57]. The core idea of these very local models is to characterize sequential structure by identifying possible element-to-element transitions (how elements may follow or precede each other). This characterization formally amounts to a table that lists grammatical relationships between each possible combination of elements (such as chord, note, or root transitions). This account is easily extended to larger context-lengths: the next element may be related not only to its predecessor, but also to the sequence of 2, 3, or more preceding elements. What such accounts have in common is the assumption that there are no (unbounded) dependencies between events longer than the relevant context of the model. In general, finite-context models correspond to the formal subcategory of strictly local languages (k-factor languages) and are also referred to as Markov or n-gram models.

A *k-factor language* is formally defined by a set of factors (strings of length k). A sequence is grammatical iff every subsequence of length k is part of the set of factors. Several models have been proposed in music theory and cognition that contain, in part, *k-factor* models [25.58–60]. It is important to note here that schema-theoretic approaches [25.61–63] do *not* naturally correspond with *k-factor languages* without modification (since they involve reductions, nonlocal patterns, and the ability to distinguish notes that are structurally important from those that are not).

These characterizations of structure, however, only draw a distinction between regular and irregular sequences, yet within those categories, they consider every possible sequence equally. For many theoretical purposes this is insufficient as some of these structures occur very frequently whereas other transitions are rare, less common, or unlikely. This theoretical requirement demands a characterization that is based not only on grammaticality but also on probability. It is straightforward to expand the above definition to incor-

porate probabilities: every entry in a transition matrix is associated with a probability. Probabilistic instantiations of the approach, therefore form a superset of the nonprobabilistic versions, which only allow the probabilities 0 (nongrammatical) and 1 (grammatical). Often these probabilities are estimated through analysis of frequency counts of events in a corpus [25.64, 65]. Such probabilistic extensions of k-factor languages are referred to as Markov models or n-gram models (for which n-grams correspond to probabilistic versions of k-factors). In an n-gram model, the sequence $e^{j}_{(j-n)+1}$ is called an n-gram (note that the subscript and superscript symbols denote the beginning and ending of a subsequence in the string; in the previous case it refers to the subsequence, from index $(j-n)+1$ to the index j) which consists, conceptually, of an initial subsequence, $e^{j-1}_{(j-n)+1}$, of length $n-1$ known as the *context* and a single symbol extension, e_j, called the *prediction*. The quantity $n-1$ is the *order* of the n-gram rewrite rule.

Such models are frequently used in computational models of music (see below), and also some music theoretical accounts (e.g., Piston's table of common root progressions, shown in Table 25.1).

By definition all types of strictly local or Markov models share the Markov assumption (25.1) and (25.2): the grammaticality (gr) of a subsequence or the probability (p) of a symbol appearing in a sequence depends only on its immediate preceding context of length k. This assumption means that these models cannot represent any nonconsecutive dependencies between musical elements beyond a fixed finite length.

$$gr\left(e^{i}_{1}\right) = gr\left(e^{i}_{i-n+1}\right) \tag{25.1}$$

$$p\left(e^{i}_{1}\right) \approx p\left(e^{i}_{i-n+1}\right) \tag{25.2}$$

Markov models provide powerful approximations to sequential structure for numerous practical applications independently of whether those sequences obey the Markov assumption. Nonetheless, such models are theoretically as well as practically limited in the extent to which they can capture and represent more complex structural features such as nonlocal dependencies, nested structures, and cross-serial dependencies. To some extent these limitations can be addressed by using sophisticated representation schemes such as the multiple-viewpoint formalism [25.64, 65] that extends the range of context that a Markov model can take into account by combining several Markov models over different feature spaces and (possibly) time scales, including nonadjacent events.

Table 25.1 Table of common root chord progressions (after [25.60])

	Is often followed by	Sometimes by	Less often by
I	IV or V	VI	II or III
II	V	IV or VI	I or III

IV	V	I or II	III or VI
V	I	VI or IV	III or II
VI	II or V	III or IV	I
VII	III	I	

25.4.2 Finite-State Models

Several theoretical approaches can be viewed as having equivalent representational power to *finite-state or regular grammars* in Chomsky's terminology. In contrast to *k-factor languages*, such models involve grammars that distinguish between (hidden) variables (nonterminal symbols) and surface symbols (terminals). Accordingly, *regular grammars* (i. e., grammars that only have rules of the form $A \rightarrow aB$; in which a refers to a terminal and A, B to nonterminals; see the appendix below) characterize sequential structure by building up a string from left to right. They form a true superset of *k-factor* languages. The formal machine that recognizes the set of strings generated by such a grammar is a *finite-state automaton* (informally, a flow-chart). The probabilistic counterpart to a regular grammar is the *Hidden Markov Model* (HMM; [25.66]).

25.4.3 Context-Free or Equivalent Models

There are several accounts of structure in music theory which go beyond the expressive power of finite-context and finite-state grammars (for further discussion [25.38]):

- Differences of structural importance
- Dependency structure, preparation, and ornamentation
- Headedness
- Nested structures
- Functional categories.

A useful starting point is the insight that the elements in a sequence may differ in structural importance, i. e., some can be left out without impairing grammaticality whereas others cannot. An early account by *Kostka* and *Payne* [25.67] refers to this as *levels* of harmony (note, however, that the observation is not restricted to harmony). Second, musical structure expresses dependencies: e.g., in a I II V or I III IV progression, the II or III chord may be understood as preparation for V or IV and not simply a sequential succession of I; accordingly, it is *dependent* on V or IV, not on I. This is expressed by the rules V $\rightarrow$ II V or *IV* $\rightarrow$ III IV

(for further details the reader is directed to [25.68]). This further entails that goals are structurally more fundamental than their preparations and, conversely, that ornamentation and variation adds new material to basic structure. This notion of dependency structure further entails a notion of *headedness*, namely that in the II V progression, V is the fundamental chord, i. e., the head (as expressed in the left-hand side of the rules above).

Another central formal concept concerns nested structures: the notion of dependency introduced above may lead to the formation of dependent subsubsequences within a dependent subsequence within a sequence (and so on). For instance, the II chord (which is the preparation of the V chord) in the above sequence may be further elaborated, ornamented, or prepared. This leads to recursive structures in the form of tail recursion (chains) and nested recursion (sequence in a sequence). One prominent example of nested structure in tonal music is modulation (e.g., an early account by [25.69]; the reader is also directed to [25.38, 68, 70]; for nested structure in music see [25.1, 38, 71, 72]). Finally, *Riemann* [25.73] introduced the notion that chords can be classified into different functional categories (such as tonic, dominants, and subdominants) that may be functionally interchangeable, such as II and IV leading to V. Riemann considered harmonic sequences to be hierarchical [25.74], and *Rohrmeier* [25.38, 68] developed a context-free formalism for the functional approach to harmony. In this formalism, tree structures represent different harmonic sequences that fulfill identical harmonic functions in the same way in higher parts of the tree.

Context-free languages and hierarchical tree-based accounts are well-suited for representing these kinds of structural dependencies in sequences. A number of theories account for music in such theoretical terms: *Schenker* [25.75], *Lerdahl* and *Jackendoff* [25.71]; *Keiler* [25.77, 78]; *Steedman* [25.1, 72]; *Narmour* [25.30]; *Lerdahl* [25.37]; *Tidhar* [25.79]; *Rohrmeier* [25.38, 68]. Various partial or full computational implementations of these theories exist, as discussed below.

Schenker [25.75] proposed a theoretical account of music based on reductional analysis that reveals different layers of musical structure ranging from surface to foreground, middle ground and Ursatz. Briefly construed, his account entails that principles of counterpoint (such as neighbor notes) may be used to distinguish the structural importance of musical events.

Lerdahl and *Jackendoff*'s Generative Theory of Tonal Music [25.71] (GTTM) provides an account that brings the ideas expressed by Schenker into a rule-based theoretical framework, inspired by the generative approach to grammar in linguistics. It is, for example, founded on the assumption that a piece of music can be partitioned into hierarchically organized segments which may be derived through the recursive application of the same rules at different levels of the hierarchy. Specifically, the theory is intended to yield a hierarchical, structural description of the final cognitive state of an experienced listener to that composition.

According to GTTM, a listener unconsciously infers four types of hierarchical structure in a musical surface (Fig. 25.2): first, *grouping structure* which corresponds to the segmentation of the musical surface into units (e.g., motives, phrases, and sections); second, *metrical structure* which corresponds to the pattern of periodically recurring strong and weak beats; third, *time-span reduction* which represents the relative structural importance of pitch events within contextually established rhythmic units; and finally, *prolongational reduction* reflecting patterns of tension and relaxation amongst pitch events at various levels of structure. According to the theory, grouping and metrical structure are largely derived directly from the musical surface and these structures are used in generating a time-span reduction which is, in turn, used in generating a prolongational reduction. Each of the four domains of organization is subject to *well-formedness rules* that specify which hierarchical structures are permissible and which themselves may be modified in limited ways by *transformational rules*. While these rules are abstract in that they define only formal possibilities, *preference rules* select which well-formed or transformed structures ac-

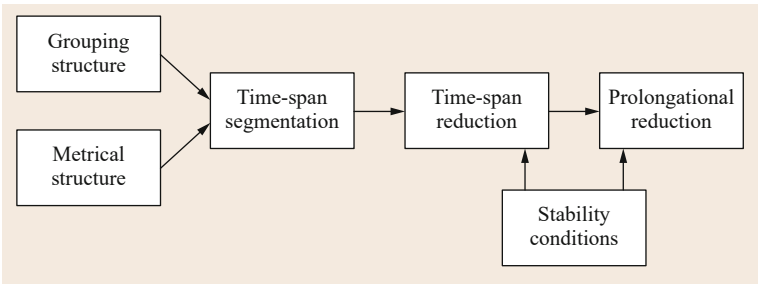

Fig. 25.2 The overall structure of GTTM (after [25.76, Fig. 10.6])

tually apply to particular aspects of the musical surface. Time-span and prolongational reduction additionally depend on tonal-harmonic *stability conditions* which are internal schemata induced from previously heard musical surfaces.

When individual preference rules reinforce one another, the analysis is stable and the passage is regarded as stereotypical whilst conflicting preference rules lead to an unstable analysis causing the passage to be perceived as ambiguous and vague. In this way, according to GTTM, the listener unconsciously attempts to arrive at the most stable overall structural description of the musical surface. Experimental studies of human listeners have found support for some of the preliminary components of the theory including the grouping structure [25.80] and the metrical structure [25.31].

The theory constitutes a formal predecessor to *Jackendoff*'s later parallel architecture framework of language [25.81, 82]. It is important to observe that the GTTM is not a *grammar* or a *syntax* of music: it provides a model of parsing but contains no generative rules or mechanisms to derive the musical surface, further it does not model a distinction between regular and irregular sequences. Rather than generating the musical surface, the GTTM is a theory of musical processing with only limited applicability as a theory of structural syntax per se.

It is highly challenging to develop formal context-free grammars that account for musical surface structure but several efforts have been made (e.g., [25.83, 84] for reviews). *Johnson-Laird* [25.85] used grammatical formalisms to investigate what has to be computed to produce acceptable rhythmic structure, chord progressions, and melodies in jazz improvisation. While a finite-state grammar (or equivalent procedure) can adequately compute the melodic contour, onset, and duration of the next note in a set of Charlie Parker improvisations, its pitch is determined by harmonic constraints derived from a context-free grammar modeling harmonic progressions. In a more recent approach, *Rohrmeier* [25.38, 68] introduces a set of context-free rules modeling the main features of tonal harmony from the common-practice period.

Context-free languages (and more complex formalisms) constitute supersets of regular and suprareglular languages. In fact, the latter constitute local boundaries of context-free languages (i. e., substrings that do not use the features of nested embedding are regular; it is further possible to derive precise models of local transitions from context-free models). Accordingly, the distinction between these types of languages does not imply a forced alternative – rather, context-free language models can result from the addition of the above structural features to regular language accounts. Put another way, we can add degrees of context-free character to regular grammars.

25.4.4 Beyond Context-Free Complexity

Are there aspects of musical structure that require greater than context-free power to be modeled? Debates in theoretical linguistics of the past 25 years have reached a fairly consensical view that human language is mildly context sensitive [25.86, 87]. It requires syntactic power that is stronger than context-free but considerably less strong than the immense computational power of full context-sensitive grammars. One example of this context-sensitive complexity is given by cross-serial dependencies (as in Dutch or Swiss German relative clauses [25.86, 88]) that cannot be expressed by context-free grammars. In the Chomskian tradition, minimalist grammars, that are equally mildly context-sensitive [25.89], adopted two mechanisms of external merge (similar to a context-free tree building operation) and internal merge (combining an already derived branch of a tree with different free positions in the tree). Internal merge may express features such as movement (*Sue wondered which book Peter read?*). *Katz* and *Pesetsky* [25.90] argue that musical and linguistic structure are formally equivalent in the sense that both require structure-building operations based on external and internal merge.

What about music? In his review, *Roads* [25.83] argues that the strict hierarchy characteristic of context-free grammars is difficult to reconcile with the ambiguity inherent in music. Faced with the need to consider multiple attributes occurring in multiple overlapping contexts at multiple hierarchical levels, even adding ambiguity to a grammar is unlikely to yield a satisfactory representation of musical context. The use of context-sensitive grammars can address these problems to some extent but this also brings considerable additional difficulties in terms of efficiency and complexity. There are several attempts to model music using grammatical formalisms which add some degree of context sensitivity to context-free grammars without adding significantly to the complexity of the rewrite rules. An example is the Augmented Transition Network (ATN) which extends a recursive transition network (formally equivalent to a context-free grammar) by associating state transition arcs (rewrite rules) with procedures which perform the necessary contextual tests. *Cope* [25.91] describes the use of ATNs to rearrange harmonic, melodic, and rhythmic structures in EMI (experiments in musical intelligence). Another example is provided by the pattern grammars developed by *Kippen* and *Bel* [25.10] for modeling improvisation in North Indian tabla drumming.

Steedman [25.1, 72] has developed a categorial grammar (augmented context-free) to account for the harmonic structure of 12-bar blues, based on a theory of tonal harmony due to *Longuet-Higgins* [25.45, 46]. Although it is less ambitious than that of *Johnson-Laird* [25.85], this allows a more elegant description of improvisational competence since it does not rely on substitution into a previously prepared skeleton. However, in using the grammar to generate structural descriptions of blues chord progressions, Steedman had to introduce implicit meta-level conventions not explicit in the production rules of the grammar. The extent of context-sensitivity required to adequately model musical structure requires further investigation.

25.5 Discussion

This discussion of theoretical accounts of musical syntax raises several issues and questions which are driving current research:

1. How powerful a grammar do we need to represent the relationships present in musical structure? Are there examples of syntactic musical structures that require (mild) context sensitivity? How can multiple, polyphonic streams be represented by formal approaches?
2. How does musical syntax interact with other aspects of musical structure such as rhythm, metre, and timing? Or are these aspects also best explained using syntactic formalisms?
3. To what extent does real music, and listeners' perception of music, exhibit features of recursion, nonlocal dependencies, single or multiple center-embedding?
4. Which kinds of formal structures are listeners (musicians or nonmusicians) sensitive to?
5. Can such syntactic structures and relationships be learned, and if so, how and which kinds of predispositions need to be assumed as innate?

The power of a particular syntactic formalism is independent of whether it is probabilistic or deterministic. Probabilistic models have distinct advantages in terms of the subtlety with which they can capture structural dependencies for application in prediction, classification, parsing, and learnability/inference as well as in terms of robustness and graded grammaticality. For each of the model classes of the extended Chomsky hierarchy probabilistic counterparts have been proposed (e.g., finite-context grammars: *n*-gram models; regular grammars: Hidden Markov models; context-free grammars: probabilistic context-free grammars). These developments suggest as a general strategy that it may be beneficial to move from deterministic to probabilistic models for implementation and evaluation. It is important to note here that the Chomsky hierarchy is just one way of characterizing the power of grammatical formalisms but it does not necessarily lend itself naturally to every aspect of musical structure. Furthermore, as we noted above degrees of context-free character may be added to regular grammars and degrees of context-sensitivity added to context-free grammars.

While Markov and *n*-gram models are easily learned and are useful for prediction, they are barely capable of modeling more complex structures, nonlocal and hierarchical dependencies in music described above that are essential in musical implicative structure, stability, tension, and similarity. Conversely, more powerful types of syntactic formalisms are considerably more difficult to infer from data. It is not currently clear that we can develop one overarching theoretical stance that generalizes across musical styles and cultures. As in other areas of empirical musicology, the majority of research on musical syntax has focused on Western music and harmony in particular (with a few notable exceptions including [25.10, 12] and recent work by *Mavromatis* [25.92]). Different musical styles or traditions may emphasize different kinds of building block or show different degrees and kinds of complexity in their syntactic structure. Cross-cultural comparisons may have implications for evolutionary theories of music. While each process of inference requires predetermined (innate) assumptions about at least the search space and the structure of the model, it must be noted that cross-cultural universality by no means implies innateness of more than these assumptions.

Many of these questions are best addressed by implementing a computational theory as a computer model that embodies a particular theoretical stance on musical syntax and testing the model by comparing its behavior with human behavior. Modeling requires the theory to make all its assumptions explicit and permits the analysis of complex examples and large corpora. It is also possible to conduct a quantitative comparison of the behavior of a computational model with the behavior of listeners, allowing a rigorous empirical test of the theory as a psychologically plausible model of cognitive representation and processing of musical syntax. We address these points in detail in the following chapter, *Musical Syntax II*.

25.A Appendix: The Chomsky Hierarchy

Noam Chomsky introduced a containment hierarchy of four classes of formal grammar in terms of increasing restrictions placed on the form of valid rewrite rules [25.52]. A formal grammar consists of a set of nonterminal symbols (variables), terminal symbols (elements of the surface), production rules, and a starting symbol to derive productions. In the following description, $a \in T^*$ denotes a (possibly empty) sequence of terminal symbols, $A, B \in V$ denote nonterminal symbols, $\alpha \in (V \cup T)^+$ denotes a nonempty sequence of terminal and nonterminal symbols, and $\beta, \beta' \in (V \cup T)^*$ denote (possibly empty) sequences of terminal and nonterminal symbols. The difference between different formal grammars in the Chomsky hierarchy relates to different possible production rules.

Every grammar in the Chomsky hierarchy corresponds with an associated automaton: while formal grammars generate the string language, formal automata specify constraints on processing or generating mechanisms that characterize the formal language. Automata provide an equivalent characterization of formal languages as formal grammars.

25.A.1 Type 3 (Regular)

Grammars in this class feature restricted rules allowing only a single terminal symbol, optionally accompanied by a single nonterminal, on the right-hand side of their productions

$$A \to a$$
$$A \to aB \quad \text{(right linear grammar) or}$$
$$A \to Ba \quad \text{(left linear grammar)} .$$

Regular grammars generate all languages which can be recognized by a finite-state automaton, which requires no memory other than a representation of its current state.

It is essential to note that regular grammars are *not* equivalent to Markov models or k-factor languages (see Sect. 25.4.1 above).

25.A.2 Type 2 (Context Free)

Grammars in this class only restrict the left-hand side of their rewrite rules to a single nonterminal symbol – i. e., the right-hand side can be any string of nonterminal symbols

$$A \to \alpha .$$

The equivalent automata characterization of a context-free language is a nondeterministic pushdown automaton, which is an extension of finite-state automata that employs memory using a stack and state transitions may depend on the current state as well as the top symbol in the stack.

25.A.3 Type 1 (Context Sensitive)

Grammars in this class are restricted only in that there must be at least one nonterminal symbol on the left-hand side of the rewrite rule and the right-hand side must contain at least as many symbols as the left-hand side, i. e., string length increases monotonically in the production sequence.

$$\beta A \beta' \to \alpha, \quad \left|\beta A \beta'\right| \leq \alpha$$

Context-sensitive languages are equivalently characterized by a linear bounded automaton, that is a state-machine extended by a linear bounded random access memory band, whose transitions depend on the state, the symbol on the memory band.

25.A.4 Type 0 (Unrestricted)

Grammars in this class place no restrictions on their rewrite rules

$$\alpha \to \beta$$

and generate all languages which can be equivalently characterized by a universal Turing machine (the recursively enumerable languages), which is the same as the linear bounded automaton for context-sensitive languages without bounds on the memory tape.

26. Musical Syntax II: Empirical Perspectives

Marcus Pearce, Martin Rohrmeier

Efforts to develop a formal characterization of musical structure are often framed in syntactic terms, sometimes but not always with direct inspiration from research on language. In Chap. 25, we present syntactic approaches to characterizing musical structure and survey a range of theoretical issues involved in developing formal syntactic theories of sequential structure in music. Such theories are often computational in nature, lending themselves to implementation and our first goal here is to review empirical research on computational modeling of musical structure from a syntactic point of view. We ask about the motivations for implementing a model and assess the range of approaches that have been taken to date. It is important to note that while a computational model may be capable of deriving an optimal structural description of a piece of music, human cognitive processing may not achieve this optimal performance, or may even process syntax in a different way. Therefore we emphasize the difference between developing an optimal model of syntactic processing and developing a model that simulates human syntactic processing. Furthermore, we argue that, while optimal models (e.g., optimal compression or prediction) can be useful as a benchmark or yardstick for assessing human performance, if we wish to understand human cognition then simulating human performance (including aspects that are nonoptimal or even erroneous) should be the priority. Following this principle, we survey research on processing of musical syntax from the perspective of computational modeling, experimental psychology and cognitive neuroscience. There exists a large number of computational models of musical syntax, but we limit ourselves to those that are explicitly cognitively motivated, assessing them in the context of theoretical, psychological and neuroscientific research.

26.1 Computational Research

26.1.1 Foundations

Different approaches to building computer models of musical structure can be characterized, and distinguished, in terms of how expressive they are in terms of the degree of structural complexity they are capable of representing. Therefore, there is a direct link between the theoretical characterization of musical syntax (discussed in Chap. 25) and the implementation and testing of these theories as computational models of cognition, discussed here. Implementing a theory of musical syntax and processing has several potential advantages,

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_26

following well-known examples in cognitive science:

1. Implementing a theory as a computer program (which must run, generating output from the data and parameters supplied as input) ensures that it takes as little as possible for granted and any assumptions are explicitly stated [26.1–3].
2. Experiments can be run to evaluate the implemented theory by comparison of its behavior with the output expected from theoretical accounts or directly with human behavior given the same inputs [26.3, 4].

It is important to distinguish between models whose knowledge is provided to them by a human expert (in the style of good, old-fashioned artificial intelligence, GOFAI) and those that acquire knowledge about musical structure by learning (either supervised or unsupervised) from experience of music, given some predefined structural representation, the parameters of which are learned (in the tradition of machine learning), be it a neural network, a Markov model or grammatical inference. The appropriate approach depends on the goal of the modeling. However, in many cases the two approaches are complementary in that successfully learning complex representations (e.g., context-free rules) is extremely challenging but the alternative approach can result in models that do not generalize far beyond the musical domain for which they were developed (e.g., *Steedman*'s [26.5, 6] grammars for blues harmony). In the past, tasks that required context-free representations have usually been hand coded while tasks that require simpler representational relationships have been able to benefit from the flexibility of machine learning. However, methods have now been developed in computational linguistics to learn certain kinds of context-free representation [26.7]. Note that if we are interested in cognitive representations of music, there is the additional issue of the extent to which the representations in question are actually learned or inherited (i. e., innately specified) by human beings ([26.8] as, e.g., discussed in the poverty of the stimulus debate [26.9]).

As mentioned above, we must also emphasize the distinction between finding an optimal structural description of a piece of music and modeling the cognitive representation of that piece in the mind of a listener. The former bounds the latter but listeners are likely to be subject to constraints of perception and cognition (e.g., limitations of working memory load), which would prevent them reaching an optimal structural description. Note also that it is problematic to assume the existence of an *average listener* without understanding all the factors (e.g., musical training, environmental context, degree of attention etc.) that could influence the structural descriptions that listeners form. Nonetheless, it is often useful to identify theoretical bounds on structural complexity using an optimal model. Furthermore, theoretical models of musical structure can help us understand the hypothesis space that human learners are faced with when they acquire the syntactic structure of a musical style. In artificial intelligence research, we distinguish between the representation defining the search space and algorithms for traversing the space. Similarly in machine learning, we distinguish between the hypothesis space and learning mechanisms for traversing the space. In the case of musical syntax, the hypotheses correspond to potential stylistic grammars generating structural descriptions of music and we can think of the learning as traversing the space of possible grammars, specifying the parameters distinguishing those grammars along the way.

The following sections illustrate these points, using different kinds of computational models that have been proposed for understanding musical syntax.

26.1.2 Early Approaches: Pattern Processing

We begin with a review of two early approaches that are of historical importance because they laid the foundations for symbolic models that subsequently became influential. One early approach was based on the assumption that listeners use pattern induction processes to develop predictions for successive events in melodies [26.10, 11]. These models attempt to define formal languages for describing the patterns perceived by humans in temporal sequences (such as music) and use them to explain how these patterns are applied for prediction. *Simon* and *Sumner* [26.11], for example, begin with ordered alphabets for representing the range of possible values for a particular musical dimension (e.g., note names, note durations). Simon and Sumner restrict their attention to the dimensions of melody, harmony, rhythm and form and use alphabets for diatonic notes, triads, duration, stress and formal structure. The operations they consider are *same* (when the subsequent symbol is identical to the previous one) and *NEXT* (the subsequent symbol is obtained by taking the next symbol in the specified alphabet a specified number of times). Sequences of symbols may then be described more compactly as a sequence of these operations.

Deutsch and *Feroe* [26.10] extended the model of Simon and Sumner in several ways, in particular defining structures as sequences of elementary operators and sequence operators such as prime, retrograde, inversion and alternation. They apply their pattern language to various alphabets, corresponding to collections of pitches, such as the major and (natural, harmonic and melodic) minor scales, major, minor and diminished tri-

ads, and seventh chords. They argue that the pattern language facilitates processing in four ways:

1. Reduced redundancy of representation
2. Distinct alphabets may be invoked at different levels
3. Embedded sequence structures and their associated alphabets may be encoded as chunks
4. The chunking of structures allows for the representation of configurations that satisfy proximity and the differentiation of different members of the alphabet in terms of frequency.

Deutsch and Feroe propose that multiple representations may be formed by listeners who, according to the model, will tend to choose the most parsimonious. The acquisition of a representation is an ongoing process of generation and testing of multiple hypothesized structural representations [26.12, 13].

26.1.3 Markov Modeling

Another early approach to modeling musical structure was based on statistical learning and information theory, in particular using *information content* and *entropy* to measure the complexity of a musical style. It is interesting to note that information theory was applied to music as early as 1955 [26.14–17] just a few years after *Shannon*'s foundational work was published [26.18]. Typically, this approach involves representing a musical work as a sequence of symbols drawn from an alphabet (e.g., a melody might be represented as a sequence of pitch symbols, harmonic movement as a sequence of chord symbols). The learning task is to estimate a conditional probability governing the next symbol in the musical sequence, given the preceding symbols. Such models (in various guises) have been highly influential in terms of understanding predictive processing in human cognitive processing of music [26.19, 20].

It is possible to vary the length of the context used in estimating the probability, known as the *order* of the model (a zeroth-order model has no context, a first-order model a context of one symbol and so on). Usually the probabilities (i. e., the parameters of the model) are estimated through statistical analysis of a corpus of musical works. These models are also known as Markov models because the probability of an event is only dependent on the immediately previous context (the Markov property), or, in other words, the model does not take into account any nonlocal dependencies. Once a probability distribution has been generated in a particular context, the *entropy* of that distribution reflects the model's uncertainty about the following musical event before it arrives while the *information content* (the negative log probability) reflects how unexpected the next note is, once it has arrived – given a local model [26.21]. Note that the entropy and information content of a musical event or sequence are not properties of the music per se, but properties of the music from the perspective of an underlying model.

It is interesting that one of the first nonmilitary applications of early computers was software to generate music incorporating grammatical representations of musical styles corresponding to probabilistic Markov models [26.22]. Early work using these models tended to focus on fixed, low-order models with simple representational building blocks (e.g., chromatic pitch) to estimate and compare the average entropy of different musical works and corpora [26.16, 23–26] rather than dynamic prediction of ongoing sequential musical structure.

More recent research addressed these limitations by using variable-order Markov models, where the order varies depending on the context to generate accurate predictions dynamically throughout pieces of music [26.27, 28]. Prediction performance may also be improved by combining predictions from a long-term model (trained on a large corpus of music in the style) and a short-term model (which starts with an empty model and learns incrementally from the current musical work) [26.27, 28]. The long-term model represents the effects of long-term schematic exposure to a musical style while the short-term model reflects more local learning of repeated structure within a musical work. The probability distribution generated by the two models may be combined using arithmetic or geometric averaging, weighted by the entropy of the distributions [26.29].

Improved prediction performance can also be achieved by allowing the model to estimate and combine probabilities based on multiple features of the musical surface. Multiple viewpoint frameworks were originally developed by *Darrell Conklin* [26.27, 30, 31] to allow the integration of information from models of different features (inspired in part by *Ebcioğlu* [26.32]). The framework assumes a symbolic representation in which music is represented as a sequence of discrete events composed of a finite number of attributes each of which may assume a value from a finite alphabet. For example, a melody is often represented as a sequence of notes, each of which is composed of a pitch, onset time, duration and loudness.

A viewpoint is a mapping from a sequence of musical events to an element from the alphabet associated with the viewpoint. Basic viewpoints are projection functions associated with the attributes of the events (i. e., pitch, onset, duration and loudness in the example above). The framework also allows the specification of derived viewpoints (e.g., pitch interval, contour, scale

degree), which are derived from a basic viewpoint (e.g., pitch in this case). Note that some viewpoints may be undefined at particular locations (e.g., pitch interval for the first event in a melody). Test viewpoints are viewpoints that return a Boolean value (e.g., whether a note falls on a tactus beat or not) and threaded viewpoints represent a base viewpoint (e.g., pitch interval) at points where a test viewpoint is true (e.g., pitch interval between notes falling on tactus beats) thereby allowing for sequences of nonsequential events. Finally, linked viewpoints represent the Cartesian product of two or more primitive viewpoints – for example, a link between pitch interval and scale degree will have an alphabet composed of pairs, whose first element is a pitch interval and whose second is a scale degree.

When modeling music with a multiple viewpoint system, separate models are constructed for each viewpoint included in the system and the resulting distributions are combined in much the same way as the long-term and short-term model outputs are combined. The distributions are first mapped back into distributions over the alphabet associated with the basic feature from which they are derived (e.g., pitch in the above examples) so that they can be combined. Typically, the viewpoint models are combined in a first stage separately for the long- and short-term models, which are then combined [26.27, 28, 33]. Multiple-viewpoint models have been developed for the domains of melody, harmony and voice leading [26.28, 33, 34].

When configured appropriately and trained on relevant corpora, these methods both improve prediction performance of the models [26.27, 28] and also account accurately for listeners' pitch expectations in melody [26.28, 35–40]. In some cases, the model parameters that optimize prediction performance do not improve fit to human perception and vice versa [26.28] suggesting that human expectation may be subject to constraints (such as memory or representational limitations) that prevent optimal prediction.

26.1.4 Beyond Simple Markov Models: Hidden Markov Models and Dynamic Bayesian Networks

The models of the Markov and *n*-gram family discussed in Sect. 26.1.3 are essentially equivalent to probabilistic versions of strictly local grammars (Chap. 25). One important feature of Markov models is that they can only model local sequential dependencies and do not assume any underlying deep structure (hidden variables). Although they operate directly on surface symbols, it is possible to use multiple viewpoint frameworks to allow such models to operate on nonsequential events (e.g., notes on tactus beats or phrase-final events, [26.27, 28]) and on representations of higher-order structure (e.g., phrase classes). However, although some of these formal limitations in expressive power may be addressed in part with the multiple-viewpoint approach, more expressive models of sequential structure have been developed in machine learning research, many of which have been applied to music. In the Chomsky hierarchy, the different model classes (from finite-state to finite-context) assume an underlying deep structure (represented using nonterminal symbols) that predicts the surface terminal symbols (Chap. 25); in an analogous way, many modeling approaches take advantage of an explicit representation of deep structure in music.

One well-known example is hidden Markov models (HMMs, e.g., [26.41, 42]; for an introduction see the comprehensive review by [26.43]), which correspond to probabilistic extensions of finite-state automata. As an extension of Markov models, the hidden Markov model assumes the Markov transition matrix not as a model characterizing transitions between surface symbols (as in the *visible* Markov models described above), but as transitions between deep structural (hidden) states that themselves emit surface symbols from associated emission distributions over the terminal alphabet. In other words, it assumes a Markov model as the underlying deep structure of states that govern the symbol distribution over subsections of the sequence.

HMMs have been employed to model various aspects of music, including, for instance, melodic structure [26.44, 45], meter and rhythm [26.45, 46], text setting [26.47] and harmonic structure [26.34, 48, 49]. Modeling harmony in a corpus of jazz standards, *Rohrmeier* and *Graepel* [26.34] found that a simple HMM modeling chord sequences exhibited barely any overfitting of its training data. Dynamic Bayesian networks (DBNs, [26.50]) generalize HMMs and constitute a family of graphical models that model the dependency structure of different (temporal) deep-structural features. DBNs were applied to modeling music by *Paiement* et al. [26.51] as well as *Raczynski* et al. [26.52] to model polyphonic pitch structure. Furthermore, DBNs can be straightforwardly adapted to modeling the interaction of different parallel feature-streams in the framework of HMMs. *Rohrmeier* and *Graepel* [26.34] implemented a DBN modeling Jazz harmony using features of duration and mode to improve predictive power though the approach does not extend to derived viewpoints.

Most of the models of sequence processing discussed so far drew their motivation from the modeling of musical expectation (see also [26.53], for an extensive account of the role of expectation in music perception). Models with a rich deep structure, however, may be used to understand other aspects of music

processing such as inferring information encoded in the deep structure of the sequence. For instance *Raphael* and *Stoddard* [26.48] used a type of DBN for the inference of harmonic structure from the surface sequence of events. *Mavromatis* [26.45] employed a model selection procedure to find the optimal topology for a HMM, using this to draw theoretical and cognitive conclusions regarding representation of deep structure. He applied the model to two cases, the statistical learning and segmentation paradigm used by Saffran and colleagues (e.g., [26.54]) and metrical induction from rhythmical patterns in a corpus of Palestrina's vocal music. *Mavromatis* [26.46] extended this approach and drew computationally informed conclusions regarding a discussion surrounding Renaissance meter.

In summary, while the application of deep structure models and DBNs in cognitive music research is growing, there is a great potential to employ these models (in combination with model selection) to understand the role of deep structure in the representation and processing of musical syntax.

26.1.5 Hierarchical Models

While computational implementations of Markovian approaches (and derived approaches such as HMMs and DBNs) have largely addressed the problem of modeling effects of expectancy and prediction, many computational approaches have sought explicitly to implement hierarchical generative models of music. The motivation derives from theoretical insights that tonal music is organized in a hierarchical fashion and, accordingly, cognitive models of music processing should be able to account for such structural complexity. Moreover, theoretical hierarchical accounts of music stress that human music cognition involves substantially more than computation of sequential predictions including, in particular, the perception of large-scale processes (e.g., musical form), reductive listening, experience of hierarchical tension and recognizing similarity (see Chap. 25 for a discussion of various ways to motivate and explore the understanding of musical syntax). Accordingly, computational models of hierarchical structure have been inspired by a diverse array of modeling goals.

The hierarchical and generative branches of music theory mainly trace back to Schenkerian theory [26.55, 56]. Apart from Schenkerian theory itself, there have been three major lines of hierarchical modeling research: the generative theory of tonal music (GTTM) and tonal pitch space [26.57, 58], which originated from the goal of framing Schenkerian analysis in terms of formal linguistic approaches; *Narmour*'s theory of melodic expectancy and complexity [26.13, 59]; and approaches to tonal harmony that employ methods from generative linguistics and formal language theory [26.5, 6, 60, 61]. Each of these formal approaches have inspired efforts to build computational models.

Schenkerian Analysis and Derivative Models

Schenkerian theory constitutes one of the earliest and most comprehensive formal approaches to syntax in tonal music and remains dominant in music-theoretical teaching. It has been the object of several computational approaches from the early days of computing to the present day.

Early work by *Kassler* focused on understanding Schenkerian-like operations of analysis from the perspective of formal languages [26.62]. He formalized a subset of Schenkerian derivations with primitive-recursive functions [26.63] and described a basic implementation of a (presumably two-voice) model of Schenkerian analysis in terms of primitive operations on a matrix representation of pitch sequence, such as an Ursatz axiom, arpeggiation, neighbor note prolongation, simplified interruption (termed *articulation*), octave adjustment, bass ascent, mixture, etc. [26.62, 64, 65]. In a separate modeling attempt based on functional programming, Smoliar and colleagues used a recursive list structure of musical events that encoded a set of Schenkerian elaboration operations in terms of Lisp function calls. Drawing a direct formal analogy between (generative) linguistic parse trees and musical structure, they developed a tree-based structural representation of a Schenkerian reductive analysis [26.66–68]. In an approach similar to Schenkerian analysis techniques, *Baroni* and colleagues applied formal grammars to melodic structure [26.69, 70]. However, none of these early approaches resulted in a complete, fully automatic functioning model of Schenkerian analysis. *Marsden* [26.71] suggested that this may be due to to the massive explosion of combinatorial complexity that arises when encoding a formal account of Schenkerian-style reductive analysis at the level of notes.

With greater computational resources available, a number of researchers have recently returned to the problem of implementing Schenkerian analysis. *Mavromatis* and *Brown* [26.72] proposed a theoretical approach to modeling Schenkerian analysis with probabilistic context-free grammars. However, their model did not reach the stage of a full implementation due to issues of complexity (see [26.71]). *Marsden* [26.73] proposed a graph-theoretical representation of reductive structures (termed *E-Graph*) suitable for computational implementation. Subsequently, *Marsden* [26.74] proposed an expanded representation of Schenkerian reduction in a generative framework. Using the limited case of short musical phrases, Marsden

developed a preliminary implementation of Schenkerian analysis [26.74] and building on this theoretical framework, a first proof-of-concept prototype was developed [26.71].

Recent research on implementing Schenkerian theory includes *Yust* [26.75], who proposed the structure of *maximal outerplanar graphs* (MOP) as representations for the structure of Schenkerian prolongation, and the work of *Kirlin* (e.g., [26.76]) who has developed a corpus of 41 pieces annotated with corresponding Schenkerian analyses in machine-readable format [26.77]. *Kirlin* and *Jensen* [26.78] use supervised probabilistic learning to uncover deep hierarchical musical structure, including an algorithm for deriving the most probable analysis for a given piece of music.

The Implication–Realization Model

Breaking with Schenkerian tradition (see [26.79]), *Eugene Narmour* developed a distinct theoretical approach to modeling melodic expectancy [26.13] as well as melodic complexity and reduction [26.59]. The *implication-realisation model* is based on the implications that a melodic interval (the implicative interval) has for the following interval (the realized interval) and presents a detailed classification of interval pairs based on the size and direction of the component intervals. The model consists of two independent perceptual systems – the bottom-up and top-down systems of melodic implication. While the principles of the former are held to be automatic, unconscious and universal, the principles of the latter are held to be learned and hence culture dependent. Although the model is presented in a highly analytic manner, it has psychological relevance because it proposes hypotheses about general perceptual principles that are precisely and quantitatively specified and therefore amenable to empirical investigation [26.80, 81]. Research has also compared the implication-realization model with variable-order Markov models in terms of how well they account for listeners' pitch expectations [26.28, 36, 37]. Furthermore, Grachten and colleagues have examined the use of the implication-realization model in a computational model of similarity for use in music information retrieval [26.82].

Furthermore, *Narmour* [26.59] presents detailed proposals for the ways in which basic musical structures (pairs of intervals) may form larger sequential units (chains) and larger hierarchical units (transformations) based on the idea of closure, which occurs when a structure does not generate a strong implication. However, these hierarchical aspects of the theory have been somewhat neglected in terms of computational modeling and empirical evaluation.

The Generative Theory of Tonal Music (GTTM)

The GTTM [26.57] constitutes probably the most influential model in empirical musicology to date. It models the perception of musical structure in term of the interaction of four levels of structure: grouping structure, metrical structure, time-span reduction and prolongational reduction (see [26.58, Ch. 1] for a review); these levels are defined in terms of *well-formedness rules* exhaustively defining the (very large) set of well-formed candidate analyses and *preference rules* that define rules to select the best analysis from the well-formed candidates. Although it is partly inspired by generative grammars for language, it is important to note that the GTTM is not a formal grammar because no (tree-defining) context-free rules are specified, and it is unclear whether it could be developed into one. Furthermore, the GTTM is a model of the final representation of a piece of Western tonal music as it might appear in the mind of an idealized listener, enculturated in Western music. It does not account for any effects of stylistic enculturation nor make any predictions about the dynamic nature of structure perception during listening (this was later addressed by *Jackendoff* [26.83]).

While the GTTM is specified to a much higher degree of detail and specificity than Schenkerian theory, it is still highly imprecise from a computational point of view. For instance, it does not specify a ranking for the preference rules and in some cases assumes human musical intuition for making analytical decisions. These factors pose challenges for computational implementations of the GTTM. Nonetheless, *Lerdahl* [26.58] has devised a model of musical tension that is based on a complete GTTM analysis and predicts musical tension based on local and global factors [26.58]. The model has been found to predict participants' continuous ratings of musical tension for a small number of musical pieces [26.84]. To date, the most extensive progress towards an implementation of the GTTM has been made by *Hamanaka* and colleagues [26.85, 86].

Generative Grammars for Music

Many authors have proposed recursive generative grammars for modeling the hierarchical organization of harmonic sequences, an idea whose essence goes back to *Riemann* [26.87]. Following the formalization of context-free rewrite grammars and the Chomsky hierarchy, a number of earlier approaches applied these techniques to music (e.g., [26.69, 70, 88, 89]). More recent approaches include *Steedman* [26.5, 6] and *Rohrmeier* [26.60, 61]. Based on Steedman's categorical grammar formalism [26.90], *Granroth-Wilding* and *Steedman* [26.91] implemented a model of jazz harmony that extends Steedman's earlier theoretical gram-

mars for blues harmony [26.6]. Similarly, *De Haas* et al. developed an implementation of Rohrmeier's grammar for the purposes of music information retrieval, such as harmonic similarity and transcription [26.92–94]. *Tidhar* [26.95] implemented adapted versions of a context-free grammar formalism for the parsing of Couperin's unmeasured preludes.

Other approaches have attempted to combine context-free grammars with probabilistic learning. *Gilbert* and *Conklin* [26.96], for example, have employed a probabilistic context-free grammar for modeling melodic reduction. *Bod* [26.97] argues for a memory-based approach to modeling melodic grouping structure as an alternative to the Gestalt approach based on rules. He used grammar learning techniques to induce the annotated phrase structure of the Essen Folk Song Collection [26.98, 99]. Three grammar induction algorithms were examined: first, the treebank grammar learning technique, which reads all possible context-free rewrite rules from the training set and assigns each a probability proportional to its relative frequency in the training set; second, the Markov grammar technique, which assigns probabilities to context-free rules by decomposing the rule and its probability by an n-th-order Markov process, allowing the model to estimate the probability of rules that have not occurred in the training set; and third, a Markov grammar augmented with a data-oriented parsing (DOP) method for conditioning the probability of a rule over the rule occurring higher in the parse tree. A best-first parsing algorithm based on Viterbi optimization was used to generate the most probable parse for each melody in the test set given each of the three models. The results demonstrated that the treebank technique yielded moderately high precision but very low recall ($F = 0.065$), the Markov grammar yielded slightly lower precision but much higher recall ($F = 0.706$), while the Markov-DOP technique yielded the highest precision and recall ($F = 0.810$). A qualitative examination of the folk song data reveals a number of cases (15% of the phrase boundaries in the test set) where the annotated phrase boundary cannot be accounted for by Gestalt principles but that are predicted by the Markov-DOP parser.

26.1.6 Neural Networks

Neural networks represent a different class of models that have been used to understand the representation and processing of musical syntax. Rather than basing the model on a specific representation of musical structure (e.g., n-grams, production rules, music-theoretic principles), neural networks are biologically inspired in the sense that they take their motivation from basic properties of the brain (e.g., parallel processing across simple units, distributed representations, synaptic connectivity, graceful degradation and Hebbian learning). Note, however, that while they are *biologically inspired*, most neural network models (especially so-called connectionist models) are not actually *biologically plausible* models of neural processing. Thus they remain at *Marr*'s [26.100] algorithmic/representational level rather than at the implementational/physical level of description. At this level, one practical difficulty with neural networks as simulations of cognitive processing is that the nature of the learned representations are often not easily interpretable.

Mozer [26.101], for instance, developed a model based on a recurrent artificial neural network (RANN, [26.102]) and used psychoacoustic constraints in the representation of pitch and duration. In particular, the networks operated over predefined, theoretically motivated multidimensional spatial representations of pitch (which emphasized a number of pitch relations including pitch height, pitch chroma and fifth relatedness, [26.103]) and duration (emphasizing such relations as relative duration and tuplet class). These neural networks are trained within a supervised regime in which the discrepancy between the activation of the output units (the expected next event) and the desired activation (the actual next event) is used to adjust the network weights at each stage of training. When trained and tested on sets of simple artificial pitch sequences with a split-sample experimental paradigm, the RANN model outperformed simple digram models. In particular, the use of cognitively motivated multidimensional spatial representations led to significant benefits (over a local pitch representation) in the training of the networks. However, the results were less than satisfactory when the model was trained on a set of melodic lines from ten compositions by J.S. Bach and used to generate new melodies; the neural network architecture appeared unable to capture the higher-level structure in these longer pieces of music.

The question arises of whether these neural network models provide good simulations of human processing. In an artificial grammar learning paradigm of melodic structure [26.40, 104], a simple recurrent network model [26.102] was compared with an n-gram model [26.28] and a chunking model [26.105]. Results indicate that the n-gram model achieved by far the best performance, yet the simple recurrent network exhibited characteristic patterns of performance (including errors) that were closer to the human level [26.106, 107].

One approach to addressing the apparent inability of RANNs to represent recursive constituent structure in music involves what is called auto-association. An auto-associative network is simply one that is trained

to reproduce on its output layer a pattern presented to its input layer, generally forming a compressed representation of the input on its hidden layer. For example, training a network with eight-unit input and output layers separated by a three-unit hidden layer with the eight one-bit-in-eight patterns typically results in a three-bit binary code on the hidden units [26.108]. *Pollack* [26.109] introduced an extension of auto-association called recursive auto-associative memory (RAAM), which is capable of learning fixed-width representations for compositional tree structures through repeated compression. The RAAM architecture consists of two separate networks: first, an encoder network that constructs a fixed-dimensional code by recursively processing the nodes of a symbolic tree from the bottom up; and second, a decoder network that recursively decompresses this code into its component parts until it terminates in symbols, thus reconstructing the tree from the top down. The two networks are trained in tandem as a single auto-associator. *Large* et al. [26.110] examined the ability of RAAM to acquire reduced representations of Western children's melodies represented as tree structures according to music-theoretic predictions [26.57]. It was found that the trained models acquired compressed representations of the melodies in which structurally salient events are represented more efficiently (and reproduced more accurately) than other events. Furthermore, the trained network showed some ability to generalize beyond the training examples to variant and novel melodies although, in general, performance was affected by the depth of the tree structure used to represent the input melodies with greater degrees of hierarchical nesting leading to impaired reproduction of input melodies. However, the certainty with which the trained network reconstructed events correlated well with music-theoretic predictions of structural importance [26.57] and cognitive representations of structural importance as assessed by empirical data on the events retained by trained pianists across improvised variations on the melodies.

Recent developments in neural networks have led to successful modeling of musical structure using restricted Boltzmann machines (RBMs) [26.111, 112]. RBMs appear to be approaching the prediction performance of the best-performing variable-order Markov models described in Sect. 26.1.3 [26.112]. However, these neural network models are difficult to analyze and it remains to be seen how successful they will be in modeling cognitive processing of musical syntax. Nonetheless, they do at least demonstrate that such processing can be implemented using parallel distributed (and potentially nonsymbolic) representations.

26.2 Psychological Research

Computational models shed light on the plausibility of specific assumptions about, and constraints on, the nature of the cognitive representations and algorithms underlying music perception and serve as analytical tools to explore the types of syntactic structures present in music. However, to understand the kinds of syntactic structures that are perceived and represented by listeners, it is important to compare empirically the output of a model with the responses of listeners. Empirical research on musical listening can help identify the power, the limits and constraints of human perception and cognition of musical syntax. In this context, computational models are useful for generating hypotheses and selecting stimuli that differ quantitatively in terms of their syntactic properties (e.g., grammaticality, uniformity, see Chap. 25). Although there are notable differences between language and music (e.g., in terms of lexical categories and the nature of semantic content), cognitive scientific research on music follows an analogous approach, exploring processing via a combination of theoretical inquiry, computational modeling and psychological/neuroscientific testing [26.113]. Furthermore it has been suggested that music and language, which are both sequential auditory forms of human communication, may share similarities at more abstract levels of cognitive and neural representation [26.114–116], a point to which we return below.

Psychological research has established that enculturated listeners are sensitive to sequential structure in music; however, research paradigms have sometimes been driven by (overly) simple representational assumptions. We will examine the evidence relating to harmonic movement, melody and high-level form. One topic that continues to attract debate is the extent to which listeners are capable of representing hierarchical, nonsequential relationships in music. We examine research on this question below.

26.2.1 Perception of Local Dependencies

As discussed in Chap. 25, harmony constitutes one of the core building blocks in Western tonal music and it has been studied in the context of different theories of syntax. Accordingly, a large number of experimental studies have focused on the perception of harmonic structure from a variety of perspectives.

At a local level, listeners are able to detect harmonic relations between successive chords as evidenced by longer reaction times to in-key than out-of-key harmonic transitions in the paradigm of musical *priming* studies ([26.117, 118], see [26.119] for a review). These findings have been replicated with longer sequences of chords and more complex harmonic relations [26.120, 121]. Furthermore, there is evidence that these harmonic priming effects are affected both by the global context of the prevailing key (which determines the overall stability of a chord), by the local harmonic context and by the rhythmic organization of the progression [26.120]. Research has also examined whether these effects are best explained by learned properties of harmonic movement or by sensory properties of the target chords [26.121–123]. The results consistently show that the structural properties of harmonic movement have a stronger effect than sensory influences such as repetition priming [26.124, 125], even when efforts are made to make these sensory influences very strong. Furthermore, *Tillmann* et al. [26.126] used self-organizing maps (a variety of neural network) to argue that these priming effects can be explained by learning of tonal organization through musical exposure.

We can ask similar questions about the perception of structure in melody. Early work on predictive processing of musical structure focused on rules of melodic organization and how they influence pitch expectations [26.13, 80, 81]. Empirical studies of these rules have found that listeners' melodic expectations do generally exhibit influences of pitch proximity (smaller intervals are more expected) and pitch reversal (large pitch intervals are expected to be followed by smaller ones in the opposite registral direction) [26.53, 127]. Actual melodies also exhibit these properties [26.128], possibly reflecting physical constraints of performance – the difficulty of producing large intervals accurately and tessitura constraints producing regression to the mean after large intervals [26.129–131]. Therefore, it remains possible that listeners learn these regularities (or variants of them, subject to cognitive constraints, [26.53, 132]), which are then reflected in their pitch expectations.

In fact, there is empirical evidence of implicit learning of regularities in musical melody and other sequences of pitched events ([26.40, 54, 104, 133]; see [26.8] for a review on implicit learning of music). Consistent with an approach based on statistical learning, melodic pitch expectations vary between musical styles [26.134] and cultures [26.135–140], throughout development [26.141] and across degrees of musical training and familiarity [26.36, 37, 134]. Furthermore, pitch expectations appear to be informed both by long-term exposure to music [26.142] and by the encoding of regularities in the immediate context [26.133]. As with harmonic expectations, computational models relying on nonhierarchical statistical learning of regularities have proved highly successful in predicting listeners' melodic expectations [26.28, 37, 38].

All of these effects can be accounted for by local models corresponding to strictly local grammars. Therefore, it is crucial to ask which aspects of hierarchical and nonlocal structures affect music listening and processing.

26.2.2 Perception of Nonlocal Dependencies

There are several ways in which nonlocal dependencies can be expressed in music, ranging from short chord sequences (such as "I IV V/ii ii V I", in which the IV chord implies the V chord and not V/ii, and the second I chord prolongs the initial one, rendering the whole sequence a constituent of a prolonged tonic) to dependencies between (sub)phrases (e.g., antecedent-consequent patterns) and between larger formal units like the parts of a minuet or a sonata [26.143]. It may even be possible to understand these dependencies at different timescales (chords, parts of phrases, phrases, movements) as recursive instantiations of similar structures [26.57, 143].

Deutsch [26.144] describes experiments in which subjects were presented with sequences of 12 notes, which they recalled in musical notation. Half the sequences were structured in accordance with the model of *Deutsch* and *Feroe* [26.10], described above, such that a higher-level subsequence of four elements acted on a lower-level subsequence of three or four elements while the remaining sequences were unstructured. Sequences were presented in one of three conditions: first, with no temporal segmentation; second, temporally segmented in accordance with tonal structure; and third, temporally segmented in violation of tonal structure. The results demonstrated that recall was high in the first and second conditions and low in the third condition and for unstructured sequences, suggesting that hierarchically structured sequences are better encoded in memory. However, on a similar task, *Boltz* and *Jones* [26.145] have found that rule recursion has only a modest effect on memory for melodies and only in certain conditions.

Regarding large-scale form, researchers have studied the aesthetic judgments of musicians and nonmusicians for pieces of music in which the large-scale tonal form has been disrupted by rearranging or rewriting certain parts. These studies have been conducted by rearranging the various movements of Beethoven sonatas and string quartets [26.146], reordering the variations making up Bach's Goldberg variations [26.147],

altering the endings of excerpts from Romantic and Classical works (1–6 min) such that they start and end in a different key ([26.148]; methodologically criticized by *Gjerdingen* [26.149]) and using rearranged versions of the opening movement of Mozart's Symphony in G Minor [26.150]. The results consistently suggest that listeners gain as much pleasure from the altered versions as the unaltered versions and musicians are no more affected than nonmusicians by these disruptions [26.148, 150]. In a study of musicians listening to original and rearranged versions of six keyboard works by Handel [26.151] found that both versions were deemed equally conforming to stylistic expectations and accuracy in judging whether the starting and ending key were the same was at chance. These findings suggest that there are severe constraints on the ability to build cognitive representations of large-scale formal relationships in music, even for musicians (though none of these studies examined professional musicians with a very high level of expertise).

However, there is crucial evidence that listeners are sensitive to long-distance hierarchical dependencies at the phrase-level and midrange timescales. *Koelsch* et al. [26.152], examined responses to the final chord in a pair of chorale melodies composed of two subphrases, together with modified versions in which the first phrase was altered to break tonal closure with the final phrase. The results showed strong characteristic differences between the two versions in the neural response (the early right anterior negativity (ERAN), Sect. 26.3.2) to the final chord. In addition, behavioral measures showed that there were no differences in emotional response (valence and arousal) between the versions, suggesting that nonlocal harmonic dependencies are independent of emotional expression. Further behavioral measures showed that the final chord of the original version was judged to close the sequence better than the final chord of the altered versions (although the difference was relatively small, pointing towards the use of implicit rather than explicit knowledge). Fundamentally, because the harmonic dependencies in this study exceed ten chords, it is impossible that nonveridical *n*-gram or Markov models could explicitly represent the difference. Accordingly, this evidence for nonlocal dependencies affecting the perception of phrase closure falsifies the assumption that simple local models of harmony can adequately model human perception of musical syntax.

26.3 Neuroscientific Research

26.3.1 Introduction

It is pertinent to ask what cognitive neuroscience can tell us over and above research in experimental psychology and cognitive science [26.153–156]. Clearly, it can tell us something about the neural basis of psychological processes; less obviously, but perhaps more importantly, it can also tell us something about those psychological processes themselves. Once a neural response has been linked to a specific psychological process (and this itself may require great effort to establish), then we can use it as an additional measure of that process, alongside behavioral measures. Such neural responses have the potential advantages that they may be more sensitive and less prone to various kinds of bias than behavioral measures. Potential disadvantages include the difficulty of establishing direct, specific relationships between features of the neural response and particular psychological processes.

26.3.2 Neural Basis of Syntactic Processing in Music

Neuroscientific research has used electroencephalography (EEG) to investigate event-related-potential (ERP) responses to violations of harmonic syntax [26.157–164]. Two characteristic brain responses have been reported: an early anterior negativity (EAN) with a latency of 150–280 ms (sometimes right lateralized and referred to as the ERAN – early right anterior negativity), and a later bilateral or right-lateralized negativity (N5) with a latency of 500 ms [26.157, 161]. The EAN is thought to reflect the violation of harmonic expectation, while the N5 is thought to reflect the higher processing effort needed to integrate unexpected harmonies into the ongoing context [26.163]. The amplitude of the EAN is related to the long-term transition probability of the chord [26.165, 166] suggesting that it reflects implicit learning of harmonic movement through experience (see Sect. 26.1.3 above). Consistent with this proposal are findings that the EAN is attenuated (though still present) in five to six-year-old children compared to adults and accentuated in adult musicians, relative to adult nonmusicians [26.159].

To date, less is known about the neural correlates of structural processing in other aspects of music such as pitch, rhythm and timbre. Early studies [26.167–171] identified a late positive component (LPC) peaking between 300–600 ms at central and posterior sites in response to stylistically unexpected notes in a melody.

The amplitude and latency of the LPC are sensitive to musical expertise, the familiarity of the melody, the degree of expectancy violation [26.167], and also to the timing of the unexpected note [26.168].

There is an important distinction between schematic representations of the syntactic rules governing a musical style and veridical memory for the structure of a familiar piece of music [26.172]. *Miranda* and *Ullman* [26.173] describe a functional dissociation between two ERP components: an early (150–270 ms) anterior-central negativity (i. e., the EAN) associated with out-of-key violations in both familiar and unfamiliar melodies, and a subsequent (220–380 ms) posterior negativity elicited by both in-key and out-of-key violations of familiar melodies only. They suggested that these two components are driven by violations of musical rules (of tonality/harmony) and of veridical memory representations of familiar melodies respectively. In order to focus exclusively on schematic acquisition of syntax, *Loui* et al. [26.166] examined neural responses to deviant melodic endings in pitch sequences generated according to an artificial (strictly local) grammar, using pitches taken from the unfamiliar Bohlen–Pierce scale. They report an EAN, whose amplitude increased with greater learning of the grammar (measured by degree of exposure and performance in a grammaticality decision task). Again, this suggests that the EAN reflects a process of implicit statistical learning of sequential dependencies in the auditory environment (Sect. 26.1.3).

The EAN to violations of melodic syntax tends to occur earlier (around 100 ms) than to violations of harmonic syntax (circa 180 ms) [26.37, 38, 174], perhaps indicating that single notes are processed more quickly than chords. Using a computational model of auditory expectation [26.28], which makes probabilistic pitch predictions based on statistical learning, to identify notes in melodies that varied systematically in information content (IC), *Omigie* et al. [26.39] showed a linear relationship between the amplitude of the EAN and IC. *Pearce* et al. [26.37] reported an increase in the amplitude of beta oscillations for high information content (low probability) notes at a latency of around 500 ms in centroparietal regions and in phase locking in the same time window between electrodes located over centroparietal and occipital regions. Again these results are consistent with the proposal that these neural indicators of syntactic processing reflect probabilistic inference based on implicit statistical learning.

26.3.3 Syntax in Music and Language

EEG research has also addressed the question of whether there exists an overlap in neural processing of musical and linguistic syntax. Violations of syntax in language often generate two characteristic ERPs: a left anterior negativity (LAN) peaking around 300–450 ms at frontal scalp locations, and a positive-going deflection termed the P600 at a latency of about 600 ms with a posterior distribution. An early study suggested that violations of harmonic syntax generate an increased P600, which is very similar to that induced by violations of linguistic syntax [26.162]. More recent research has presented music synchronously with visually presented sentences where each word coincides temporally with a note or chord in the music. Introducing syntactic violations in the music and language allows the investigation of conditions where the violations are congruent or incongruent in the two domains. This research suggests that the LAN to syntactic violations in language is reduced by unusual harmonic movement (e.g., a Neapolitan chord, [26.175]) and also by low-probability notes in melodic phrases [26.176]. There is also evidence that the ERAN is reduced when presented concurrently with a linguistic violation [26.177]. Interestingly, these interactive effects are not in evidence when musical violations are paired with semantic incongruities in language [26.176, 177].

Analogies have been drawn between the ERAN and the early left anterior negativity (ELAN) often observed in response to violations of syntax in language [26.178]. Interestingly, children with specific language impairment not only show characteristic changes in the ELAN to language [26.179] but also a reduced ERAN to harmonic violations [26.180]. Broca's aphasics also show reduced neural responses to harmonic violations in music [26.181] and there is evidence from magnetoencephalography (MEG) research that the ERAN to violations of harmonic syntax originates in Broca's area and its right hemisphere homologue [26.182]. Furthermore, functional magnetic resonance imaging (fMRI) studies [26.183–186] suggest that violations of harmonic syntax induce activation in the inferior frontal cortex, which is also suggestive of a relationship between the neural processing of syntax in music and language [26.114].

26.3.4 Grouping Structure

One other aspect of musical structure that has been studied from the perspective of cognitive neuroscience is grouping structure. Using EEG and MEG, *Knösche* et al. [26.187] found that phrase boundaries in melodies generated a late (500–600 ms for EEG, 400–700 ms for MEG) positive deflection, which they termed the *closure positive shift (CPS)*. Source localization suggested that the CPS was generated by structures in the limbic system, including anterior/posterior cingulate and pos-

terior mediotemporal cortex. Similar neural responses have been observed at syntactic phrase boundaries in language [26.188], which seem to be related to prosodic cues [26.189, 190]. A subsequent study showed that the CPS to musical phrase boundaries is stronger in musicians than in nonmusicians [26.191], suggesting that strategies for segmenting music are influenced by musical training.

26.4 Implications and Issues

We have reviewed empirical research on musical syntax from computational, psychological and neuroscientific perspectives. We close with a discussion of two issues that naturally arise during this discussion: first, the extent to which the different perspectives on musical syntax converge; and second, the relationship between syntax and semantics in music, which naturally invokes the question of affective responses to music.

26.4.1 Convergence Between Approaches

One of the key challenges facing future research is to integrate insights from these different methodological and epistemological approaches. Computational modeling allows us to implement theories of musical structure and syntax and examine the behavior of the implemented algorithm when supplied with musical examples. This can provide insights into optimal syntactic representations and absolute constraints on the syntactic structure of a musical style [26.192]. Psychological research, on the other hand, can indicate the kinds of syntactic forms and relationships that listeners are capable of perceiving, representing and learning. Implementing a psychological theory as a computational model requires the theory to be precisely expressed and also allows the theory to be tested and refined through quantitative comparison of human and model responses. It also allows comparison of human performance at different levels of experience and expertise with optimal syntactic parsing. Finally, neuroscientific research provides information about the neural basis of syntactic processing, which can impose constraints on human syntactic processing and also provide data that is more sensitive to implicit knowledge than behavioral methods (e.g., [26.193, 194]. Therefore, future research should triangulate more explicitly between computational modeling, psychological experimentation and cognitive-neuroscientific investigation in further developing our understanding of musical syntax [26.37, 195].

26.4.2 Syntax, Semantics and Emotion

Musical styles can be said to possess syntax in an analogous way to that in which natural languages (or programming languages) do. However, music is different from natural language in that musical elements do not usually carry clear referential and propositional semantics in the way that linguistic atoms do. It is sometimes possible to establish indexical references for appropriately enculturated listeners – the old castle, the sea, a storm, the spring, love, James Bond's theme or Brunhilde's leitmotif being good examples taken from various pieces of music. However, it is impossible to communicate complex statements like *had he not gone to sea last spring and then returned to the old castle, James Bond would not have fallen in love with Brunhilde* (see [26.113, 196, 197] for further discussion). Therefore, meaning in musical communication is borne to a large extent by syntactic structure and the listener's perception of structural relations between musical elements [26.198]. In particular, the syntactic structure of music affords the communication of patterns of tension and resolution, through the systematic manipulation of the listener's structural expectations, based in turn on their internalized syntactic representations of the style.

There is one prominent theoretical perspective on affective responses to music that is relevant here since it relates the expression and perception of meaning to predictive processing of musical structure, using information-theoretic principles [26.53]. Building on arguments made by *Hanslick* [26.199], *Meyer* [26.198, 200] examines from a theoretical perspective the dynamic cognitive processes in operation when we listen to music and how these processes not only underlie the listener's understanding of musical structure but also give rise to the communication of affect and the perception of meaning in music. Meyer proposes that meaning arises through the manner in which musical structures activate, inhibit and resolve expectations in the listener about forthcoming musical structures. He notes that these expectations may differ independently in terms of the degree to which they are passive or active, their strength and their specificity. He contends, in particular, that affect is aroused when a passive expectation induced by antecedent musical structures is made active by it being temporarily inhibited or permanently blocked by consequent musical structures. Meyer discusses three ways in which the listener's expectations may be violated. The first occurs when the

expected consequent event is delayed, the second when the antecedent context generates ambiguous expectations about consequent events, and the third when the consequent is unexpected. While the particular effect of music is clearly dependent on the strength of the expectation, Meyer argues that it is also conditioned by the specificity of the expectation.

Meyer [26.200] discusses the relationship between his theory of musical expectancy and concepts in information theory. He starts with the suggestion that [26.200, p. 414]:

> *once a musical style has become part of the habit responses of composers, performers and practiced listeners it may be regarded as a complex system of probabilities*

and that expectations arise out of these internalized probability systems. In particular, he suggests that a musical style may be conceived as a Markov process (Sect. 26.1.3) and that experienced listeners possess internalized models of that process. The degree to which hypothetical meanings provide ambiguous expectations about consequent structures can be measured by entropy (or uncertainty) [26.200, p. 416]:

> *The lower the probability of a particular consequent* [...] *the greater the uncertainty (and information) involved in the antecedent-consequent relation.*

An unexpected consequent conveys a maximum of information. The process of revaluation corresponds to the feedback of information such that future behavior is conditioned by the results of past events.

Meyer notes that uncertainty may arise from different sources. Thus, systemic uncertainty decreases throughout the experience of a piece of music as the listener's model develops and the composer may deliberately introduce designed uncertainty to combat this effect. Furthermore, the redundancy (lack of uncertainty) inherent in a style serves to combat noise, be it cultural (resulting from discrepancies between the habit responses of a given listener and those operating in the style) or acoustical. *Witten* et al. [26.201, p.71] make a similar distinction between perceptual uncertainty (that which is relative to a particular listener's model) and stylistic uncertainty (that which is inherent in the musical style).

As noted above, the most obvious emotional response to expectancy violation and uncertainty in music is tension but according to *Meyer* [26.198], these processes may also give rise to a range of specific emotional experiences including apprehension/anxiety (p.27), hope (p.29), and disappointment (p.182) (see also [26.202]). Convergingly, empirical research has found that stylistically unusual chord progressions do stimulate increases in physiological arousal [26.177] while notes that have a low probability of occurrence in performed melodic music [26.28] have been found to be associated with increased arousal, reduced valence, increased skin conductance and reduction in heart rate [26.35].

27. Rhythm and Beat Perception

Tram Nguyen, Aaron Gibbings, Jessica Grahn

From established musicians to musical novices, humans perceive temporal patterns in music and respond to them. There is much that we still do not understand, however, about how the temporal patterns of music are processed in the brain. Understanding the neural mechanisms that underlie processing of temporal sequences will help us learn why humans perceive the temporal regularities, or periodicities, in musical rhythms. Therefore, in this chapter, we discuss the latest findings in beat perception research, touching on both behavioral and neuroimaging findings from studies that have used electroencephalography (EEG), magnetoencephalography (MEG), functional magnetic resonance imaging (fMRI), and transcranial magnetic stimulation (TMS). Overall, the findings establish the importance of both auditory and motor brain areas in rhythm and beat processing. The authors also discuss the implications of beat perception research and highlight the challenges currently facing the field.

27.1 Temporal Regularity and Beat Perception

Picture yourself at a concert listening to your favorite band. The music is booming over the speakers and it engulfs the entire room. Take a look around you. From the established musicians on stage to the musical novices in the crowd, people are bobbing their heads, tapping their feet, clapping their hands, or swaying their bodies along to the music. It is evident from this picture that all humans, to some extent, have the ability to perceive the temporal patterns in music and respond to them. Although music seems to universally and automatically affect humans, there is still much that we do not know about how the temporal patterns of music are processed in the brain. Understanding the mechanisms in the brain that underlie time-keeping will help us learn why humans perceive the temporal regularities, or periodicities, in musical rhythms. The ability to perceive these temporal periodicities has been termed *beat perception* or *beat-based timing* [27.1–3]. Research on beat perception has been tackled with a variety of methodologies in both humans and animals, including behavioral work and brain imaging techniques such as electroencephalography (EEG), magnetoencephalography (MEG), functional magnetic resonance imaging (fMRI), and transcranial magnetic stimulation (TMS). In this chapter, we will consider the latest findings in beat perception research, touching on both behavioral and neuroimaging findings. We will also discuss the implications of this research and highlight the challenges facing the field today.

Understanding the structure of temporal patterns in our environment is crucial for many aspects of perceptual, cognitive, and motor function. For example, humans rely on accurate temporal perception and production for normal hearing, speech, motor control, and music [27.4, 5]. In fact, the ability to perceive temporal patterns in our environment is evident even

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_27

in infancy [27.6–8]. Some characteristics of temporal pattern perception appear to be unique to humans, including our receptiveness to musical rhythm and more specifically, our ability to perceive the beat [27.9, 10]. As many of the words associated with rhythm and beat have different meanings in different fields, we will define how they are used in this chapter. A musical *rhythm* is a pattern of temporal intervals in a stimulus sequence (Fig. 27.1). The rhythmic pattern is indicated by the onsets of a stimulus, usually a tone, a click, or some other sound. The length of the temporal intervals in the sequence is defined by the time between onsets, termed interonset intervals. Listening to a musical rhythm often gives rise to a sense of *pulse*, or sometimes referred to as a *beat*. The beat is a series of regularly recurring, salient psychological events [27.1, 11]. The beat is a psychological event because it is not stimulus driven, even though it usually arises in response to a rhythmic stimulus [27.12–15]. The psychological internalizing of the beat is why we can sense it even when music is rhythmically complex or has notes occurring off the beat.

Individual beats are frequently perceived to possess different degrees of accents, or stress, which gives rise to meter. *Meter* (or metrical hierarchy) is the grouping or temporal organization of beats, in which some beats are perceived as more salient than others [27.13, 16]. For example, in a march rhythm, every other beat is accented (**1** 2 **1** 2), whereas in a waltz it is the first of every three beats (**1** 2 3 **1** 2 3). These patterns therefore differ in their perceived meter: the 1's are *strong* beats and the others are *weak* beats. Depending on the metrical structure, feeling the beat is harder in some musical rhythms than others [27.17, 18]. Different researchers also define structural complexity differently, but one common definition involves the presence of simple integer ratios between intervals in a sequence [27.19, 20]. For example, a sequence containing intervals of 250, 500, 750, and 1000 ms has a 1 : 2 : 3 : 4 simple integer ratio relationship between its intervals. Simple integer ratios are not the only factor used to defined complexity. Another factor is whether there is an onset of a tone occurring at regularly spaced intervals, generally between 300–900 ms [27.21]. Using these two factors, researchers have created rhythms of different complexity [27.22, 23]. For example, *metric simple* rhythms have intervals that are related by simple integer ratios. However, integer ratios alone are not sufficient to induce a beat. Regular occurring *perceptual accents* or cues may also be necessary [27.24]. Therefore, the intervals are also arranged so that an interval onset occurs every four units (e.g., **4 3** 1 **1** 1 2), creating a perceptual accent that induces perception of a regular beat at those times [27.25]. For *metric complex* rhythms, the intervals are arranged so that they are not reliably grouped into having an onset every four units (e.g., 2 1 3 2 1 4 1). Therefore, metric simple rhythms induce a stronger percept of a beat than metric complex rhythms [27.22]. In music, the beat is often emphasized by nontemporal accents or cues such as pitch, timbre, or loudness [27.26–28]. For example, changes in loudness (or intensity) cause louder notes to be perceived as more prominent. Perceiving the beat through changes of loudness requires very little effort. In fact, the beat can be perceived even if one is barely attending to it. However, even rhythmic patterns without changes in nontemporal accents, can induce listeners to feel the beat. In this case, any perceptual accents that occur are due to the temporal accents rather than the nontemporal accents [27.29].

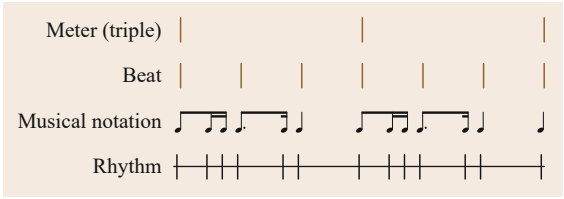

Fig. 27.1 Illustration of a musical rhythm and its associated metrical hierarchy. Rhythm (*bottom*) shows the waveform of a rhythmic sequence. The *vertical lines* show where notes occur and the *horizontal line* indicates time between note onsets. Musical notation (*second from the bottom*) of the same rhythmic pattern is shown. Beat locations (*third from the bottom*) in the rhythm are shown. Sounds under the *light brown beat lines* are perceptually accented and are perceived as louder, or more salient, than the other sounds. Meter (*top*) shows a metrical organization of the beats in the rhythm. Beats under the *light brown metrical lines* are perceived as more salient than other beats

27.2 Behavioral Investigations

Beat perception in humans can be studied using *sensorimotor synchronization* (SMS), a technique where a movement (motor), such as the tap of a foot, is temporally synchronized with a predictable external event (sensory), such as a beat [27.30]. Humans have the unique ability to move in (and out of) phase with a beat using different body parts and it is this coupling of the sensory and motor systems that has made SMS a popular technique to study beat perception [27.31]. Although SMS is a skill that is refined in many musicians, even

musical novices are able to move in synchrony with the beat [27.32], yet another reason why SMS is a practical technique. Beat-finding studies using SMS often focus on synchronizing finger tapping to auditory sequences that consist of tones or clicks. In many beat perception studies, synchronization is less accurate when the beat is more difficult to perceive [27.31]. For example, synchronizing to rhythms with a structured timing pattern is easier than synchronizing to rhythms with an unstructured timing pattern [27.33], suggesting that metrical structure influences the precise timing of an individual's movement [27.2]. Likewise, rhythms with complex interval ratios are more difficult to synchronize to than rhythms with simple interval ratios [27.34]. Metrical levels, which are regular time points at integer multiples or fractions of the basic (or referent) beat level, can also influence an individual's ability to synchronize with the beat [27.26]. For example, although synchronization is better with musical pieces that are temporally regular compared to musical pieces that are temporally less regular and thus more expressive, tapping to expressive pieces occurred at a higher metrical level than the less regular pieces. Therefore, the timing variation in expressive music reduces synchronization accuracy, but seems to aid the recovery of the music's metrical structure [27.35].

Synchronizing to auditory sequences of tones or clicks differs from synchronizing to music. Unlike the auditory sequences created in the laboratory, music is usually more variable and contains information about tempo, harmony, pitch, etc. There is evidence that melodic, harmonic, and pitch structure influence beat perception [27.36–38]. For example, synchronizing to expressively timed music is easier than synchronizing to metronomic sequences with the same timing pattern [27.33]. However, one study found that removing melodic and harmonic information had little effect on pianists' ability to find the beat in ragtime music [27.39]. However, when participants heard only the right-hand part, not the left-hand part, tapping the beat was more variable and less accurate. The authors found the following factors were important for accurate tapping to the beat: a predictable alternating pattern in the left-hand part and a majority of notes on metrically strong positions (on the beat) in both the right-hand and left-hand parts. Thus, metrical structure has a strong influence on beat perception. Rhythms with strong metrical structures often correspond with high temporal expectations. Therefore, synchronization accuracy is high [27.40, 41].

For the most part, beat perception is believed to be universal in humans. However, there are factors that give rise to large individual differences. Musical training or experience is one such factor. Many laboratory studies of SMS have shown that musical experts are better at synchronizing to the beat (producing smaller asynchronies between taps, smaller variability and tapped to a wider range of metrical levels) than musical novices [27.32, 35, 42]. Performance on other rhythm tasks is also improved by musical training [27.43, 44]. For example, musically trained individuals are better at detecting changes in rhythms than musically untrained individuals [27.35, 45, 46], regardless of whether the rhythms are metrically simple or complex [27.35]. This improvement may be because formal lessons emphasize explicit learning of many complex rhythmic structures, allowing musicians to better parse both metrically simple and complex rhythms [27.43]. Another possibility, however, is that musical training enhances sensitivity to underlying temporal structures that make the beat more salient.

SMS has allowed researchers to examine many aspects of beat-finding behavior within a single task. These aspects include, but are not limited to, the variability of tapping and the deviations of taps from the beat [27.30]. Another advantage of the technique is that it provides researchers with the opportunity to study the interaction between the perceptual systems and the motor systems. However, this advantage is also a drawback for many studies using SMS because it can be challenging to separate the perceptual processes from the motor processes [27.47]. Thus, it is still unclear what cognitive principles govern how humans perceive the beat and what mechanisms might underlie these principles. The use of brain imaging techniques attempts to resolve some of these questions.

27.3 Electrophysiological Investigations

Electroencephalography (EEG) or magnetoencephalography (MEG) are examples of nonbehavioral techniques used to study beat perception. An advantage of electrophysiological techniques is that they can provide temporal resolution at the millisecond level [27.48, 49]. Electrophysiological methods work because communicating neurons send and receive signals through the movement of either positive or negative ions (depending on whether the signal is excitatory or inhibitory). The movement of ions creates a current flow, which results in an electrical potential (i. e., an unequal distribution of electrical charges). Individually, these po-

tentials are too small to be detected, but when numbers of neurons in the outer cortical layers all function in synchrony there is a summative effect of individual electrical potentials that gives rise to the signal detected by surface EEG readings at the scalp.

27.3.1 Electroencephalography

A common use of EEG is to record the brain responses to particular events (e.g., on-beat and off-beat notes in a rhythm) and compare them to look for differences. The brain response is recorded as a waveform that shows the changes in strength of electrical potentials over time (Fig. 27.2). Responses that are triggered by a specific event are called event-related potentials (ERPs). To obtain ERPs, waveforms from each electrode are averaged over many presentations of the same stimulus. Many presentations are required to overcome the large amount of electrical activity in the brain that is unrelated to the task of interest. The electrical *interference* from this superfluous activity is also captured in the EEG signal as noise, but the noise is averaged out when the large number of presentations is combined (Fig. 27.3). This time-locked, averaged response is called an *evoked response* because it is the average response evoked by a stimulus.

One question in regard to beat perception has been whether the perception of metrical structure requires attention, or is perceived even without attention. Two EEG studies have been successful in using evoked responses to test for distinguishable neural components (positive or negative *peaks* in the waveform of the evoked response) related to rhythm and meter processing. In the first, *Geiser* et al. [27.50] measured changes in ERP responses to alterations of metrical organization (shifting the metric structure from 3/4 to 5/8 or 7/8 by adding or omitting an 8th note in a repeating rhythm) and rhythmic patterns (replacing one long note with two faster ones). Participants either attended to the rhythm and meter directly (pressing a key when rhythmic/metrical changes were detected) or attended and responded to unrelated pitch changes. In line with previous work, other researchers found that changes to the rhythm elicited a negative ERP component between 100 and 150 ms after the perturbation, regardless of attention [27.51, 52]. Perturbations to the metric structure, however, only elicited a negative ERP when attended. The fact that negative ERPs were observed for rhythmic violations regardless of attention, but to metrical violations only when attended, suggests that processing of meter is a more complex, attention-demanding process than processing of rhythm. One caveat, however, is that the metrical violations used in these studies were more difficult to detect than the rhythmic violations. Therefore, the lack of negative deflection to meter changes in the pitch-detection condition may indicate that these particular metric violations were difficult and required attention to detect, rather than *all* metric encoding requiring attention.

On the contrary to previous findings attention may not be necessary to encode metrical structure [27.53]. Participants heard repeating rhythms, but rather than changing the rhythms by adding or subtracting notes similar to the manipulation in the *Geiser* et al. [27.50] study, certain notes in the rhythm were omitted entirely and there was silence where the note should have been. The omissions occurred on notes that were either metrically strong (e.g., downbeats), or metrically weak. The beauty of comparing omissions on strong and weak metric positions is that both omissions are acoustically identical (silence is silence), but if participants had a metrical representation of the rhythm then omission of metrically strong notes should produce a greater response than omissions of metrically weak notes. To manipulate attention, participants were asked to either monitor the rhythm and indicate when an omission occurred, or to monitor a stream of white noise presented at the same time as the rhythm and indicate when the noise intensity changed. Metrically strong omissions elicited a larger brain response compared to metrically weak omissions, as measured by an ERP component called the mismatch negativity (MMN). The MMN was also larger for strong omissions in the white noise condition, when participants were not attending to the rhythm but rather to the white noise stream, suggesting that, encoding of metrical structure does not require attention.

27.3.2 Magnetoencephalography

Another method for investigating the neural components of beat perception is to use MEG rather than EEG. Both EEG and MEG measure signals from the movement of ions into and out of neurons, but they do so in different ways. Rather than detecting the electrical changes like EEG, MEG detects the changes in magnetic fields [27.54] caused by the current flow of the ions. The magnetic fields produced by even thousands of synchronously firing neurons are very small, so an array of hypersensitive sensors is required to detect the changes (Fig. 27.4). MEG measures the average magnetic field strength at each sensor positioned around the head, over time. Similar to event-related potentials in EEG, average stimulus-locked waveforms can be generated from the MEG output. These waveforms, called event-related fields (ERFs), can be analyzed and interpreted much the same as ERPs. ERF components that are equivalent to ERP components are even named accordingly, with ERF components given an “m” suffix

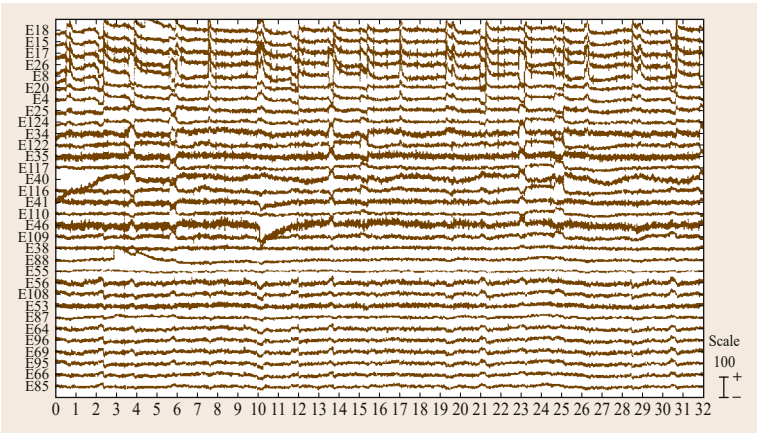

Fig. 27.2 Sample of electroencephalography (EEG) waveforms. Each line, called a trace, shows the changes in scalp-recorded electrical activity at a particular electrode (*y*-axis) recorded over time (*x*-axis)

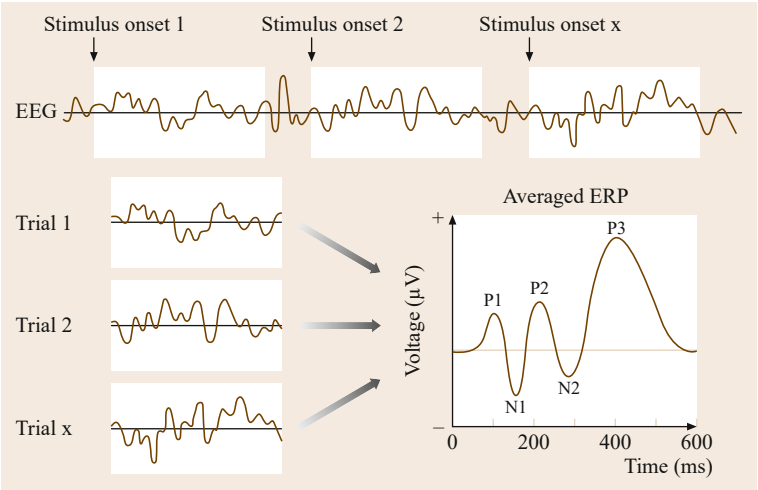

Fig. 27.3 Simplified illustration of averaging electroencephalography (EEG) signal over many presentations to reduce noise in the signal. (*top*) An example of an EEG trace over time from a single electrode, with stimulus onsets and trial epochs marked by the *white boxes*. The data outside the *white boxes* are removed leaving only data collected during the trial epoch (time-locked to the stimulus onset) in the analysis. (*bottom*) Trial epochs are then averaged together to remove noise, leaving a smoothed event-related potential (ERP)

to differentiate that they are magnetic field peaks in MEG (e.g., a mismatch negativity (MMN) is called an MMNm when recorded with MEG).

A recent study used MEG to study changes in ERF responses to increasingly salient violations of rhythmic expectancy [27.55]. One of the key consequences of listening to rhythm is the setting up of expectancy. We make predictions about how the rhythm will continue based on what we have already heard and we expect the events occurring *on-beat* (e.g., the *downbeat*) to be more salient than events occurring *off-beat*. *Vuust* et al. [27.55] had participants listen to repeating rhythms in which there were occasional violations of rhythmic expectancy. In line with the researchers' predictions, when the rhythmic violations occurred, two neural components were observed in the ERFs: an MMNm, associated with expectancy violation detection and a P3am, associated with the internal evaluation of the rhythmic sequence. The components were strongest for the condition with the largest violation of expectancy. Moreover, consistent with behavioral [27.15, 56] and ERP work [27.57, 58], musicians showed a greater sensitivity than nonmusicians to violations, with larger, earlier MMNm peaks. The authors suggest that musicians have a better internal representation of the metrical structure, which allows them to make more precise predictions about the incoming stimuli. Therefore, even small violations elicit stronger, more rapid responses when those precise predictions are violated.

27.3.3 Oscillatory Activity and Auditory Steady-State Response

When perceiving a beat, we form an expectation about when the beat will occur. ERPs and ERFs have proven useful in detecting violations of beat expectations, but one does not have to use violations to measure expectancy based on beat perception. Another method is to study the oscillations of populations of neurons in response to rhythmic stimuli. Oscillatory activity in pop-

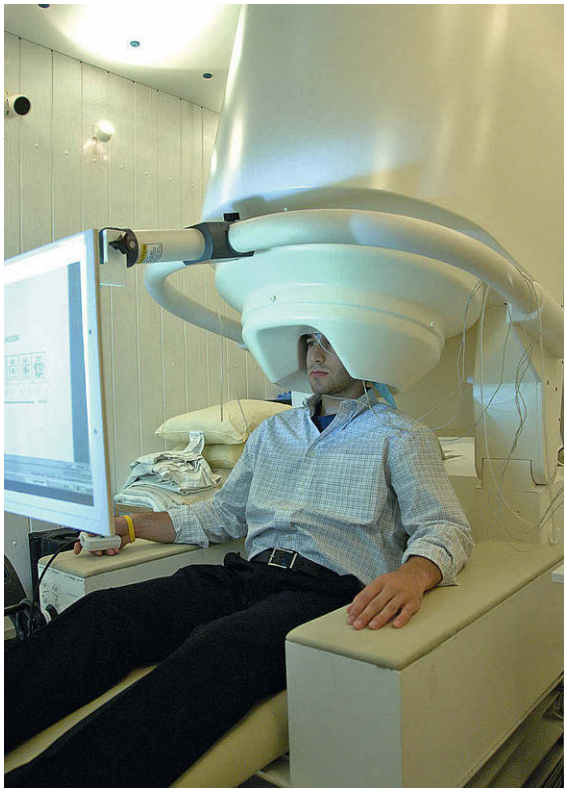

Fig. 27.4 A magnetoencephalography (MEG) machine. Participants sit comfortably in the chair while the large array of sensors, housed in the large white cylinder on the top of the machine, are lowered onto their head. The sensors detect very small changes in magnetic fields caused by neural firing (Photo: National Institute of Mental Health, National Institutes of Health, Department of Health and Human Service)

ulations of neurons arises from feedback connections between the neurons that lead to the synchronization of their firing patterns. Neural oscillations can occur at different rates, or frequency bands: one well-known example is the alpha band ($\approx 8-12$ Hz), associated with relaxation. Neural oscillatory responses form the basis of an emerging theory of beat perception called resonance theory [27.11, 59, 60]. The basic idea of resonance theory is that subpopulations of neurons entrain to (or fire in synchrony with) an incoming auditory stimulus, for example, a rhythm. As more neurons fire in synchrony with the rhythm, the notes of the rhythm that occur at the times of peak firing may be perceived as more salient and are processed more accurately. The increased neural firing that is in synchrony with the incoming stimuli could explain how feelings of pulse and meter arise, which is something that other theories struggle to explain [27.61].

Investigations of oscillatory processes related to rhythm and timing have found changes in both the gamma (> 30 Hz) and beta ($13-30$ Hz) frequency bands. Gamma band oscillations have been associated with anticipation [27.62] and attention [27.63]. Oscillations in the beta band have been strongly associated with motor tasks and have been observed in the sensory and motor cortices [27.64]. In studies of rhythm, beta and gamma band activity have been linked to the anticipation of tones [27.65, 66].

A study by *Snyder* and *Large* [27.66] measured gamma band oscillatory brain responses to examine rhythmic expectancy and metric encoding when listening to an isochronous tone sequence. The researchers accented (made louder) every other tone in the sequence to induce perception of a duple meter (**1** 2 **1** 2, etc.). The researchers found a greater evoked neural oscillatory response for strong beat (accented) tones compared to weak beat tones. This finding was consistent with findings in ERP studies [27.50, 53]. Moreover, in line with neural resonance theories of timing, they found increases in induced oscillatory activity when the omitted strong beat tone *should* have occurred. The higher induced gamma activity (even in the absence of a tone) was interpreted as evidence of the participant's expectancy of a strong beat. Thus, their meter perception could be measured by the neural oscillations. As metrical perception and attentional processes are both linked to gamma band activity, the findings may support the hypothesis that detection of metrical violations [27.50] requires attention.

Extending the findings of *Snyder* and *Large* [27.66], *Iversen* et al. [27.65] used MEG to examine oscillatory neural responses evoked by a repeating rhythmic pattern consisting of two tones followed by a rest. Listeners were instructed to impose different metrical interpretations on the rhythm by placing mental accents on either the first or second tone. The early evoked response, specifically in the upper beta range (20–30 Hz), was stronger for the beat that was mentally accented. A second experiment established that the beta band increase was very similar to the increase seen when tones were physically (rather than mentally) accented by being made louder. Increased beta band activity (which is typically linked to motor control/movement) may parallel fMRI findings that activation in motor networks correlates with metrical interpretation of rhythm, even in the absence of movement [27.22, 67], although strong conclusions cannot be drawn because the relationship between neural synchrony and fMRI activation is only beginning to be investigated [27.68, 69].

In addition to increases in beta and gamma band oscillatory activity, recent studies have found increases in

a lower frequency band called the delta band (< 4 Hz). Delta band activity is generated by populations of neurons firing at the same rate as (i. e., resonating with) a periodic stimulus [27.70, 71], in this case: the beat of a rhythm. This low-frequency resonance can be captured with EEG by measuring steady-state-evoked potentials (SSEPs). A pair of studies by *Nozaradan* et al. [27.70, 71] has found that the SSEP response is larger at the frequency of the beat rate when participants listen to rhythm, suggesting a greater number of neurons are firing at the time the beat occurs. In the first study, participants were asked to mentally accent either every other (**1** 2 **1** 2, binary meter), or every third (**1** 2 3 **1** 2 3, ternary meter) tone in an isochronous tone sequence. The researchers found that the SSEP was larger at the frequency of the imagined-to-be-accented tones for each condition (Fig. 27.5). These findings indicate two things: that participants can impose a perceptual metric interpretation on isochronous tone sequences and that entrained neural responses occur at the rate of the imposed interpretation. A second study extended these findings with short, repeating, syncopated rhythms instead of isochronous tones. The rhythms induced the perception of a regular beat but didn't necessarily have a note occurring on every beat. The participants still *felt* a beat, even when the beat occurred when no note was being played. Therefore, if an enhancement of the SSEP response was seen at the beat rate, the researchers could conclude that this enhancement was, at least in part, driven by perception of a beat, rather than being only driven by the notes in the rhythmic stimulus. This is indeed what the researchers found. Taken together, the findings of these different studies provide compelling evidence that enhancements of neural synchrony measured in the delta, beta, and gamma bands could be neural markers of our perception of pulse and meter.

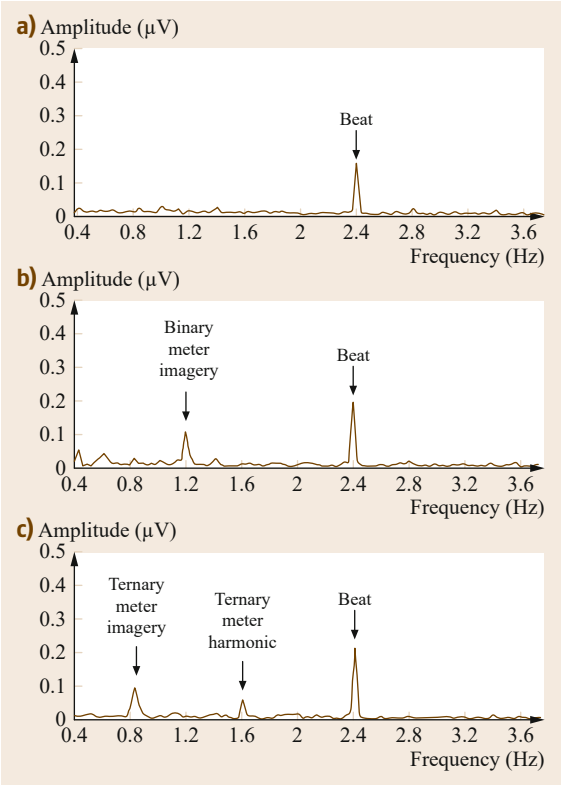

Fig. 27.5a–c Perceived meter is evident in neural response. In the control condition **(a)**, participants heard a stimulus with an evident 2.4 Hz beat. In the binary meter imagery condition **(b)**, participants heard the same stimulus as the control condition, but imagined an accent on every second beat. The *peak* at 1.2 Hz in the binary meter condition reflects the perceived beat rate (half as fast as the control). In the ternary meter imagery condition **(c)**, participants heard the same stimulus, but imagined an accent on every third beat. The *peak* at 0.8 Hz (and its harmonic at 1.6 Hz) reflects the perceived ternary meter (a third as fast as the control). As the stimulus was always the same, the different EEG responses between conditions reflect changes in the imagined beat rate

27.3.4 Limitations of Electrophysiological Methods

Although EEG and MEG are very useful techniques for investigating the neural response to beat and rhythm, these methodologies are not without their limitations. For example, it is difficult with EEG to tell *where* in the brain the activity is occurring. The skull, membranes covering the brain, cerebrospinal fluid, and even other neurons can *blur* the signal, obscuring the true intracranial source of the signal. The simplest model of activity is that the signal is coming from a single source, called a *dipole*. The goal of *source localization* is to determine, for each point in time, where in the head the dipole is, what its orientation is, and how strong it is (the dipole moment). The difficulty in determining these things is that an infinite number of combinations of intracranial sources could give rise to a particular signal distribution on the scalp; this is what's known as the *inverse problem* [27.72]. In essence, trying to determine the source of an EEG signal based on its distribution on the scalp is akin to trying to reconstruct an unknown object (or set of objects) using its shadow as your only reference. To narrow down the number of possibilities it is necessary to use complicated modeling algorithms and information from other neuroimaging techniques (e.g., PET or fMRI) about possible activation centers (or *seeds*) for dipole locations [27.73, 74].

MEG is slightly better for source localization because magnetic fields are not distorted as much by bone and tissue. However, magnetic fields decay more quickly as a function of distance than electric fields so they can only be recorded from the surface of the cortex. This means that MEG signals have even less contribution from deeper sources than EEG signals [27.49]. To see deeper into the brain and to obtain better spatial resolution, we need to use alternative neuroimaging techniques.

27.4 Hemodynamic (fMRI/PET) Investigations

Techniques such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) are better at indicating where in the brain the activity is occurring. The hemodynamic approach offers fMRI superior spatial resolution that cannot be accomplished with EEG or MEG. The approach relies on the principles of neurovascular coupling. Simply put, when a brain region is more active, it consumes oxygen, thus requiring increased blood flow to the region to replenish the depleted oxygen. The increase in oxygenated blood leads to a magnetic signal variation, known as the blood-oxygen-level-dependent (BOLD) response, which can be detected using an MRI scanner [27.75–77] (Fig. 27.6). Therefore, fMRI works by detecting changes in blood oxygenation related to increased regional blood flow [27.78]. The change is detectable around 2–3 s after the start of neuronal activity. In comparison to electrophysiological methods (EEG and MEG), hemodynamic methods (fMRI and PET) have poorer temporal resolution, but the trade-off is better spatial resolutions.

Fig. 27.6 A functional magnetic resonance imaging (fMRI) machine. Participants lie on the bed, which is moved until their head is in strong magnetic field in the bore, the small hole in the middle of the round structure. The coil (small round cage-like structure on the bed, close to the magnet) is used to detect changes in the blood-oxygen-level-dependent (BOLD) signal, which denotes brain activity (Photo: Siemens 3-Tesla Prisma MRI scanner with 64-channel head coil, housed at the Centre for Functional and Metabolic Mapping at The University of Western Ontario, London, Ontario, Canada)

Several studies have used fMRI to investigate how the brain responds during beat perception and rhythm perception and production. These studies generally show activation in several brain areas traditionally associated with movement: the premotor cortex (PMC), the supplementary motor area (SMA), the cerebellum, and the basal ganglia [27.22, 79–82] (Fig. 27.7). These motor areas are active during rhythm listening even when no movement is involved, suggesting that the brain areas associated with the control of movement are involved in the perception of rhythms [27.22]. To isolate the brain areas that respond specifically to the beat, the neural activity to beat-based rhythms (e.g., metric simple rhythms, or other rhythms that induce beat perception) and nonbeat-based rhythms (e.g., metric complex rhythms, or rhythms that do not induce beat perception) are compared. The basal ganglia, the SMA, and the superior temporal gyri (STG) generally respond more to beat-based than nonbeat-based rhythms, whereas other motor areas (the PMC and the cerebellum) respond similarly to both rhythm types [27.22, 67, 83]. Similar findings are shown for simpler regular (isochronous) and irregular auditory sequences. Regular tone sequences generate greater basal ganglia activity than irregular tone sequences [27.84].

Activity in the motor areas during beat perception has led to an emerging perspective that beat perception relies on the interaction between the auditory and the motor systems. That is, the basal ganglia exhibits greater communication, or coupling, with other motor areas during beat perception [27.67]. Specifically, beat perception leads to increased coupling between the basal ganglia and the SMA and the PMC [27.67]. A network including the basal ganglia, SMA, and PMC responds when participants need to internally predict or generate a beat in a rhythm. Therefore, the ability to tap along to the beat may be facilitated by this network, which enables predictions to be formed about when the beat will occur [27.67]. Greater connectivity is also shown between the putamen and the ventrolateral prefrontal cortex (VLPFC) when synchronizing finger taps to the beat, suggesting that the basal ganglia play an important role in beat perception by interacting with auditory work-

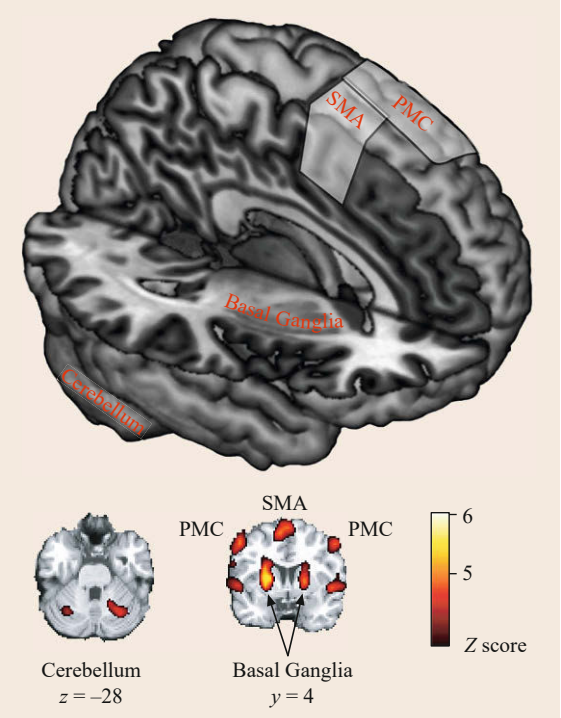

Fig. 27.7 Functional magnetic resonance images of motor areas that are active when listening to rhythms. (*top*) A *cut away* anatomical image with labels for the motor regions involved in beat perception: the premotor cortex (PMC), the supplementary motor area (SMA), the cerebellum, and the basal ganglia. (*bottom*) Functional images showing increased activation in motor areas when participants listened to rhythms, but did not move to them. The *bottom left image* is a horizontal slice (nose would be at the top) showing increased activation in the cerebellum. The *bottom right image* is a coronal slice showing increased activation in the SMA, as well as bilaterally in the PMC and basal ganglia

ing memory mechanisms in the inferior frontal cortex [27.85].

fMRI has also been used to investigate individual differences in rhythm and beat perception. These differences might correlate with the communication between auditory and motor areas. Musical training or experience appears to influence auditory-motor communication. Although both musicians and nonmusicians show auditory-motor coupling between left auditory and premotor cortex, only musicians show significant coupling in the right hemisphere [27.44]. Other work has found greater auditory-motor coupling for musicians compared to nonmusicians, but this time in both hemispheres [27.67]. Increased coupling between the STG and the PMC might be important for integrating auditory perception with motor production [27.44, 67]. Musical training may lead to greater integration because of the extensive practice at using auditory feedback to alter motor production.

Interestingly, basal ganglia activity does not appear to correlate with the speed of the beat, instead showing maximal activity around 500–700 ms, the beat rate that humans find ideal [27.86, 87]. Findings from behavioral work that used both musical and nonmusical stimuli suggest that beat perception is maximal at a preferred beat period near 500 ms [27.21, 60, 88]. Therefore, the basal ganglia are not simply responding to any perceived temporal regularity in the stimuli, but are most responsive to regularity at the frequency that best induces a sense of the beat.

Further evidence for the basal ganglia role in beat perception comes from cross-modality research of rhythms. Beat perception is not necessarily restricted to the auditory modality. There is evidence that it can also exist in the visual modality [27.89], but in many beat-based timing tasks the auditory system consistently outperforms the visual system [27.90–92]. However, when visual rhythms are presented after beat-based auditory rhythms with the same pattern, the beat can subsequently be induced in the visual rhythm [27.89]. One fMRI study showed that activity in the basal ganglia during visual rhythm presentation significantly predicted whether the visual rhythms induced a beat or not [27.93], suggesting that the basal ganglia are not only responsible for beat perception in the auditory modality, but may be responsible for beat perception in the visual modality as well.

27.5 Patient and Brain Stimulation Investigations

The disadvantage of fMRI is that it cannot be used to tell us whether an activated brain area is *necessary* for a given process to occur, only that it responds when that process is being carried out. Data from patients with impaired brain function can establish causal relationships. Thus, patients with impaired basal ganglia function can clarify whether the basal ganglia play a causal role in beat perception. Parkinson's disease (PD) is one example of a neurological disorder that affects basal ganglia function. PD results from death of dopaminergic neurons that project to the basal ganglia, therefore affecting normal basal ganglia functions,

leading to complications with movements. Therefore, if the basal ganglia are essential for normal beat perception, healthy controls should be better at discriminating beat-based rhythms than individuals with PD. This prediction is supported; in PD patients, the ability to detect changes in beat-based rhythms is significantly impaired compared to healthy controls [27.94]. The controls were significantly better at discriminating beat-based rhythms than nonbeat-based rhythms, but PD patients did not benefit to the same degree from the presence of the beat. These findings support the fact that the basal ganglia have a pivotal role in beat perception.

Brain stimulation techniques can also establish whether a brain area is necessary for a particular cognitive function. Transcranial magnetic stimulation (TMS) is a noninvasive stimulation technique that excites neurons in the cortex with a rapidly changing magnetic field placed at the surface of the scalp. A rapidly changing current is run through the TMS coil (Fig. 27.8), which generates rapidly changing magnetic fields around the coil. These magnetic fields subsequently generate weak electric currents in the underlying tissue. TMS is a technique that disrupts neuronal processing; making it ideal for determining whether a brain area is necessary for a particular task or function. However, it is only ideal for stimulating the cortical surface. Therefore, deeper structures such as the basal ganglia may be out of reach, but other motor areas, such as the cerebellum or premotor cortex can be tested. TMS work in the domain of beat perception is emerging [27.95–99]. A study on healthy controls found that after the application of TMS over the medial cerebellum, duration-based timing was significantly impaired [27.96]. A follow-up study using fMRI was able to support these findings, suggesting that motor areas are implicated in beat perception [27.83]. Although beat perception research has advanced quickly, there are still many unanswered questions and unresolved issues, but with new techniques (or novel combinations of current techniques), the future of beat perception research is looking upbeat.

Fig. 27.8 Example of a transcranial magnetic stimulation (TMS) experiment. The experimenter uses a TMS coil to stimulate the participant's premotor cortex (PMC). TMS is a non-invasive stimulation technique used to excite neurons in the cortex by creating a rapidly changing magnetic field at the surface of the scalp

27.6 Discussion

A wide variety of computational approaches have been used to model timing and rhythm perception. Although the findings of recent neuroscientific investigations support some of the predictions of neural resonance theory there is still no consensus about which model is best. Both EEG and MEG have found neurological markers of anticipation and representations of metric structure, especially in beta and gamma bands and SSEPs appear to mark beat and meter perception in the delta band. Beat perception may rely on automatic, preattentive processes, in contrast to metrical encoding which may require attention (although this is not certain). Neuroimaging studies have found evidence of specific auditory-motor networks of neural areas that support beat perception, arguably a crucial process for musical rhythm perception.

While it is true that a great deal has been learned from neuroscientific research techniques, the methodologies have drawbacks as well. Two major criticisms of neuroscientific research are the unnecessary expense of the methodologies and the current inability to distinguish between psychological models [27.100, 101]. Many of the techniques also require participants to remain virtually motionless for long periods, sometimes in very noisy environments (e.g., the bore of an fMRI). In addition, the relative novelty of the investigative techniques and increasing complexity of preprocessing and statistical analysis of the data may lead to flaws in the analysis being overlooked or unrecognized. For example, it is difficult for a researcher to remain familiar with all the details of the variety of statistical procedures that correct for multiple comparisons across brain regions in fMRI, or time windows in EEG/MEG.

Despite these issues, neuroscientific techniques have some undisputable advantages over behavioral techniques. One advantage is that it provides another

independent variable to test: the brain's response can provide valuable information even if an overt behavioral response cannot be measured. A study by *Winkler* et al. [27.102] illustrates this advantage nicely. The researchers investigated whether the ability to *feel the beat* was present in newborns. To test this, infants (2–3 days old) listened to rhythms while their brain activity was recorded using EEG. Occasionally part of the rhythm was omitted; sometimes this omission was on a beat, other times it was off the beat. If newborns have beat perception, the omissions of beats should be more salient than the omissions of off-beats. Obviously, the researchers could not ask infants to make a behavioral response, but changes observed in the EEG recordings could be used instead. A clear difference in the EEG responses to omissions and off the beat was detected, which the experimenters interpreted to mean that beat perception might be innate. As a caveat, the interpretation of these findings may or may not prove to be true and depend heavily on one's specific definition of the word *innate*; infants can hear in the womb from as early as six months after conception and this prenatal learning could potentially contribute to the effect. Even prenatal dancing by the mother may need to be taken into account, as there is evidence that infants' rhythm perception is influenced by being *bounced* in time with music [27.103]. At the very least, findings that rhythm perception can be influenced by culture suggests that if the innate ability does exist it is also shaped by subsequent experience [27.8, 65, 104, 105]. Interpretation of the findings aside, the *Winkler* et al. [27.102] study does nicely illustrate how neuroscientific methods can provide meaningful information in the absence of behavioral response.

Another important use of neuroscientific methods is when behavioral results do not allow for two competing models to be distinguished. One example of this is how electrophysical research has led to entrainment models (timing in relation to a steady pulse) gaining evidence, in addition to the more traditional interval-based models (timing of discrete events) of timing [27.3, 106–108]. Interval-based timing theories have the advantage of parsimony: many things that we time have no regular beat, so if a beat-based timing system were to exist, it would be in addition to an interval-based system. The existence of an additional beat-based system would be justified, however, if it provided more accurate timing. While some studies show increased temporal accuracy in beat-based timing tasks [27.3, 109] others have failed to show this advantage [27.108]. *Grahn* and *Brett* [27.22] designed a study to reconcile these conflicting findings. In a two-part behavioral and fMRI study, there was an advantage for reproducing beat-based rhythms over nonbeat rhythms. In the fMRI portion, using the same stimuli, but in a discrimination task that equated performance between the two rhythm types, the researchers found increased activation in a specific network of areas (including the basal ganglia) when perceiving beat-based rhythms, even though no behavioral advantage was present. This showed that a beat-based mechanism could be active, even when performance improvements were not observed. Thus, even when behavioral results do not distinguish between the predictions of beat-based and interval-based models, neuroscientific methods can indicate whether or not the brain is using the same mechanisms. Adding to the support for entrainment theories are recent EEG findings showing entrainment of neural populations to the beat [27.70, 71] and oscillatory synchronization in the beta and gamma bands [27.65, 66] discussed earlier.

Ultimately, for the field to move beyond measuring neural correlates of rhythm and beat perception and simple localization of cognitive processes to brain areas, the delineation of specific neurobiological timing components and mechanisms is required. This will rely on greater integration between neurosciences and modeling is crucial. As techniques for data acquisition and analysis advance, so does the richness of neuroscientific data. Continued interdisciplinary communication and collaboration promises to yield further advances in our understanding of how rhythm and beat perception comes about.

28. Music and Action

Giacomo Novembre, Peter E. Keller

In this chapter, the relationship between music and action is examined from two perspectives: one where individuals learn to play an instrument, and another where music induces movement in a listener. For both perspectives, we review experimental research, mostly consisting of neuroscientific studies, as well as select behavioral investigations. We first review research examining how learning to play music induces functional coupling between motor and sensory neural processes, which ultimately changes the way in which music is perceived. Next, we review research examining how certain temporal properties of music (such as the rhythm or the beat) induce motor processes in a listener, depending on or irrespective of musical training. The coupling of perceptual and motor processes underpins predictive computations that facilitate the anticipation and adaptation of one's movement to music. Such skills in turn support the capacity to coordinate one's movements with another in the context of joint musical performance. This picture emphasizes how studying the relationship between music and action will ultimately lead us to understand music's powerful social and interpersonal potential.

When we consider music as a form of human action, it is easy to become astonished by the remarkable complexity and precision achieved by expert musicians during a performance. Yet it is under such exceptional conditions that the human brain discloses its capability for *orchestrating* multiple body parts in terms of their timing, force, and kinematics, which undergo dynamic transformations throughout ever-changing musical pieces. But this is only part of the puzzle. Music can be read from a score or recalled from memory. It can be rehearsed, but also improvised. It can be performed solo or in an ensemble, which necessitates coordination at a millisecond timescale between individuals who may be perfect strangers. When all this is considered together, it becomes clear that music is not just an artistic form of expression, but also a behavioral trace of the outstanding resources of the human brain and body. Somehow complementary with these observations, music is known to induce movement responses in a listener, a phenomenon that starts in the fetus during the final weeks of gestation [28.1], and develops through infancy [28.2, 3] into more complex forms of actions [28.4] including dance. The present chapter is intended to give an exposé of the significant advances that has been made towards understanding the cognitive and neural mechanisms that link music and action.

Several different psychological and physiological processes take place simultaneously during music production (sensory, motor, memory, emotional), and because all of these are intrinsically linked with one another, it is challenging for scientists to examine specific functions in isolation. Let us take a basic example: striking a piano key with a finger. The movement (striking the key) is intended to generate a goal (a piano tone). When this is observed from the *outside* perspective of another individual, this seems straightforward: the movement preceded its goal. However, when con-

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_28

sidering a *first person* perspective, it is the musician's intention (i. e., producing a piano tone) that leads the generation of a movement: moving the finger toward the piano key.

This distinction might seem trivial, but in fact it represents a fundamental step to understanding that movements and their ensuing effects are intrinsically *coupled* in the human brain and cognition. More specifically, a representation of a perceptual effect can trigger the movement necessary to produce the effect itself, particularly in musicians, who display special benefits of brain plasticity [28.5–7]. This notion has strongly influenced the study of music cognition and its underpinning neural correlates, and it has been inspired by converging evidence from the fields of cognitive psychology [28.8, 9] and neurophysiology [28.10, 11], as well as computational neuroscience [28.12, 13].

While focusing on the notion of action-perception coupling, we will examine two distinct perspectives on this issue. Firstly, we will examine the role of experience and musical training in binding sensory and motor neural processes. Secondly, we will consider certain temporal properties of music, such as its rhythm or the musical beat, that induce motor processes in a listener. For both perspectives, we will pay particular attention to the predictive character of these neural processes, and their crucial role in allowing individuals to physically respond to music, including interpersonal coordination with other musicians in the context of a joint musical action. We will focus our attention on neuroimaging studies that place special emphasis on cognitive mechanisms, mostly run with musically trained participants (or directly relevant for them), with only a few references to purely behavioral investigations.

28.1 Coupling Action and Perception Through Musical Experience

The highly plastic nature of the musician's brain has been emphasized in the literature in recent years (for reviews, see [28.6, 7]). In this section, we will focus on studies that specifically addressed action-perception coupling in musicians or in individuals who received musical training for experimental purposes. We will first list some behavioral investigations (Sect. 28.1.1), and then move on to neuroimaging evidence from studies using hemodynamic measures (fMRI) and electrophysiological techniques (EEG, MEG), as well as brain stimulation methods (TMS) (Sect. 28.1.2). Finally, special attention will be given to recent studies addressing the predictive character of action-perception coupling, and related mechanisms such as *internal models* [28.14–16] (Sect. 28.1.3).

28.1.1 Behavioral Evidence

Research in experimental psychology has explored action-perception links in music through the use of action-effect compatibility manipulations. *Drost* et al., have conducted a number of behavioral studies [28.17–19] comparing pianists and nonmusicians in the context of an interference paradigm where participants had to play a chord on a piano in response to visual imperative stimuli. These visual stimuli were accompanied by simultaneously presented task-irrelevant sounds, which could either match or not match the target chord. It was found that incongruent sounds delayed execution time in pianists but not nonpianists [28.17]. In addition, these incongruent sounds tended to induce false responses, i. e., production of the heard chord, instead of the imperative one [28.18]. Moreover, this interference could only be observed when the timbre of the musical sound matched the participant's instrument background [28.19]. The studies by Drost and colleagues demonstrate that auditory perception primes action if strong action-perception links have been established through instrument-specific training.

In related research, *Keller* and *Koch* [28.20] found that mental images of anticipated action effects can prime responses to a similar degree as is observed with congruent and incongruent sounds, highlighting the role of action-perception coupling in action preplanning (i. e., before sounds are actually perceived) [28.20, 21]. Subsequent studies investigated such preplanning in sequential actions – a definitive aspect of music performance – by requiring participants to respond to visual imperative stimuli by producing a series of finger taps on vertically aligned keys. Taps triggered tones in some conditions, where the key-to-tone mapping was manipulated (between blocks of trials) to be either congruent or incongruent in terms of pitch and spatial height. One version of this task [28.22] required participants to respond as quickly as possible to the imperative stimuli. Results indicated that reaction times were shorter in conditions where sequences of finger taps and tones were congruent in *height* than when they were incongruent. This effect was restricted to musicians and, furthermore, increased in size with years of musical experience. Therefore, action-perception coupling associated with musical training allowed participants to plan their actions by imagining the auditory sequences in an

anticipatory fashion, and the efficiency of such preplanning was greatest when movements and their auditory effects were congruent. Further studies using a version of the paradigm that required taps to be produced at a specific tempo (rather than rapidly) demonstrated that action-perception coupling not only enhances the efficiency of action planning, but also facilitates timing accuracy and economical force control by optimizing movement kinematics [28.21, 23].

Taken together, this behavioral evidence indicates that the perception or mental imagery of sounds – which would normally be associated with specific movements – trigger representations of those specific movements (see also [28.24, 25] for additional evidence supporting this notion).

28.1.2 Neuroimaging Evidence

Neuroimaging research has shed light on the neurophysiological mechanisms underpinning action-perception coupling in the musician's brain. *Haueisen* and *Knösche* designed a magnetoencephalography (MEG) study that allowed them to investigate brain responses to well-known piano pieces in musicians with or without piano experience [28.26]. In piano players, perception of these pieces led to an increase in neural activity over the motor cortex hand area. Most interestingly, the authors found a distinct spatial response to notes that would be preferably played with the thumb versus the little finger, which matched the homuncular organization of the primary motor cortex (M1). The finding that the acoustic perception of music within an individual's behavioral repertoire led to an increase of motor cortical activity in musicians has been replicated in other neuroimaging studies using different methods. For example, *D'Ausilio* et al., used transcranial magnetic stimulation (TMS) to trigger motor evoked potentials (MEP) in a forearm muscle normally used to play the piano [28.27]. Corticospinal excitability (which was indexed by the amplitude of the MEPs) was found to increase while pianists listened to a rehearsed piano piece compared to an unrehearsed one. In another study, *Bangert* et al., ran an fMRI study where professional pianists and nonmusicians heard novel piano sequences that were synthesized online (and therefore could not be familiar) [28.28]. Compared to nonmusicians, professional pianists showed a broad network of motor areas responding to the piano sequences, including both primary motor and premotor (BA 4/6) regions, inferior frontal cortex and Broca's area. Interestingly, to explore whether this auditory-to-motor transformation was bidirectional, the authors also examined the effect of producing piano tones in the absence of auditory feedback. This latter task led to the activation of auditory-related brain regions, such as the superior temporal gyrus (BA 22) in professional pianists.

Motor activations in the musician's brain can not only be elicited by the acoustic presentation of music, but also visual presentations of musical actions. In fMRI experiments, *Haslinger* et al., and *Hasegawa* et al., presented video recordings of hands playing a silent keyboard [28.29, 30]. Despite the fact that these videos were mute (i. e., no sounds were presented), the authors reported the activation of a frontoparietal brain network – including premotor cortex (BA6) and inferior parietal cortex – which was similar to the one revealed in the study by *Bangert* et al. [28.28] (who presented sounds, instead of silent videos).

Taken together, these data indicate that musical training leads to the emergence of cross-modal action-perception coupling, where the effects of musical actions (either the sounds produced or the visual presentation of the movement patterns) trigger a representation of the movements necessary to produce these effects. This idea has profound implications for human cognition more broadly, because it could be applied to other motor tasks and therefore generalize across individuals with different types of experience. For this reason, other research has investigated to what extent these results could be replicated in naïve participants who received musical training only shortly before taking part in an experiment. *Lahav* et al. [28.31] trained nonmusicians to play a piano piece by ear (without notation) over a period of five days. Following the training, participants were presented with either the trained pieces, untrained pieces (having the same notes, but in a different order) or familiar but motorically unknown pieces [28.31]. Remarkably, the frontoparietal motor-related network discussed above (here comprising Broca's area, the premotor region, the intraparietal sulcus, and the inferior parietal region) responded most strongly to the trained pieces, weakly to the untrained ones, and not at all to the motorically unknown pieces (relative to a rest baseline condition). Thus, a few days of training were sufficient to replicate the effects – previously described in studies with experienced musicians – in a group of nonmusicians (see also [28.32] for earlier EEG evidence supporting this).

A few recent studies have made noteworthy progress towards understanding the functioning of this action-perception coupling mechanism, and how it emerges through learning. *Engel* et al. [28.33] trained nonmusicians to play melodies either by ear (and without seeing their hands) or by imitating visual movement patterns (without auditory feedback) [28.33]. Following training, participants were able to recognize melodies

learned in one modality upon presentation in the other (i. e., untrained) modality. However, recognition accuracy and fMRI data indicated the cross-modal transfer was stronger when the melodies had been trained by ear. Moreover, in order to demonstrate that sensory-motor coupling emerges as a result of motor learning, and not visual familiarity, *Candidi* et al. [28.34] trained nonmusicians to recognize piano fingering errors during the visual presentation of silent musical sequences [28.34]. Expert pianists showed a somatotopic corticospinal facilitation – indexed by the amplitude of motor-evoked potentials triggered by transcranial magnetic stimulation (TMS) – of the finger that committed the error (consistent with the study by *Haueisen* and *Knösche* [28.26], who also reported finger-specific activations, but in response to acoustically presented music). Visually-trained nonmusicians, however, did not show the same facilitation effect, although they were equally able to recognize the errors. Thus, visual experience is not sufficient to recognize movement patterns if motor learning has not taken place, at least for low-level (i. e., fingering) motor representations.

Taking together the studies reviewed above, there is converging evidence from both behavioral and neurophysiological methods (including EEG, MEG, TMS and fMRI) that, given an association between movements and their ensuing effects, the perception of an effect can trigger a representation of the movement necessary to execute it. The musician's brain is an excellent example of action-perception coupling because movements and intended sounds become strongly associated after long-term musical training. On the behavioral level, it has been consistently shown that the representation of a musical sound and the motor resources necessary to perform the sound are represented by a comparable code and can interfere with each other [28.17–19, 22] see also [28.35]. On the neural level, listening to a trained musical sequence activates the motor brain areas necessary for executing it, as evidenced by measures such as corticospinal excitability [28.27], blood oxygen level dependent signal [28.28, 31], EEG potentials [28.32] and MEG fields [28.26]. Conversely, the visual perception of (silent) musical actions leads to similar brain co-activations [28.29, 30, 33, 34], demonstrating that action-perception coupling in the musicians' brain is multimodal (i. e., visual and auditory). Additional research has shown that these coupling effects can also result after a short period of musical training (with naïve participants), implying that such an action-perception matching system is not necessarily musician-specific, but rather stands as task-specific example of a cognitive mechanism with broader relevance [28.31–33, 36].

28.1.3 The Temporal Dynamics and Predictive Character of Action–Perception Coupling

The studies reviewed above were not designed to address the temporal dynamics of action-perception coupling in the brain, but this aspect is fundamental to understanding the cognitive and behavioral relevance of such coupling.

Let us come back to the example of the finger striking a piano key (movement) to generate a sound (goal). As we noted, from a first-person perspective, it is the musician's intention (i. e., to produce a piano tone) that leads to the execution of a movement. Given this, one would hypothesize that – in the musician's brain – the two processes associated with intending to perform a specific keystroke, and hearing the auditory feedback, are at least in part independent and have different priorities, i. e., the actual sound of the key should be predicted on the basis of its preceding *intended* neural representation.

Following this reasoning, *Maidhof* et al. [28.37] and *Ruiz* et al. [28.38] conducted similar EEG studies [28.37, 38] where they examined the event-related potentials (ERPs) preceding the execution of piano errors. Both these studies reported both a behavioral and an electrophysiological marker of performance errors. First, erroneous keystrokes were produced with less force, and therefore generated a softer sound. Second, an early negative deflection (or error-related negativity, ERN) of the EEG signal was found to anticipate the actual mistake by 100 ms [28.37] and 50–70 ms [28.38]. Source localization analysis revealed that these responses were generated by the anterior cingulate cortex (a brain region implicated in action monitoring [28.39, 40]) and, most interestingly, this effect was independent of whether or not auditory feedback was available [28.38]. Thus, errors were detected *prior* to their execution, and this occurred independently of whether the pianists could hear the actual feedback of the performance.

These findings are particularly important because they provide evidence that, during performance, internal forward models predict the outcome of an ongoing motor command by comparing it with an efference copy (i. e., a prediction of the perceptual effects of the motor command) [28.41]. This indicates that, during the execution of a musical sequence, images of the *intended* sounds are formed well ahead their generation, and compared in real time with the state of the body. Thus, the coupling of sensory and motor cortices is a dynamical process with a strong anticipatory character that, given the existence of an association between movements and their ensuing effects, permits the generation

of predictions about the state of one's own body and the sensory consequences of movements.

Further evidence has supported the proposal that internal models play a role in real-time prediction during online action planning. *Maidhof* et al. [28.42] compared EEG brain responses to expectancy violations in musical action (i. e., during piano performance) and perception (i. e., during listening) [28.42]. Both types of violation led to a negativity peaking at around 200 ms after tone presentation. However, the amplitude was larger for the action violation compared to the perceptual violation, indicating that the expectations associated with the intention to produce a tone override those based on perceptual processes alone. Furthermore, *Ruiz* et al. [28.43] explored EEG oscillatory markers predicting an error during musical performance [28.43]. It was shown that a burst of beta-band oscillations that originated from the posterior frontomedial cortex (pFMC, which includes the anterior cingulate cortex, see [28.38]) anticipated the error by 120 ms. Moreover, the efficiency of motor control correction mechanisms, i. e., the reduction of the force utilized to execute a wrong note, could be predicted based on the beta-band synchronization (note that beta oscillations are associated with sensorimotor and, especially, motor functions [28.44, 45]) between pFMC and brain regions implementing control adjustments (i. e., lateral prefrontal cortex) ([28.37, 38]). Taken together, these data indicate further that musical training leads to a tight coupling between sensory and motor cortices, which might underpin the generation of sensory predictions – based on internal models – *within* the musician's brain.

A remarkable property of this dynamical process is that it does not only permit predictions of our own movements, but can also be used to generate predictions about others' actions [28.14, 46]. *Lee* and *Noppeney* [28.47] designed an elegant combined psychophysical-fMRI study to investigate the temporal binding between sensory and motor processes in musicians and nonmusicians [28.47]. Participants were required to attend to musical or speech stimuli in which the synchrony between sounds and images (of either a speaking face or a hand playing the piano) was manipulated parametrically. As could be expected, the two groups were equally sensitive to the temporal asynchronies in the speech domain, but the musician group was superior in detecting temporal asynchronies in the musical domain. Dynamic causal modeling revealed that this superior performance was associated with greater effective connectivity within a network of brain regions including the superior temporal sulcus, the premotor cortex and the cerebellum. Thus, cross-modal plasticity due to musical training (as reviewed in Sect. 28.1.2) led to the fine-tuning of internal forward models (Sect. 28.1.3) that, critically, permit the generation of predictions of observed actions with high temporal resolution. Accordingly, coupling emerges within an individual brain, but can also be used to generate predictions about others' actions.

These fine-tuned internal forward models might allow musicians to predict not only *when* an event will occur, but in some cases also *what* event will occur. Through training, the musician's brain does not only bind specific events across sensory and motor modalities. In addition, the brain learns which successions of tones are most likely to occur according to statistical regularities associated with the rules that govern harmony (i. e., sequential chord progressions) in a given musical tradition. This phenomenon has been studied for some time in the context of purely auditory perceptual experiments. Participants with and without musical backgrounds were presented with sequences of chords containing or not a violation of their harmonic structure, while event-related potentials (ERP) were quantified using EEG. In a series of experiments [28.48, 49], it was shown that the perception of a harmonic violation led to an early right anterior negativity (ERAN) peaking at around 200 ms after chord presentation. By comparing expert musicians with novices, it was further shown that the amplitude of this negativity was larger for expert musicians [28.50]. This finding indicates that musical experience led to the generation of stronger expectancies in the perceptual domain. It should be noted, however, that expert musicians acquire these rules not only by means of perceptual exposure (as a naïve listener), but also by means of intensive practice. Therefore, given the tight functional link between sensory and motor cortices highlighted by previous studies, it remained to be explored to what extent expectancies in the auditory domain extend to the motor domain.

A few recent studies examined this issue. First, in a behavioral study, *Novembre* and *Keller* [28.51] presented expert pianists with silent videos displaying a musician's hand performing mute sequences, including occasional chords that were harmonically incongruent with the preceding musical context [28.51]. The pianists were asked to imitate the chords as quickly and accurately as possible. It was shown that, despite the absence of auditory feedback, imitation was faster and more accurate for chords that were preceded by a congruent context. This result suggests that the harmonic rules implied by the observed actions induced strong expectancies that influenced action execution. Thus, this study provided first behavioral evidence in favor of harmonic structures regulating not only perceptual processes (as shown by the previous studies), but

also the motor processes involved in producing these structures.

This finding was replicated in a subsequent study [28.52] where EEG was recorded during task performance. ERP data from this investigation revealed a negativity following the presentation of the final incongruent sequential chord [28.52]. The negativity resembled the ERAN that follows auditory presentation of a harmonically incongruent chord [28.48, 50], or possibly the ERN that anticipates keystroke errors in piano performance [28.37, 38]. Additionally, a second negativity with more posterior distribution was observed, which anticipated the time during which the chord was imitated. This ERP was taken as evidence of response reprogramming.

A follow-up study examined the specificity of this latter ERP, where pianists were presented with photos of a model hand performing the chords, hence addressing more directly the motor – as opposed to the perceptual – component of the task [28.53]. Besides replicating the later negativity observed by *Sammler* et al. [28.52], *Bianco* et al. [28.53] demonstrated that such neural signatures were specifically linked to movements that had to be reprogrammed in terms of *what* to do (type of chord), and was different from the ERP elicited by the revision of *how* to perform the chord (e.g., which set of fingers to employ) [28.53]. Moreover, contrary to results for *how* to perform, imitation time relative to *what* to do was influenced by length of the sequence, indicating that the motor plan for the congruent chord was prepared ahead based on contextual information [28.51]. Most strikingly, recent fMRI results have shown that motor predictions based on implicitly acquired rule-based structures (harmonic relationships) are associated with a network comprising the right homologue of Broca's area (the dorsal part of BA44, bordering premotor cortex – PMC) interlinked with visuomotor parietal areas (bilateral superior parietal lobe) [28.54]. These findings, together with the established involvement of the right homologue of Broca's area in detection of auditory musical irregularities, support the hypothesis that this area is fundamentally involved in structural integration and prediction of complex musical material in both perception and production.

The above findings are particularly noteworthy in that they offer evidence that the well-known predictive character of the motor system is strongly based on a musician's knowledge of harmonic principles. This latter piece of evidence indicates that the motor system predicts not only when an action will occur, but also what kind of action will occur [28.55]. Rule-based predictions in the motor system are consistent with other accounts postulating a sensorimotor processing of syntax, including harmony [28.56, 57].

In conclusion, the studies reviewed in this section suggest that the coupling between sensory and motor cortices underpins predictive computations by means of internal models. The studies by *Maidhof* et al. [28.37, 42] and *Ruiz* et al. [28.38, 43] explored this notion within the musician's brain by looking at the relationship between intended sounds and executed movements. The studies by *Lee* and *Noppeney* [28.47], *Novembre* and *Keller* [28.51], *Sammler* et al. [28.52], and *Bianco* [28.54] examined the prediction of another musician's musical actions. Taken together, the results of this research suggest that musical training shapes and develops a sensorimotor system that generates predictions about the identity and timing of upcoming events. In the next section, we discuss how these processes affect the control of an individual's own movement timing and potentially support real-time interaction between ensemble musicians.

28.2 Responding to Music with Action and (Social) Interaction

Recent research has explored to what extent action–perception coupling functions as a resource for moving our bodies in response to music, which is likely to be a fundamental skill supporting interpersonal behavior and ensemble musical coordination. In this domain, three fundamental mechanisms have received particular attention. Firstly, perceptual investigations have examined the neural correlates mediating the processing of temporal properties of music (such as the rhythm or the musical beat) that induce motor processes in musically trained and untrained individuals. Secondly, sensorimotor tasks have examined the neural correlates that underpin the human ability to coordinate and adapt body movement with an external signal, with special focus on the social processes involved. Finally, we review recent studies that addressed how action representations of self and other emerge and are eventually integrated in the context of joint musical actions that require synchronization between multiple musical parts. We will focus on cognitive and neural mechanisms that are likely to support interpersonal coordination, with a special emphasis on studies conducted with musically trained participants.

28.2.1 Temporal Properties of Music that Induce Motor Processes

From a behavioral perspective, the most straightforward way to explore timing mechanism in the context of action-perception coupling is to employ sensorimotor synchronization tasks that require minimal movement (hence allowing movement artifacts to be controlled for during neuroimaging measurements). The most commonly used approach consists of finger-tapping tasks, where a participant taps his/her finger in time with a pacing signal (often an auditory sequence). Over the course of many decades, behavioral research using finger-tapping tasks has made significant advances in understanding the mechanisms governing sensorimotor synchronization (for a review see [28.58, 59]). Only recently, however, neuroimaging methods have extended this body of knowledge by allowing researchers to observe the brain response to musical properties, such as rhythm, independently of a participant's behavioral response, e.g., during a passive perception task.

In a series of neat studies, *Chen* et al. [28.60] investigated action-perception coupling by using fMRI to measure brain activity while nonmusician participants tapped along with isochronous auditory rhythms [28.60]. The study compared brain and behavioral (tapping) measures across conditions in which the rhythm had different levels of metrical saliency (i. e., sound intensity was manipulated in order to accent every third tone to varying degrees across conditions). It was shown that, as metric saliency increased, louder tones were associated with longer tap durations and, most interestingly, stronger coupling between auditory and motor (especially dorsal premotor) cortical regions. In order to dissociate activations related to rhythm perception from motor processes involved in the behavioral tapping task, a second study used a listening task, and demonstrated that a neural network of motor regions including the supplementary motor area (SMA), mid-PMC and cerebellum, was activated similarly as in the synchronization task [28.61]. Finally, and particularly germane to the theme of the present chapter, a third study compared the activation of this network of motor brain regions across musicians and nonmusicians [28.62]. It was found that regions within this network responded to rhythmic stimuli independently of musical training. Thus, the perception of rhythm evoked motor responses in the brains of musicians and nonmusicians alike.

Another musical property that has been associated with motor activations in the brain is the musical beat. The term *beat* refers to the psychological sense of a regular pulse underlying a rhythm pattern. In an fMRI study, *Grahn* and *Brett* [28.63] measured the response of motor brain regions to the beat of auditory rhythms in participants with and without musical training [28.63]. These authors reported that rhythms having perceptual accents at regular intervals (i. e., hence inducing a stronger sense of the beat) were better reproduced, and associated with increased activation of SMA and basal ganglia in both groups of participants. Another study compared rhythms in which beats were accentuated physically by increasing either the intensity or the duration of tones within cyclically presented patterns (as well as a condition in which the beat was imagined and *nonbeat* conditions without a regular underlying beat) [28.64]. It was reported that, relative to the nonbeat conditions, all three beat conditions were associated with putamen activation (one of the structures of the basal ganglia) and increased connectivity between putamen and premotor, SMA and auditory cortex. The strength of this coupling (particularly for patterns with duration-based accents) was higher in musicians than nonmusicians, indicating that – to some extent – these activations can be boosted through musical training.

A final study shed light on the nature of these activations. *Grahn* and *Rowe* [28.65] aimed at establishing whether the putamen response to beat perception reflected the process of finding the beat (i. e., extracting regularity from the pattern's temporal structure) or the process of generating temporal predictions based on the beat [28.65]. The authors compared conditions in which participants (with varying degrees of musical training) listened to series of rhythmic sequences in which a given sequence could be preceded by a sequence with the same beat, a different beat (faster or slower), or an irregular *nonbeat* sequence. These conditions required beat continuation, beat adjustment, and beat finding respectively. The authors reported that beat continuation was associated with an increase in putamen activity, and that this effect was independent of musical expertise. These data were taken to indicate that putamen activation reflects the generation of online predictions about when a future event will happen in the context of the beat-based musical rhythms. This finding, which is consistent with other evidence that the basal ganglia play a key role in associating auditory stimuli with motor responses (see e.g., [28.66]), has important implications for several musical skills underpinning the interpersonal coordination of multiple musicians (Sects. 28.2.2 and 28.2.3 will address this point directly). More generally, these studies shed light on the neurobiological structures that mediate movement responses to music perception (independently of musical training), such as when listeners tap their feet or sway their bodies to music [28.4, 67].

While the perception of rhythm and beat is a temporally dynamic process, the series of studies described

above utilized fMRI – a technique with very low temporal resolution – to explore these neural processes. This approach was optimal for identifying networks of brain regions responsive to these musical properties, but was not well suited to providing fine-grained information about the temporal dynamics of these activities. EEG and MEG are better equipped for this aim. *Fujioka* et al. [28.68] conducted an MEG study in which neuromagnetic beta-band oscillations (which are associated with sensorimotor and, especially, motor functions [28.44, 45]) were recorded while participants listened to isochronous auditory rhythms (at different rates) or randomly timed sequences [28.68]. While a decrease in beta amplitude occurred after each sound onset in both isochronous and random sequences, the subsequent beta rebound anticipated the next sound onset in a rate-dependent manner only for isochronous sequences. This finding was taken to indicate that the time course of beta modulations reflects the internalization of rhythmic periodicities and that this internalization facilitates predictive timing (a finding that is also consistent with animal studies [28.69]). These periodic beta modulations were localized to auditory and motor brain regions – including the pre- and postcentral gyrus, SMA and the cerebellum. Most importantly, corticocortical phase coherence between primary auditory (Heschl's gyrus) and motor regions (especially SMA) was observed to unfold as a function of stimulus rate. Therefore, these results illuminate the time course of auditory-motor coupling in response to rhythmic stimuli, and indicate directly their relevance for generating temporal predictions.

It is worth noting that auditory-motor coupling effects have also been observed at different temporal scales, such as those that match the signal's periodicities [28.70, 71], using EEG-recorded steady-state-evoked potentials (SSEPs). A recent advance in this field is to link individual differences in covert neural entrainment, indexed by SSEPs, with overt behavioral measures, as in a study showing that stronger endogenous neural entrainment to the rhythmic beat is associated with superior temporal prediction abilities during sensorimotor synchronization with auditory sequences [28.72]. Although it is currently not clear whether the generators of such effects are specifically auditory and motor regions, and the interaction among them (as in the study by [28.68]), it is undeniable that SSEPs are a promising index to tag neural entrainment or attention allocation to the musical beat.

In sum, the fMRI studies reviewed earlier were successful in demonstrating that temporal properties of music, i. e., rhythm and beat, led to activation of a corticosubcortical network of brain regions that underpin auditory-motor interactions. The fine-grained temporal resolution of these cross-modal activations highlighted in electrophysiological results supports the hypothesis that they are implicated in the prediction of sensory events (see also [28.73]). It is important to note that these neural processes could have not been discovered through behavioral methods alone, as in fact they can be generated during the passive perception of a rhythm (i. e., in the absence of behavioral responses). In this sense, the coupling of perception and action during perception of rhythms or beats reflects a spontaneous association of music and action that is independent of movement production (and independent of musical training as well). We argue that this is a fundamental mechanism that permits the binding of movements and percepts in real time (either to precisely time self-produced movements, or predict other-related ones). These computations might be a fundamental resource for mediating interpersonal coordination, i. e., the temporal coordination between multiple individuals, by triggering synchronized motor responses in one individual to perceived sounds produced by another. We will now turn to a body of literature that explored this issue directly.

28.2.2 Sensorimotor Coordination, Prediction and Social Processes

The motor responses to musical rhythm and beat may drive music-induced movement, such as when we tap our feet or sway our bodies to music [28.4, 67]. Likewise, when considering musically trained individuals, these responses may facilitate interpersonal coordination, as when performing music with another individual, where the shared goal is to maintain synchrony [28.74]. Synchronizing with another individual often comes easily, and has proven to be an unintentional phenomenon in many contexts. For instance, two people seated in rocking chairs tend to involuntarily synchronize their rocking frequencies [28.75] or audiences clapping tend to fall into unison [28.76]. Recent research has used paced finger tapping as a model for exploring the neural mechanisms that permit individuals not only to predict others' action-timing, but also to adapt their movements accordingly [28.59, 77]. Thus, this research explores the social functions of action-perception coupling, and its relevance for sensorimotor synchronization [28.74].

In an fMRI study, *Fairhurst* et al. [28.78] simulated the temporal dynamics of a joint action by having musicians tapping with an adaptive auditory pacing signal: a computer-controlled virtual partner [28.78]. The degree of cooperation of the virtual partner was manipulated to elicit different levels of interagent synchrony with the participant ([28.79]). The results in-

dicated that a small change in the cooperation of the virtual partner led to a large-scale shift in activated brain networks. Uncooperative virtual partners who were overly adaptive led to poor synchronization and the activation of lateral prefrontal areas associated with cognitive control. Cooperative virtual partners who adapted to the participant's tap timing to an optimal degree facilitated precise interagent synchrony, accompanied by activation of cortical midline structures associated with socio-affective processes. These findings are thus potentially informative about the neural underpinnings of phenomena whereby actions of groups of individuals that are well synchronized feel effortless and promote cohesion [28.74]. Indeed, other research using behavioral methods has revealed that interpersonal synchronization can lead to prosocial behavior [28.80], feelings of affiliation [28.81], in-group cooperation [28.82] or trust [28.83]. Moreover, the findings of *Fairhurst* et al. [28.78] are consistent with other neuroimaging evidence for an association between experiencing interpersonal synchronization and activity of brain areas implicated in reward (such as the caudate) [28.84].

Successful coordination, however, it not entirely an automatic process, but might vary depending on an individual's skills, such as the capacity to predict others' behavior. The anticipatory mechanisms that enable these predictions have been associated with motor-related brain regions (see Sects. 28.1.3 and 28.2.1) and, in part, might be independent of musical background. However, the way in which these mechanisms operate in the context of a sensorimotor synchronization task might vary across individuals according to personal tendencies, abilities and/or cognitive strategies adopted [28.85]. In a relevant study, *Pecenka* and *Keller* [28.86] measured individual differences in musicians' temporal prediction abilities in a task that required sensorimotor synchronization with auditory pacing sequences that contained tempo changes (accelerando and decelerando) resembling those found in expressively timed music [28.86]. Based on these estimates of temporal prediction, individuals were classified as *high predictors*, i. e., individuals whose tap time series indicated that they anticipated the tempo changes, and *low predictors*, i. e., those who tended to track the tempo changes at a lag [28.87]. These prediction/tracking tendencies were not related to participants' motivation and, importantly, were stable when tested after several months. Next, *Pecenka* and *Keller* [28.86] assessed the musicians' abilities to tap in synchrony with one another in dyads comprised of two high predictors, two low predictors, and mixed pairs. Consistent with the hypothesis that that prediction is a key requirement for achieving good coordination, dyads composed of high predictors were more precise than low predictors and mixed pairs.

In order to explore the brain networks underlying these temporal prediction abilities, a subsequent fMRI study [28.88] manipulated cognitive load (using a visual working memory task of variable complexity) while musicians tapped along with tempo-changing pacing sequences. These sequences resembled another human's actions to the extent that their temporal profiles matched those found in expressive music performance. Estimates of the degree to which musicians predicted the tempo changes indicated that prediction ability decreased gradually with increasing cognitive load, and the related reduction in sensorimotor synchronization accuracy was accompanied by a modulation of a network of brain areas including premotor and motor regions, SMA, inferior parietal cortex and the cerebellum. It is noteworthy that some of these areas are considered to be crucial for achieving audio-motor synchronization, as indicated by TMS studies showing that interfering with the ventral [28.89] or dorsal [28.90] premotor cortex causes a drop in synchronization accuracy, which may be compensated for by an increase in activity of the cerebellum [28.89].

Another important component of successful interpersonal coordination in music performance is the capacity to adapt to another's action timing. Even if one can predict the timing of another's actions accurately, synchronization may be less than perfect if these predictions are not used effectively to guide self-generated behavior or due to biological noise in central and peripheral nervous systems. It is therefore necessary to employ adaptive timing mechanisms that facilitate interpersonal coordination by correcting for synchronization errors in a reactive fashion (see [28.77]). A recent study [28.91] indicates that the capacity for adaptive timing may be a factor that influences musical ensemble coordination by affecting who adapts to whom and to what degree. *Fairhurst* et al. [28.91] conducted an fMRI study in which musicians were asked to tap along with a computer-controlled virtual partner that was programmed to adapt to participants' tapping either in an optimal and reliable manner or in a way that rendered its timing unreliable and prone to tempo drift. The musicians were classified into two groups – *leaders* and *followers* – based on whether they found the interaction easier when they were required to exert control to maintain a steady tempo during interactions with unreliable virtual partners (leaders) or when they did not during interactions with reliable virtual partners (followers). This measure was correlated with scores on a questionnaire that assessed locus of control, with leaders being more likely than followers to perceive life events to a consequence of their own actions. Be-

havioral results indicated that leaders and followers employed different synchronization strategies. Leaders employed less adaptive timing than followers, suggesting that the former focused on maximizing the stability of their own tap tempo at the expense of precise synchrony with the virtual partner. Followers, conversely, employed more adaptive timing and thereby prioritized synchrony with the partner over the stability of their own tempo. This difference between groups was reflected on the neural level by higher activation in leaders of right-lateralized areas classically implicated in self-initiated movements, such as midcingulate cortex and pre-SMA, which is consistent with the prioritization of self-generated actions. Results also suggested that the precuneus, a brain area relevant to the integration of external and self-generated information [28.92], is sensitive to the distinction between focusing on actions of the self versus interactions between self and other.

Taken together, the studies reviewed in this section represent an emerging field of research that holds potential for understanding not only how motor brain regions entrain to temporal properties of music (Sect. 28.2.1), but also how these activations become relevant in the context of a social interaction such as interpersonal coordination – including joint musical performance. The studies reviewed in this section have explored the behavioral relevance of audio-motor coupling processes by which the human brain entrains to properties of music and generates predictions about the timing of others' upcoming actions. It was discussed how this mechanism might facilitate social interactions by bringing about the effortless synchronization of movements among members of a dyad or larger group. In the case of musically trained individuals, this mechanism is likely to play a significant role in enabling the precise interpersonal coordination that characterizes musical ensemble performance. Yet, these processes are subject to a certain degree of interindividual variability, most likely depending both on basic sensorimotor skills (e.g., [28.86, 88]) and on cognitive strategies [28.91]. Predictive and adaptive abilities appear to be key capacities for achieving precise interpersonal coordination, but the manner in which these are employed in the context of joint actions vary from one person to another, implying that not every dyad interacts in the same way.

28.2.3 Action Representation Mechanisms in Musical Interaction

Predicting and adapting to the timing of another individual are necessary but not sufficient skills for achieving temporally precise interpersonal coordination, e.g., in a joint musical performance. Another important skill that deserves consideration is the capacity to form integrated representations of self- and other-related actions. Such corepresentations are crucial because, in real-life situations, the actions produced by interacting individuals are often *complementary* rather than identical. Therefore, the goal in complementary joint action is not just to produce a movement, but the *appropriate* movement, in synchrony with another. This presumably requires dedicated mechanisms underpinning the integration of self-initiated action, which are generated internally, with others' actions, which are exogenous and, as such, can only be accessed via perceptual input. Action–perception coupling has been proposed a mechanism that potentially fulfills this function in joint action generally [28.93–95], as well as in musical joint action in particular [28.15, 96–98].

Behavioral research on music performance suggests that expert musicians form representations of self- and other-related actions, and that these representations are influenced by properties of the individual's own motor system. Evidence for this comes from studies demonstrating that pianists synchronize better with recordings of themselves than with those of other musicians [28.99] and with pianists who are well matched in terms of preferred performance tempo than with pianists who are less well matched in preferred tempo [28.100]. Furthermore, it has been shown that practicing a coperformer's part can in fact be detrimental to interpersonal coordination because in this case predictions about microtiming in the other's part are based upon one's own playing style, which may differ from the coperformer's style [28.101]. These findings suggest that musicians form representations of others' parts [28.16] that allow one individual to simulate another's actions. Thus, the manner in which a performer would execute a given piece strongly influences the way in which the performer synchronizes with another's performance of the piece. While this suggests that representations of others' actions are generated by means of a simulation process [28.14, 98] within one's motor system, this was not tested directly in the above-mentioned studies as they did not employ brain measures.

To address this, in a single-pulse TMS study, *Novembre* et al. [28.102] investigated the representation of self- and other-related actions in the context of a musical joint action paradigm [28.102]. Pianists learned to perform several pieces bimanually prior to the experiment. During the experiment, they were asked to perform the right hand part of the piece, while the left hand part was either not performed, or believed to be played by a coperformer hidden behind a screen (while the pianists were actually listening to a recording). This paradigm was intended to lead to a corepresentation of the left-hand part, reflecting

either the self or the coperformer. The authors examined action representation processes related to the left-hand part by stimulating the right motor cortex (using single-pulse TMS), and observing changes in the motor evoked potentials (MEPs) recorded from the resting left arm [28.27]. Results indicated that MEP amplitude was larger when the participant believed that he/she was interacting with a (hidden) coperformer. Remarkably, this effect persisted in a subsequent session in which neither visual nor auditory feedback from the coperformer were provided (though the participants were led to believe that the hidden coperformer was nevertheless playing), and was larger in individuals possessing stronger empathic traits (i. e., perspective taking skills, see [28.103]).

Thus, the study by *Novembre* et al. [28.102] indicates directly that ensemble musicians form *motor* representations of their ensemble members in the context of joint action, which is consistent with the behavioral evidence reported above. Moreover, this study suggests that these representations have an intrinsic social component, as: 1) perceptual feedback is not a prerequisite for corepresentation; and 2) individuals who are more prone to take the perspective of others form stronger corepresentations.

A study by *Loehr* et al. [28.104] used a joint musical performance paradigm similar to that employed by *Novembre* et al. [28.102] to investigate self and other monitoring and integration while EEG was recorded from pairs of pianists simultaneously [28.104]. The pianists learned to play both the left- and right-hand parts of musical pieces, and were then asked to perform one part each (while hearing and seeing each other's actions). The experimenters manipulated the auditory feedback from either pianist by creating a mismatch between piano keystrokes and produced tones. The mismatch either did or did not affect the harmony between the players' parts, hence permitting the differentiation of processes related to monitoring the self's performance and the joint action outcome. Altered outcomes elicited a feedback-related negativity irrespective of whether it occurred in the pianist's own or the partner's part, and a P300 with higher amplitude when the alteration was related to the pianist's own part. Crucially, the P300 had higher amplitude if it affected the joint outcome compared to the individual outcome, indicating that this task led to the emergence of integrated representations of self- and other-related actions.

A further study by *Novembre* et al. [28.105] used another modification of the virtual piano duo paradigm [28.102] to explore the extent to which motor representations of ensemble members support efficient temporal coordination between musicians [28.105]. To this end, pianists were required to adapt with the right hand to tempo changes contained in a recording of the left-hand part. The left-hand part either had or had not been practiced before the experiment in order to manipulate whether or not a motor representation was formed. In order to interfere with the representation of the left-hand part (which was practiced, but not performed), repetitive (double-pulse) TMS was used to disrupt the neural processing in the right primary motor cortex [28.106, 107], and tempo adaptation accuracy was measured following it. It was shown that interfering with the motor representation of the left-hand part affected temporal adaptation only when the part had been practiced (and therefore could be motorically represented). Moreover, this interference was stronger in individuals with high perspective taking skills, which is noteworthy given that *Novembre* et al. [28.102] demonstrated that these individuals also form stronger representations of others' action. This finding is also consistent with other accounts that postulate the relevance of empathic and perspective taking skills in the context of interactions between musicians [28.88, 108]. Thus, the results of *Novembre* et al. [28.105] provided evidence that motor representation processes might be a means used by musicians to maintain synchrony with one another [28.109]. This conclusion was supported, and further extended, by a follow-up experiment in which the same paradigm was employed in the context of a turn-taking task between a pianist and a virtual partner [28.110]. By delivering paired-pulses around the turn switch, the authors of the study were able to transiently impair the pianists' entry accuracy. This effect was specifically observed when the dorsal premotor cortex was targeted (while stimulating SMA did not yield any effect), and only to the extent that the part executed by the virtual partner had previously been rehearsed.

It can be noted that the studies reviewed above [28.102, 104, 105, 110] used sensorimotor training tasks as a means to build representations of self- and other-related actions. This is an important detail in that it suggests the particular relevance of the body of studies reviewed earlier in Sect. 28.1.2, where it was shown that listening to or watching the performance of a trained musical piece leads initially to the formation, and later to the activation, of motor representations in the musician's brain. Considering this, it appears clear that this recent research extends previous work by showing that action-perception coupling processes might support interaction between ensemble musicians [28.15, 96, 98].

28.3 Conclusion and Perspectives

In conclusion, we have considered the relationship between music and action from two perspectives. Firstly, in terms of how musical training can change the way in which music is perceived. Secondly, in terms of music inducing motor processes in a listener. For both, we noticed that sensory and motor brain regions become coupled in the human brain in response to music, and that this coupling underpins predictive computations that scaffold the ability to synchronize and adapt movements in response to a musical stimulus. This mechanism is likely to support the human ability not only to dance, or move, in response to music, but also to coordinate with others if music has to be jointly performed. This suggests that the relationship between music and action can be seen as a profoundly social phenomenon, for which individuals interact with one another through sounds and body movements [28.111]. This view in a sense inverts the way in which the relationship between music and action has been traditionally conceived. Progressing from increasing focus on technical and cultural factors that influence music production, we might soon witness a growing interest in the natural, intuitive, and spontaneous skills that make musical action, interaction and participation such a universal phenomenon [28.112].

29. Music and Emotions

Tuomas Eerola

The rapid rise in emotion research in psychology has brought forth a rich palette of concepts and tools for studying emotions expressed and induced by music. This chapter summarizes the current state of music and emotion research, starting with the fundamental definitions and the assumed structures of emotions (Sect. 29.2). A synthesis of the core affects, basic emotions and complex emotions is offered to clarify this complex landscape. A vital development for the field has been the introduction of a set of mechanisms and modifiers for the induction of emotion via music that are here connected to the structures of emotions (Sects. 29.3 and 29.4). Particular attention is given to challenges that are still waiting to be resolved, such as the cultural context and the situal context of music listening (Sect. 29.5).

29.1 The Rise of Music and Emotion Research

The question of how music induces emotions in listeners with such effortless grace is a puzzle worth solving not only for its myriad real-world applications, but also for its ability to address the fundamental reasons for the existence of music [29.1]. Emotions induced through music are intrinsic to most ceremonies [29.2] and may be used therapeutically [29.3], but research has not yet fully dissected the factors contributing to such effects and uses of music; in fact we are neither sure of the ways in which music engenders feelings, nor do we agree on the typology of emotions relevant for most musical episodes. Extensive summaries of music and emotion have been provided in recent dedicated books and journal articles [29.4–7]. This chapter not only reviews the topics in which consensus has emerged, but also attempts to combine some of the key themes that have perhaps become lost amongst the increasing diversity of theories and foci of research.

There has been a long-standing interest in the emotional pull of music. From ancient Greece (Aristotle, Plato) to the Enlightenment (Rousseau, Baumgarten), philosophers have attempted to account for this pull, as have the fathers of evolutionary thought (Charles Darwin) and contemporary psychology (Wilhelm Wundt). While the empirical study of emotions has been pro-

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_29

ceeding now for more than 100 years, the rise of its popularity in music research coincided with the cognitive paradigm loosening its grip on the range of permitted topics in the early 1990s. From this point on, softer topics such as emotions were allowed to flourish after several decades of focus on human information processing. Music research always had an eye on the emotions despite their unpopularity in psychology, and exceptional individuals had presented their views on the subject. For instance, Kate Hevner discovered the low-dimensional structure of affects in the 1930s, fifty years before *James Russell* [29.8] proposed the well-known affective circumplex model. Later, *Leonard B. Meyer* connected emotions to expectations [29.9], *Paul Farnsworth* developed a new emotion vocabulary [29.10], and *Daniel Berlyne* redefined the topic as a mission to find the objective properties of the stimulus that would relate to arousal [29.11].

The 1960s and early 1970s saw research that rediscovered the conceptual cartography of the emotional landscape in music, with *Rigg* [29.12], *Wedin* [29.13], and *Gabrielsson* [29.14] asking listeners to provide free verbal reports and adjective choices for the emotions represented by music examples. This line of research aimed to formulate a definitive emotion taxonomy for music, which even now has not been fully resolved. In the 1980s and 1990s, the field focused more on methodological innovations such as continuous ratings of emotions [29.15], and on specific emotional responses such as thrills [29.16] and strong experiences [29.17].

In the field of affective sciences, the 1990s witnessed a frenzy of activity when influential neuroscientists such as *Antonio Damasio* [29.18] and *Joseph LeDoux* [29.19] outlined their seminal theories of emotions. The neuroscientist *Jaak Panksepp* [29.20] soon applied these ideas to music, quickly followed by others [29.21]. The culmination of research up until the turn of the millennium was collated in the first handbook of the field [29.22], which solidified research terms and concepts. However, in the period that has followed, neither the field of affective sciences, nor the smaller subfield of music and emotion studies, have provided full answers to all fundamental issues.

This chapter comprises questions of *what* and *how* concerning emotions and music. The first section inquires into *what* the perceived and experienced emotions are; here the notions of core affects, basic emotions, and complex emotions are discussed. This is followed by a section exploring *how*, which offers a summary of mechanisms considered relevant for the emotions. Mechanisms are covered in parallel to emotion structures, and the two complementary aspects of emotions – perception and experience – are discussed within a uniform interpretative framework. In the final section, the current challenges are reviewed and discussed.

29.2 Structure of Emotions

To summarize the current state of research in music and emotions, a few definitions are first in order. The terminology used in the field is diverse, but the concentrated effort that created a dedicated handbook [29.4] has remedied the situation considerably. *Affect* is the broader domain encompassing *emotions*, *moods*, and *feelings*. Emotions, which are typically the focus of attention in this field, are distinguished from moods by their relatively short duration and moderate to high intensity, whereas moods tend to be longer and less intense than emotions. However, it has been suggested that this distinction is rather blurry and exceptions have been pointed out [29.23]. *Feelings* refer to the subjective component of the emotion whereas arousal is the physical activation of the autonomic nervous system. Under these categories, there are specialized emotional and physical reactions, such as *chills* or *goosebumps*, and, in addition, *strong emotions*, which can encompass a range of musical experiences [29.5]. Emotions have the capacity to span a broad range of topics such as motivation, preference, intensity, and affect reactivity [29.24], but these are rarely addressed in the context of music and will not be covered in this chapter.

Although consensus on the topic of emotions has been rather elusive [29.25], the main subcomponents of emotions are largely agreed on. These include (1) appraisal (one assesses a situation to be dangerous), (2) expression (one screams), (3) autonomic reaction (one starts to perspire), (4) action tendency (one moves away from the situation), and (5) feeling (one feels threatened), all of which occur more or less simultaneously ([29.26, pp. 6–8], [29.27]). Purely cognitive processing is not usually considered an emotion since all theoretical positions assume some form of arousal to distinguish emotions from processing of information [29.28]. The components occur at conceptually different levels and indeed, the outcomes of these processes are often described at different levels: physiology (changes in brain, hormonal or autonomic nervous system states), psychology (functions, appraisal, or recognition processes), or phenomenology (emotions as experienced). In this chapter, the levels are distinguished in terms

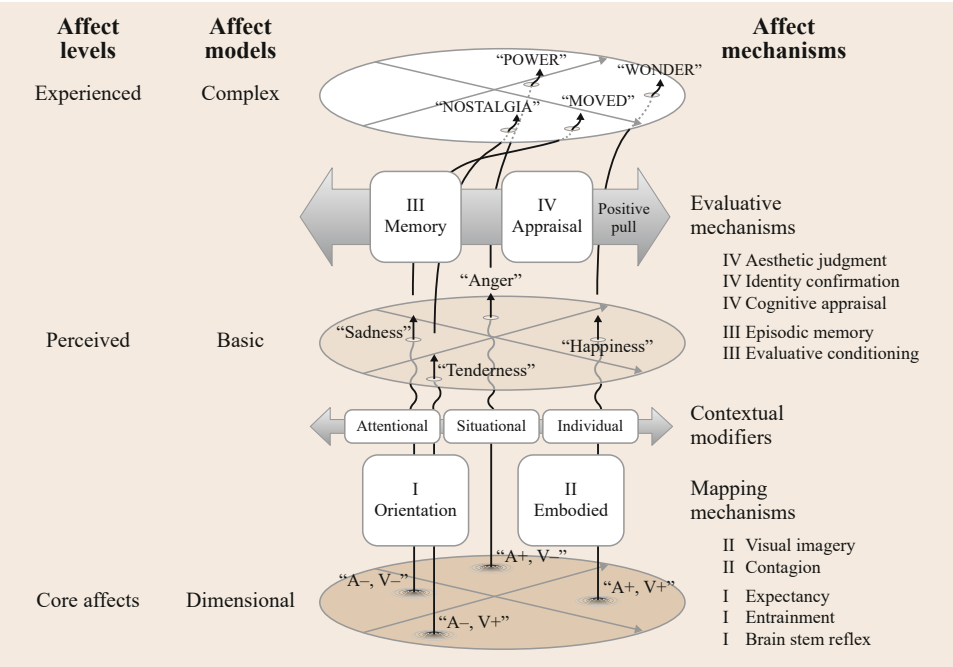

Fig. 29.1 Schematic illustration of affect concepts (levels, models, and mechanisms)

of the processes related to sensation, recognition and experience of emotions and this division shapes the models of emotions and mechanisms proposed at each level.

The aim here is to bridge the gap between what are now largely different avenues of research: the emotions perceived in music (also known as emotion recognition or expressed emotions) and emotions experienced or induced in the listener. The former was an early focus of the field [29.13, 29, 30]. In such studies, listeners were often instructed to describe the music in emotional terms (e.g., this music is sad) or describe what the music might have been expressing (e.g., this music expresses sadness). During the last decade, the emphasis has shifted towards explorations of how music makes the listeners feel. The distinction between recognized and induced emotions has been tempered by solid evidence of the way in which the two often overlap. Empirical evidence suggests that the distinction should be characterized as a question of intensity [29.31] rather than involving completely different processes, despite work considering the latter [29.32]. Although the perception and experience of emotions are intrinsically linked, increasingly refined theorizing and the proliferation of practical examples have taken the two categories in different directions. Here, instead, the intention is clarify the similarities between emotion recognition and induction processes in music by bringing the two into a framework that contains different levels of affects as well as series of mechanisms capable of producing them. This framework also attempts to locate the mechanisms within these different levels of affects.

The theoretical review of emotion models is organized with three explanatory levels of affects, starting from low-level core affects, proceeding to basic emotions, and ending with high-level, complex emotions. The first two levels refer mainly to processes involved in perception of emotions whereas the last one refers to induction of emotions, although this division risks oversimplifying matters. To help the reader interpret and keep track of the affect levels and how they are connected to mechanisms discussed in the next chapters, a schematic illustration of the key concepts is given in Fig. 29.1.

The left part of the illustration concerns the question of what the pertinent emotions are. *Affect levels* refer to distinctions between low-level sensed emotions (core affects), perceived emotions, and experienced emotions. This division corresponds approximately to the models of emotions conceived to date. The organization of affect levels as having low-level measurable properties capable of producing highly different conceptual interpretation is influenced by the hybrid model of emotions proposed by *Lisa Feldman Barrett* [29.33, 34]. In this model, the underlying physical machinery is best described by the dimensions (core affects) but the conscious interpretation of these is categorical, and influenced by the conceptual categories people have for emotions. The synthesis proposed here (Fig. 29.1) assigns different mechanisms of emotions to differ-

ent affect levels. This dynamic model claims that the way people use conceptual knowledge determines how they feel, and, due to variance in context, differences between individuals, and effects of high-level mechanisms, there is increasing variation in emotions at the highest complex and experiential level.

In the affective sciences in general, emotions have been theorized as organized along a few core dimensions (i. e., core affects), belonging to discrete categories (basic emotions), or having a complex, perhaps even a domain-specific structure. Each of these major descriptive schemes is applicable to music and will be explained in the three sections that follow.

29.2.1 Emotion Dimensions and Core Affects

A popular way to conceptualize emotions is to divide emotions into a continuum between positive and negative emotions. This dimensional approach, rooted in the work of Wilhelm Wundt [29.35], is best known as the circumplex model of emotions [29.8]. This bidimensional model assigns emotions as a mixture of two core dimensions, valence and arousal (hyphenated with A and V in Fig. 29.1), that represent two orthogonally situated continuums of pleasure-displeasure and activation-deactivation in the affective space. The circumplex model has received support in large studies of self-reported emotions [29.36], cross-cultural comparison [29.37], and psychometric studies (reviewed in [29.38]) and has thus been used in a large number of emotion studies in psychology as well as in systematic musicology. *Russell* and *Feldman Barrett* [29.34] have characterized the dimensions as *core affects*, to differentiate theirs from other dimensional models. The term *core affect* refers to the idea that such affects arise from the core of the body and in neural representations of body states. Core affects are assumed to present already in infants [29.39] and have psychological universality [29.40, 41].

Another way of expressing the dimensions of emotions has been to divide them into approach- versus avoidance-related emotions [29.42]. There have also been influential variants of the circumplex model such as the rotated circumplex model by *Watson* et al. [29.43] (titled Positive and Negative Affect Scale, or PANAS). *Thayer* [29.44] reorganized the arousal dimension into energetic arousal and tense arousal on the basis that separate psychobiological systems are responsible for energy and tension. Both formulations have been successfully applied to research on emotions in music [29.45, 46], but they remain, nevertheless, fairly unpopular in music research.

The main problem for any dimensional model is that emotions can sometimes be ambivalent [29.47, 48]. It is possible to feel both happy and sad at the same time, and indeed, empirical studies using tragicomic films [29.49] or music [29.31] seem to suggest that mixtures within the dimensions are relevant for emotional experiences. This problem is mitigated by postulating that such mixed emotions are co-occurring combinations of different activities within a dimension, or even rapid switching between the two [29.50].

29.2.2 Basic Emotions and Emotion Perception

Perhaps the most widely known way to organize emotions is to assume they are discrete categories, also referred to as *basic*, *primary*, or even *fundamental*. Such theories posit that all emotions can be derived from a limited set of innate and thus universal basic emotions, such as *fear, anger, disgust, sadness*, and *surprise* [29.51]. The actual number of categories and the label for the categories is still a source of debate, but the basic emotion model has gathered support from neural, cross-cultural, developmental, and physiological research spanning four decades [29.27]. Despite the popular appeal of such categories, doubts about their explanatory power has been raised, as, for instance, brain imaging studies have not yet delivered results consistent with the innate and distinct emotion categories [29.52]. In music, almost half of the studies focusing on emotions experienced have resorted to basic emotions [29.53]. This popularity is related to the fact that the categories are easy to use in emotion recognition studies, which are popular in developmental [29.54, 55] and production research [29.56, 57]. Similarly, when physiological or neural correlates of music-induced emotions are explored, basic emotions tend to be chosen [29.58–62], although this has started to change due to availability of emotion taxonomies made specifically for music-aroused experiences (described in the next section).

The dimensional and basic emotion models offer distinct ways to tackle musical emotions. However, when the two models are mapped onto each other in emotion expressed by music, the results have suggested that the models overlap considerably [29.63].

29.2.3 Complex Emotions and Emotion Experience

When people engage with artworks, or objects in nature, the emotional experiences are not easily explained as dimensions or discrete patterns of survival emotions [29.64]. Any fiction, including music, does not have direct material effects on the physical or psychological wellbeing of the individual in the same way that

events in everyday context do. This freedom of fiction to explore the expanses of the human mind rather than provide handy heuristics for reaction to the environment in everyday activities may expand the scope of possible emotions in fiction. It is perfectly plausible to think that emotions induced by music – or any art in general – are more contemplative, reflective and nuanced, or if we need to use one word – complex. A similar argument has been put forward to other complex emotions such as moral, social, or epistemic emotions that are not necessarily involved in everyday survival [29.27]. Such complex emotions are also more subject to cultural and social interpretations than basic emotions [29.41, 65].

In music, the desire to explain complex emotions has often been to topic of musicological writings [29.66, 67], but the empirical mapping of the topic began in the late 1960s, when *Kaarle Nordenstreng* [29.68] analyzed the structures underlying listener experiences across musical excerpts. A decade later *Edward Asmus* [29.69] carried out a large-scale study ($n = 2057$) of the affect terms relevant for music and proposed nine dimensions of affects accounting for the variety of emotion states. The decisive attempt to account for the emotional experiences induced by music was taken by *Marcel Zentner* and his colleagues [29.70]. They started with a comprehensive list of emotion terms relevant to music and validated these with iterations of surveys, and finally administered the refined lists to a festival audience. Next, the similarity between the terms was able to reduce the list into ten solid factors, which was further validated with separate ratings and confirmatory factor analysis. This final stage resulted in nine emotion factors, a model which is now known as GEMS (GEMS). The model emphasizes positive emotions (at least seven out of nine factors in the model) and provides factors particularly appropriate for contemplative emotions such as *wonder*, *nostalgia* and *transcendence*. For this reason, it fits well with the tradition of complex and aesthetic emotions, and it has been widely adopted in studies of emotional experiences related to music [29.71, 72]. It is worth noting that other proposals for the appropriate emotions induced by music have been offered as well, based on equally large samples of participants [29.73]. This proposal shares many of the factors of emotions such as *nostalgia*, *being moved*, and final differences may just be semantic and the final number of broad categories included.

To summarize, in this section I have discussed the previous models of music-related emotions and presented a new synthesis, outlined in Fig. 29.1. In this scheme, the low-level dimensional representations of core affects can be collapsed into basic emotion categories in perception of emotions using specific, well-known labels (e.g., happy, sad, etc.). However, at the level of experienced emotions, the conceptual act of labeling emotions is fundamentally modified by high-level mechanisms and modifiers as well as by language and culture. Therefore, the experiences as well as the labels applicable are different in emotion perception and experience. This fundamental difference between emotion processes and actual experience is of crucial importance here [29.33]. This perspective may explain some of the dissatisfaction scholars have had with the models designed to explain emotions as processes and objects of recognition (core affects and basic emotions) whereas others have declined to acknowledge the existence of music-specific emotions. The champion for the complex emotions is the GEMS model, but the differences between the complex and basic emotions becomes less of an issue if the differences in the processes are fully acknowledged.

29.3 Mechanisms and Modifiers of Emotions

The reasons and mechanisms of how a particular piece of music might express emotion or evoke particular emotions in listeners is not yet completely understood, although a coherent theoretical framework for experienced emotion has been proposed by *Patrik Juslin* and *Daniel Västfjäll* [29.74]. The individual mechanisms in this framework (dubbed as BRECVEMA according to eight mechanisms in a recent update, [29.75]) will, in this synthesis, be divided into four fundamental processes (physiology, embodied, memory, and appraisal), which are assigned to the different levels of affects described earlier. The purpose is to better acknowledge the interlaced nature of sensed, perceived and experienced emotions, and the thus emotion mechanisms follow the logic of the previous chapter and the diagram outlined in Fig. 29.1.

This reorganization also implies that the boundary between perceived and experienced emotions with respect to emotion mechanisms are redefined, since the BRECVEMA framework only applies to experienced emotions. However, several of the low-level mechanisms (e.g., contagion, entrainment) are appropriate also for emotion perception and by bringing these two closely related processes to the same scheme, the mechanisms previously applied only to induction may help to understand emotion perception principles. This de-

cision is also motivated by the current lack of suitable mechanisms to explain the way emotions are mapped across domains (e.g., visual, auditory). In such processes, the concept of contagion is actually dependent on recognition of the actions giving rise to emotion experiences.

Again, we start with the low-level mechanisms for emotion perception before moving on to higher-level mechanisms of emotional experiences (the right side of Fig. 29.1). The issues that are known to modify the emotion processes in music are also incorporated into this summary of mechanisms.

29.3.1 Mapping Mechanisms of Emotions

In this synthesis of the mechanisms, the BRECVEMA framework can be interpreted to have two low-level *mapping mechanisms*. These are mapping mechanisms between sound and emotion, as direct transfer – mapping – between sound and affect seems to take place. Two categories of mapping mechanisms can be distinguished. The first of these, labeled as *orientation mechanisms*, consist of the brain stem reflex, expectancy and entrainment. The brain stem reflex is hardwired attention response that is activated by any exceptional – loud, sudden, sharp, accelerating – sound, which not only directly influences core affects (e.g., increase in physiological arousal) but is also recognized as surprise and may be experienced as unpleasant or exciting [29.76]. Another orientation mechanism is expectancy, where any violation (pitch, tonal, rhythmic) of the expected musical structure creates an orientation response at the core affect level, which may be interpreted in different ways; violation of the expectations has been observed to lead to anxiety [29.76], surprise [29.77], or even to thrills [29.78]. Entrainment refers to adjustment – though not necessarily synchronization – of the internal oscillators to rhythmic periods in the music. Entrainment itself may be conceived as a multifaceted phenomenon since it can refer to perceptual, motor, physiological, or even social entrainment [29.79], which may each have different implications for emotions. For instance, motor entrainment has been shown to modulate pleasantness [29.80], but social entrainment has been judged to induce feelings of being connected [29.81]. The entrainment mechanism also facilitates orienting and attending to information in music. For this reason, entrainment acts as an attentional focus that may be capable of enhancing the delivery of other mechanisms and emotions in music. In summary, these three orientation mechanisms (brain stem reflex, expectancy, and entrainment) act as strong guides for perceptual processes and attention, are considered to be low-level processes, and often lead to changes in core affects (arousal in particular).

A second set of relatively low-level mechanisms, including contagion and visual imagery from the BRECVEMA framework, are in the synthesis presented here (Fig. 29.1) defined collectively as *embodied* mechanisms. These are embodied in the sense that they refer to reactivation of past sensory and motor mechanisms [29.82–84]). This perspective considers that the body plays a major role in all interactions with environment, and that any response to stimuli will be based on simulations, or reenactments, of others' nonverbal expressions and affective states [29.85]. Such mappings arise within expressive channels, such as matching another person's facial expressions or vocal intonations [29.86], but also across channels (between audio and visual [29.87]).

What makes contagion as a mechanism particularly relevant for embodied explanations is that it is assumed to consist of a process in which the *listener perceives the emotional expression of the music, and then* mimics *this expression internally* [29.74, p. 565]. Taken further, this must mean that most basic emotions are linked to specific bodily reactions and motor patterns that have been influenced by the production or causal results of experiencing that emotion. Because of built-in codes based on states reflecting the emotional experiences or its output (movements, expression, sounds, gestures of such states), an internal mapping between an external stimulus and our representation of the possible cue combinations is possible in contagion. If we take the example of fear, the peripheral nervous system in fear is associated with increased levels of glucocorticoids and norepinephrine [29.88] that lead to states of alarm that quickly raise autonomic arousal, which in turn leads to louder vocal output, higher pitch, brighter timbre and faster movements than in neutral state. These sets of cues, which are very similar in music and speech [29.89], are grounded in physical changes caused by underlying emotion states, in this example by fear and an ensuing state of stress, which affects said individuals' vocal expression, posture, facial expression as well as movement. Knowledge of this multimodal code allows us to decipher the intended emotional expressions, and this knowledge is assumed to be implicit and accessible by embodied simulation (*what would I feel like if I sounded like that* ...). Even when merely activating some of the motor programs used in simulations, we may catch the same emotions, or at least, our emotional reactions may be amplified [29.82].

Another mapping mechanism, visual imagery, may also be associated with embodied processes, since cross-modal correspondences are thought to occur in music [29.90] and in other domains [29.91, 92]. Vi-

sual imagery is believed to generate emotions through such correspondences. Whilst the exact mapping in this mechanism has not yet been pinned down, it is assumed to be related to metaphoric representations [29.93] that are tightly coupled with physical dimensions [29.94].

29.3.2 Evaluative Mechanisms of Emotions

In addition to the low-level automatic mechanisms of emotions, a set of high-level, largely conscious and intentional mechanisms are included in the BRECVEMA framework. In the synthesis, these are cataloged into *memory* and *appraisal* mechanisms. The BRECVEMA framework includes two mechanisms related to memory, *episodic memory* and *evaluative conditioning*. In the latter, a repeated pairing of a particular music or sound example with either a positive or negative stimuli or outcome leads to a conditioned emotional response. This can be either automatic and unconscious or conscious. In music, leitmotifs associated with particular heroes and villains may be the best example of this mechanism, and empirical work on conditioned responses to sounds have demonstrated the malleability of such conditioned responses [29.95]. *Episodic memory* as a mechanism for emotions refers to a recollection of a specific event prompted by the music. This might lead to an emotional experience that could be strikingly different from the emotion expressed by the music. For instance, in recent study, a sad musical expression was turned into happy emotional experience by inserting a short quotation from the Star Wars theme into the sad solo cello piece [29.76]. This mechanism, known also as the *Darling, they are playing our tune* phenomenon [29.96], is a potent mechanism for emotions, as autobiographical memories have been identified as the most frequently listed motive for listening to music [29.73], and, of course, the most essential mechanism for nostalgia [29.97].

Another set of mechanisms, here referred together as *appraisal mechanisms*, consists of three distinct categories: cognitive appraisal, identity confirmation, and aesthetic judgment. Cognitive appraisal is a process in which emotion is the cause of an event regarded to have significant implications for the goals of the individual [29.98]. Though this mechanism is not explicitly included in the BRECVEMA framework, it does function as a bridge between the appraisal theories of emotion [29.99, 100] and their successful use in explaining responses to arts [29.101]. Moreover, the appraisal processes, such as novelty check, goal relevance, goal congruence, and coping potential, can be considered powerful moderators of emotions [29.102]. Mechanisms labeled as *identity confirmation*, although not put forward as a category in the BRECVEMA framework, refer to the potential powerful social effects of music as carrier of self-identity [29.103, pp. 73–74] (see also [29.104]). *Juslin* et al. [29.73, p. 190] found this mechanism to be the second most important explanation of emotional episodes associated with music, yet it remains currently unexplored. The third appraisal mechanism is *aesthetic judgment*, which is simply an evaluation of the aesthetic value of music. Such evaluation may comprise initially of an aesthetic attitude [29.105], but may also comprise multiple criteria, including beauty, skill, novelty, and artistic intention [29.75]. This recent extension to the BRECVEMA framework is considerably broader than the other mechanisms.

To recapitulate the sections on affect models and mechanisms, let us go back to the theoretical synthesis (Fig. 29.1) once more. Here I will take one of the most ubiquitous hits of music and emotion studies as an example, the *Adagio in G minor for Strings and Orchestra* by Tomaso Albinoni, which has been used at least in 16 published studies, despite the probable and dubious associations such frequently heard musical piece might carry. In terms of core affects, it is fairly clear that the slow tempo, soft timbres, low dynamics, legato articulation, and gradually descending melodies lines mimic low arousal state, and perhaps even negative valence due to multiple cues consistent with sadness [29.106]. In this case simple mapping mechanisms such as contagion, entrainment, and expectations support interpretation of the music as calm and low-arousing, due to musical qualities such as predictability and ease of synchronization. Core affects could be measured through psychophysiology, self-reports consisting of dimensions, or by asking the listeners to rate what the music expresses in terms of basic emotion categories. This would most likely lead to the assessment that the piece expresses *sadness* [29.107], and perhaps tenderness. No surprises here, although such ratings of perceived emotions would be subject to minor modifications based on current mood, situation, personality traits and music preferences.

However, it is informative to consider what happens when attention is shifted to the emotions experienced when listening to the Adagio. In this case, appraisal and memory mechanisms kick into play, which may lead experienced emotions to differ markedly from perceived emotions. For example, somebody hearing the Adagio for the first time in a particularly receptive situation (say, in a cathedral when attending a memorial service) might experience the emotion as being *moved*, whereas another listener highly familiar with the piece might experience *nostalgia* due to fond recollections of past performances of the piece. For others, the ap-

praisal mechanism related to aesthetic judgment might steer the experience towards feelings of *wonder* due to the sheer beauty of the piece and aesthetic appreciation of the classical music canon. These trajectories of how the emotional experiences and their labels may systematically – but not arbitrarily – change across the levels of affects are illustrated in the schematic outline (Fig. 29.1). It is worth pointing out that many of the shifts between perceived and experienced emotions caused by the memory and appraisal mechanisms lead to more positive experiences. This *positive pull* is likely to be related to the fact that music does not have an obvious material effect on the listener's well-being; it is voluntary activity that offers a medium in which listeners can safely project their emotions. Taken further, it also implies that the experience of intense emotion of any kind may be inherently pleasurable, as long as the emotions do not come with any real-life consequences attached. The best example of the positive pull is sad music, easily recognized as such by the listeners [29.108], but usually experienced as positive, perhaps involving feelings of peace, tenderness, nostalgia, or being moved [29.53, 72].

The purpose of the concurrent presentation (Fig. 29.1) of affect levels and mechanisms in the present synthesis is to emphasize that the mechanisms together with the modifiers may lead to entirely different experiences, and that core affects, perception of basic emotions, and experienced emotions represent different yet connected explanatory levels of these processes. While the mechanisms themselves undoubtedly have a major influence on shaping the emotions, there are other factors that are known to influence emotions in particular ways, here termed as *contextual modifiers*, which will be described in the next section.

29.3.3 Contextual Modifiers of Emotions

Emotions that are experienced are more likely to be influenced by matters relating to context, whether it is the music, listener, or situation. This idea has been formally expressed by *Scherer* and *Zentner* [29.109] as a multiplicative function between structure of music, performance, listener, and context. The multiplicative nature of this scheme has not been directly tested, which suggests that the entire topic of modifiers has been considered of secondary importance in music and emotion research. Nevertheless, some contextual modifiers have been explored.

Starting with the music itself, music and emotion studies have mainly been conducted in Western art music contexts, utilizing highly educated Western listeners in particularly restricted situations (mainly laboratory settings, see [29.53]). The context created by music itself, its genre, lyrics, and cultural connotations, is perhaps the most obvious modifier of emotions. Musical devices expressing emotions vary across musical genres, periods and cultures. Despite the apparent differences in musical materials, the role played by culture in musical emotion has been considered only a modifier on emotions since it has been shown repeatedly that the basic emotions in music can be recognized across cultures [29.108, 110]. However, complex emotions and experiences appear to be more dependent on cultural knowledge since they rely on aesthetic judgments, memories, and identify formation, which all require learning and exposure to the music. This raises a more fundamental issue, which is that different genres of music have widely different functional uses. In the present synthesis, an attempt has been made to capture this issue, through the notion that situations may alter the perception and experience of emotions, and that this may be more fundamental than a mere contextual modifier. Not all emotion concepts are relevant for all types of music, and for this reason even some of the core affect dimensions (e.g., valence) have been shown to be problematic when applied across different music genres [29.111]. Moreover, when large stimulus sets provided by social tagging of music are harnessed for computational analysis of emotional expression, it has been found that contextual information such as genre brings significant improvements to prediction of emotions [29.112]. Contextual information is also known to affect perception and experience of emotions. For instance, extra-musical information intensifies [29.113], lyrics both enhance and subdue [29.114], and images amplify [29.60] the emotional experiences aroused by music.

Individual traits, moods, expertise and preferences of the listeners also modify emotions. At the broadest level, culture does contribute to the emotions since traditions, customs, and musical genres are byproducts of subcultures. As most music and emotion research has been conducted on Western listeners, there is a need to expand the sphere of investigation outside this realm (e.g., [29.115]). Of the other modifiers to emotions, musical expertise has been suggested to either amplify [29.116], or have little effect on both perceived [29.117] and experienced emotions [29.70]. Personality traits have been shown to have a small but consistent moderator role for both experience of emotions [29.118] and perception of emotions [29.119]. Music preferences and motives for listening to music also have a small but systematic impact on emotions [29.73, 116].

A number of situational factors seem to affect perception of emotions in music but many of these are particularly important for experiencing emotions. Everyday music listening studies [29.120, 121] have shown

that variations across listening contexts – whether at home, at a laboratory, on public transport, or with friends – have an effect on which emotions are likely to be experienced. These differences may not relate only to the situations themselves, but also to differences in emotion regulation goals afforded by the situation. For instance, a gym affords increase in arousal whereas a church has an entirely different set of functions, not only because these places differ acoustically. Finally, the most complex situational modifiers arise from the social dynamics of the situation. For instance, whether a listener is alone or in a group [29.122], and the opinions held by others in the group, both of which are known to affect emotions aroused by music [29.123].

29.4 Measures and Musical Materials

29.4.1 Self-Report Measures of Emotions

Most of the research on music and emotions relies on self-report measures such as Likert ratings and forced-choice designs meant to capture the emotions representing the affect models (dimensions, basic, or complex). There are numerous standardized instruments for collecting mood and emotion evaluations (such as Positive and Negative Affect Scale – PANAS, profile of mood states – POMS, and self-assessment manikin – SAM, or differential emotions scale – DES, etc.), which have been reviewed in detail elsewhere [29.124]. All self-reports measures are subject to caveats and limitations. These often relate to the confusion between perceived and experienced emotions, which can be difficult for participants to dissociate, or more generally to the demand characteristics of such methods, in which participants are biased towards complying with the inferred outcome. Despite these caveats, the standardized measures are efficient and convenient, but may either assume too much about the underlying experience or rely on specific semantic labels. Therefore it is also useful to probe experiences with open responses [29.125], interviews [29.103], and nonverbal measures such as similarity ratings [29.117]. Another way to qualify the emotions experienced is to collect peripheral and indirect measures of emotions.

29.4.2 Peripheral and Indirect Measures of Emotions

Peripheral measures of emotions, such as skin conductance response (SCR), heart rate variability (HRV), facial electromyography (EMG), respiration, and temperature have become increasingly common in studies involving experienced emotions [29.76, 126, 127]. These indicators are well established in terms of the underlying physiology and emotional correlates (reviewed by [29.128]). In research focusing on strong responses to music, it has become customary to record chill reactions [29.129, 130]. Such physiological measures are not always sensitive enough for the emotional experiences examined [29.59, 131], although they do track arousal adequately [29.127]. In addition, there are other behavioral ways of discovering whether the emotional experience is actually taking place, including indirect measures and reaction times, both of which rely on the fact that emotional experience biases cognitive judgment in a systematic fashion. For instance, a sad individual interprets ambiguous faces to be more negative and processes incongruent (e.g., happy) information more slowly than a nonsad individual. Therefore, indirect measures can be used to assess whether listeners are experiencing a negative or positive emotion [29.113], despite the considerable limitations such sensitive measures have. The three levels of affect outlined earlier (Fig. 29.1) are not all accessible with peripheral measures of emotions. Core affects may be measured with physiology, and with some caveats, the basic emotions might serve as good targets of physiological measures if the question is really about emotional experiences rather than emotion perception. Measuring complex emotions with physiology may not be feasible unless one is interested in a very specific type of emotional reaction such as chills or extremely strong, aesthetic reactions.

29.4.3 Neural and Endocrine Measures of Emotions

Measuring brain activation has become increasingly common in emotion studies, although the purpose is often not to verify the emotions experienced or perceived, but rather to pinpoint when and where processing take place. In this, electroencephalography (EEG), magnetoencephalography (MEG), and functional magnetic resonance imaging (fMRI) are the key techniques, with EEG and MEG indicating electric activity, and fMRI indicating blood flow and blood-oxygen level, both of which index the underlying brain activity. fMRI is accurate in terms of the location of the neural activity but imprecise in timing. Therefore, fMRI studies have revealed which areas are involved in emotion experiences [29.130, 132] and perceived emotions, in terms

of stimulus valence [29.133–135]. However, discovering where emotional information is processed is not the main aim of such studies as the real insights come from functional explanations of what each area of the brain area is responsible for. Such explanations allow us to associate the areas in question to plausible mechanisms. For example, a part of the limbic system called the amygdala, which itself has further specialized areas, is known to be relevant in detecting dangers and fast processing of visual information, as well as being able to code the core affect of arousal [29.136]. In neuroscience studies of music, the amygdala has been shown to be heavily involved in processing of strong emotions, such as chills, but also in strong negative stimuli, demonstrating that it captures the intensity of the stimuli [29.137]. In addition, the anterior cingulate cortex (ACC), an area involved in autonomic activity, is often implicated in music and neuroscience research. This could be taken as another index of core affects, but such activations may take place due the involvement of this area with movement and motivation.

Other brain areas such as ventral striatum and anterior insula have been associated with pleasure induced by music [29.138], which in more general terms has been connected to reward-related brain areas that regulate the release of dopamine in the brain (demonstrated by [29.139]). In research connecting brain areas to emotion mechanisms, the amygdala and ventral striatum have been associated with low-level mapping mechanisms as well as the outcomes of the emotions via higher-level mechanisms. In addition, there are more specific areas related to memory mechanisms such as the hippocampus. The anterior hippocampal formation has been observed to display activity changes in a numerous music studies [29.132, 140], and this area has a crucial role in learning and memory, as well as in expectation and the detection of novelty [29.141]. However, this is not to say that only musically induced emotions generated via memory mechanisms (episodic memory, evaluative conditioning) necessarily show hippocampus activation, as the hippocampus also serves as a switchboard between cortical and subcortical areas, and is thought to be involved in positive social emotions, and even in the experience of being moved [29.142].

In addition, studies of brain-damaged patients that demonstrate selective emotional impairments can reveal which functional brain areas are necessary for emotion perception and experience [29.143]. Electrophysiological measures (mostly EEG) have typically investigated valence as a core affect in association with music [29.133, 144, 145]. The results have shown that positive and negative emotions produce different hemispheric lateralization of neural activity; the right hemisphere is involved more during negative and the left during positive emotions. However, the results from these studies fail to paint a consistent picture, since the results tend to be dependent on the type of techniques employed.

29.4.4 Musical Materials

The availability of good-quality audio is nowadays virtually limitless, but the number of excerpts used in studies is usually limited by the length and feasibility of the experimental task. In behavioral studies that focus on perceived emotions, a large number of stimuli could potentially be used. Despite this, there are only a few exceptional cases where the number of stimuli utilized in a music and emotion study is truly large: for example the several thousands of music examples used by *Schuller* et al. [29.146]. Online annotation schemes based on self-reports have typically produced larger datasets than laboratory experiments, with up to 500 music excerpts in some cases [29.147]), but this may be at the expense of audio quality, listener attention, and overall control.

Crowdsourcing is one way of harnessing the power of the masses, often through implementation of online annotation games [29.148, 149]. It has been suggested that crowdsourcing seems to yield data of similar accuracy to that generated by expert annotations [29.150], since the sheer volume of data compensates for variation between participants and evaluation settings. Another way of obtaining large amounts of ecologically valid information pertinent to perceived emotions is to tap into social tagging services such as *Last.fm* or curated databases such as *I Like Music*. The data in these services contain, among other things, user-defined *tags* for each music track. The tags may represent genres, preferences, and situations, but a significant proportion of them relate to emotions. For this reason, the collections of tags in these services have been used to build emotion models [29.112] and to connect the emotions to musical and acoustic properties of the music [29.151]. For music and emotion research, these massive datasets have tremendous potential for formulating predictive models, and also for connecting the everyday uses of music to situations, emotions, and individual profiles of listeners (such as age, gender, music preferences, musical expertise and personality). The validity of emotion structures inferred through analysis of such noisy folksonomies remains, however, to be determined in a rigorous comparison of these and carefully constructed psychometric laboratory studies.

29.5 Current Challenges

The topic of music and emotions in systematic musicology faces several challenges, many of which have been acknowledged for some time [29.53, 75, 152]. Perhaps the most important challenges to meet concern the widening of research contexts, both in terms of culture and music listening situation, as this could lead to significant revisions of the main concepts in music and emotion research in the near future.

29.5.1 Widening the Research Context

The majority of music and emotion studies have been carried out in Western countries and amongst particularly elite groups of people (affluent, young college students) using music from a narrow repertoire (classical, jazz, and film soundtracks). It is clear that the range of people under investigation should be broader. This could mean cross-cultural studies; however, such research is increasingly difficult due to the effects of continuing globalization. Nevertheless, useful tests of generalizability of findings can be performed within different cultural practices, regions, and subcultures found in the West, and by turning attention to representative rather than convenience samples.

Another challenge for the field is the applicability of the results to situations in which music is listened to. Most studies in this field have been conducted in laboratory settings [29.53], which is unlikely to be an environment conducive to complex emotional experiences. This is particularly the case if memory and appraisal mechanisms are tightly controlled, such as when listeners are exposed to unfamiliar music that does not fit their musical identities. Although such an artificial setting is not entirely problematic for studying perceived emotions, it is likely to suppress experienced emotions to some extent. One solution is to tap into the listening activities and emotion of listeners with the experience sampling method (ESM, [29.120]), which can now be directly incorporated into smartphones [29.121]. This method, coupled with relevant information about music, environment, individual features and current activities, can lead to significantly more realistic research settings.

29.5.2 Narrowing Down the Causal Influences

Only a small minority of music and emotion studies have attempted to establish causal links between musical features and emotions perceived or mechanisms and the ensuing emotions. In order to understand how low-level mapping mechanisms contribute to contagion, entrainment, or expectancy mechanisms, factorial manipulations of key musical features are indispensable. This line of research was started in the 1970s [29.30] but has not taken hold in the field despite promising studies on production [29.56], analysis-by-synthesis [29.153], and synthetic stimulus creation [29.154]. With the formulation of emotion induction mechanisms [29.74], cause and effect has been established between some emotions and mechanisms [29.76, 155], but a great deal more has to be done in order to explain how music is able to generate emotions through separate mechanisms at different levels of explanation. The synthesis provided in this chapter attempted to bridge the gap between the existing mechanisms of music-induced emotions, emotion perception, and core affects. The low-level processes involving recognition, physical characteristics and embodiment of emotions are necessary building blocks for high-level emotional experiences.

Most of the research in the field relies on retrospective ratings of emotions. Since both music and emotional experiences unfold in time, moment-by-moment fluctuations should be better incorporated into experiment design and theories. Although continuous self-reports have been used numerous times [29.129, 156–158], the approach has not yet provided full insights into the processes, perhaps because the modeling techniques are still unresolved. The most promising way to solve this problem seems to come from modeling the neural responses to music [29.159].

The topic of music and emotion has been undergoing a profitable expansion of themes, approaches and definitions during the last decade. As a topic for systematic musicology, it offers a rich *interdisciplinary* object of study that will benefit from close cultural and historical readings of the emotions in different eras, places, and subcultures, using methods ranging from strict laboratory experiments designed to tease apart the theoretical constructs, to experiments involving biological markers of emotions. Moreover, the technological advances that have altered the way music is being consumed and analyzed (such as music information retrieval), offer yet additional motivation and research tools to make progress on this topic in a transparent, empirical, and systematic fashion.

Part D

Psychoph

Part D Psychophysics/Psychoacoustics

Ed. by Albrecht Schneider

This part deals with sensation and perception of pitch, timbre, and loudness in humans, largely from a psychoacoustic perspective. The part is organized into four chapters. Chapter 30 covers fundamentals of psychophysics in regard to sensation and perception including some theoretical and historical background information (in particular on the concepts of Fechner and of Stevens) as well as a detailed discussion of the so-called *sone* scale and the *mel* scale, taken as examples for scaling of subjective loudness and pitch respectively. Also included in this chapter is a section on types of sound phenomena relevant for auditory perception, and in particular for sensation and perception of musical sound.

Chapter 31 addresses sensation and perception of pitch mainly from a functional perspective. Anatomical and physiological facts concerning the auditory pathway are provided to the extent necessary to understand excitation processes resulting from sound energy in the middle ear as well as within the cochlea. Place coding and temporal coding of sound features are viewed as two parameters relevant for pitch perception, in regard to frequency and period The Wiener–Khintchine theorem is taken as a basis to explain the correspondence between temporal periodicity and spectral harmonicity as two principles fundamental to perception of pitch and timbre. The basics of some models of the auditory periphery suited to extracting pitch from complex sounds either in the time or frequency domain is outlined, along with examples demonstrating how such models work for certain sounds. Sections of this chapter also address tone height and tonal quality as components of pitch as well as the rather dubious nature of the so-called tone chroma. Issues such as isolating tone quality from height (as in *Shepard tones*) and an alleged preference of subjects for stretched octaves are covered in a critical assessment. Section 31.6 on psychophysics includes just-noticeable difference (JND) and difference limen (DL) for pitch, the concept of auditory filters known as critical bands, the sensation of roughness and dissonance as well as special pitch phenomena (the *residue* and the missing fundamental, the concept of virtual pitch, and combination tones). Another section covers spectral fusion, Stumpf's concept of *Verschmelzung*, and the sensation of consonance. Further, there are sections on categorical pitch perception as well as on absolute and relative pitch followed by a brief survey of scale types, tone systems and intonation. The chapter closes with a section on geometric pitch models and some basic features of tonality in music.

Chapter 32 deals with perception of *timbre* or *sound color*. Both concepts can be distinguished by terminology as well as their historical and factual background, even though both relate to some common features for which an objective (acoustic) basis exists. Sections of this chapter review, in brief, developments in (traditional and electronic) musical instruments as well as in research on timbre and sound color. Section 32.2 on sensation and perception of timbre offers a retrospect on classical concepts of tone color or sound color and reviews some modern approaches from Schaeffer's *objet sonore* to semantic differentials and multidimensional scaling. Taking a functional approach, acoustical features (such as transients and modulation) and perceptual attributes of timbre as well as interrelations between *pitch* and *timbre* are discussed. In a final section, fundamentals of sound segregation and auditory streaming are outlined. For most of the phenomena covered in this chapter examples are provided, including sound analyses obtained with signal processing methods.

Chapter 33 is on sensation of sound intensity and perception of loudness. Since some of the relevant matter (on scaling concepts of loudness) has been presented in Chap. 30 of this part, and because a considerable portion of research on loudness is done outside musical contexts (namely, in industrial and environmental noise control as well as in audiology), this chapter condenses facts and models more than the previous ones on pitch and timbre. Section 33.1 offers physical and physiological bases for sound intensity sensation while Section 33.2 discusses features of some models of loudness sensation that have been established in psychoacoustics over the past decades. Since these models originally were designed for stationary sound signals and levels, and have been tested mostly in lab situations, they could not adequately cover a range of real-world sound types found in natural or technical environments. Section 33.3, therefore, discusses features of sound material contained in techno music productions and presented, for example, to audiences in live music clubs at very high sound levels, which calls for measurement of relevant sound parameters (such as the rate of energy transmitted by pulse sequences embedded in music) as well as an appropriate assessment of sensory effects. Different from perception of pitch (where samples of subjects respond more or less in similar ways to certain types of sound signals), perception of loudness shows a high degree of variability even within groups of musically trained subjects reflecting their musical background and preferences. Finally,

there is a concluding section in which recent empirical evidence demonstrating that subjects judge loudness for various musical genres on an ordinal category scale (from very soft to very loud) is presented. However, the range for such scales and the absolute sound pressure levels that correspond to certain categories differ widely among subjects, calling into question the concept of a unitary scale for loudness (such as the *sone* scale).

30. Fundamentals

Albrecht Schneider

This part of the handbook deals with sensation and perception of pitch, timbre, and loudness in humans, largely from a psychoacoustic perspective. Since there is broad range of publications available on subjects such as hearing (including anatomy and physiology), psychoacoustics as well as signal processing in relation to perceptual modeling (for comprehensive summaries see, e.g., [30.1–12]), it would be quite difficult, if possible at all, to condense relevant matter that has found detailed discussion elsewhere so as to fit into one part of this handbook. Rather, the approach taken here is selective such that phenomena that have found extensive treatment in works on psychoacoustics and audio processing (e.g., masking) will only be briefly addressed while a number of aspects usually given less attention shall be included. The perspective chosen aims at presenting facts and models but also turns to theoretical and methodological issues deemed necessary to understand lines of development in research. To this end, Chap. 30 of this part addresses fundamental concepts such as sensation, perception, and apperception. Since such concepts have been developed in a long process of research, and from certain philosophical backgrounds, it seems adequate to refer to at least some of the discussion found in disciplines such as philosophy, psychology, and neuroscience with respect to epistemology and research strategies. Further, ideas that are of special interest in regard to the history of psychophysics and in particular concepts developed by Theodor Fechner and Stanley Stevens are given a critical examination. To illustrate certain facts or problems, examples are provided (such as sound analyses or other empirical data). Though music perception in humans seems to be unique with respect to the involvement of cognitive factors, in research involving sensation and perception (e.g., of pitch and loudness) reference must also be made to other mammals we share basic anatomical, physiological and neuronal structures and functions with [30.13, 14]. Sensation and perception of pitch and timbre basically is viewed as a functional relation between certain types of sound and processing of sounds within the sensory organ as well as on several levels along the auditory pathway (AuP). Functional in this context means that sensations and perceptions in general can be related to features inherent in sounds and that, notwithstanding variability in capabilities and performance among individuals, a relation of cause and effect holds that permits us to assume intra-individual as well as interindividual similarity and consistency of sensations and perceptions for the same set of stimulus conditions. At least it seems reasonable, as a working hypothesis, to assume the same objective causes will provoke similar effects, in human subjects, within a certain range.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_30

30.1 Theoretical and Methodological Background

Dealing with perception and cognition presupposes decisions as to epistemology and methodology. Over the past decades, there has been an intensive discussion in philosophy, psychology, and neuroscience, as well as in areas such as artificial intelligence, concerning fundamental issues like: is there any justification for separating the physical brain and its specific functions from intellectual capacities subsumed under the heading of *mind*? What is the relation of neural brain states to our experience of *consciousness* and *self-consciousness*? What exactly constitutes a *mental representation* of something? How is cognition accomplished in regard to complex tasks such as production and understanding of language or music?

30.1.1 Realism, Naturalism, Reductionism, Empiricism

A review of ongoing debates on, for example, monistic or dualistic approaches to brain and mind is beyond the scope of the present article. For in-depth treatment of central issues in philosophy, psychology and cognitive sciences, the reader is referred to publications such as [30.15–24]. We may, however, briefly address four basic concepts that have played a major role in almost all discussions of brain/mind relations as well as in regard to fundamentals of perception and cognition. These four concepts can be stated as:

1. Realism
2. Naturalism
3. Reductionism
4. Empiricism.

Realism

Ontological realism accepts there is a material world that exists irrespective of human perception and consciousness. This world contains a manifold of things including plants and animals that make up types of environments. Humans are one species (Homo sapiens) of primates living in various environments. Things have properties (e.g., solids have a mass and a density). Epistemological realism holds that humans are capable of gaining valid and reliable knowledge of things existing in this world as well as of physical, chemical, and biological processes governing nature in all its aspects. The basic ontological assumption that there is a physical world independent of the mind is idealistic since, according to *Rescher* [30.25, p. 115],

> *ultimately, it does not represent a discovered fact, but a methodological presupposition of our praxis of inquiry; it is not constitutive (fact-descriptive) but regulative (praxis-facilitating).*

While *naïve* realism guides much of our everyday experience of the world, *critical* realism seeks for principles that make coherent experience possible for individual subjects, on the one hand, and that limit our knowledge derived from such experience, on the other. For example, knowledge based on experience beyond the single case is achieved by prototyping and categorization [30.26]. Experience involves identification of things or objects presented under varying conditions as being *the same* or belonging to *the same category*. Critical realism concedes, however, that perception and even sensation, which is at the base of much of our experience, can incorporate subjective factors (giving rise to the variance found in the data from samples in experiments on sensation and perception).

Naturalism

Naturalism holds that this world (and also the universe) is governed by natural laws that are discovered by science, and suited to explain things that make up the world as well as their relations and functions. Hence, valid and reliable knowledge is as such based on natural laws and acquired by the scientific method. In a long and ongoing process of inquiry, scientific research revealed that this world consists of many systems and subsystems, many of which are dynamic in nature (as is evident from, for example, the study of molecular genetics, or of relations between climate and vegetation). Conducting *systematic* inquiry according to scientific methodology, and thereby discovering the principal *systematicity* of nature, has led to results that also can claim systematicity in regard to coherence and explanatory power. As a consequence, naturalism (that either excludes or scrutinizes whatever is deemed *supernatural*) rests on scientific methodology comprising empirical observation, controlled experiments, measurement, and mathematical modeling. It has set the standard for research including disciplines such as psychology as well as major areas of sociology.

The *naturalist* approach common now in cognitive science and psychology, as well as in philosophy, proposes that our mind, and in particular phenomenal consciousness, ultimately rests on brain structures and their functions [30.19, 20, 22]. However, rather than taking consciousness as an epiphenomenon, one may view consciousness as emerging from increasingly more complex brain structures and processes in the course of evolution that led to Homo sapiens [30.27, 28]. To explain mental phenomena in terms of neuronal activity is

an attempt at overcoming the mind/body or mind/brain dualism. It should be noted, though, that even strong dualistic concepts such as advanced by *Karl Popper* and *John Eccles* [30.27] acknowledge that mental operations rest on brain states. The dualistic concept rather implies that there are certain states of the mind and processes of *mental activity* that as yet cannot be sufficiently explained in terms of brain states, and which, for the specifics of experiences addressed as *mental*, deserve to be studied from a psychic and intellectual point of view. In this context, the sphere of *intentionality* is a matter of debate. In regard to intentionality, subjects are concerned with analyzing and evaluating their experiences and motivations, they attribute meaning to things or persons, form opinions, have beliefs or have expectations, they can understand the double meaning of certain sentences or jokes. Though all such acts can, ultimately, be performed only because subjects have a brain, it is not quite clear how brain operations may lead to specific mental experiences usually subsumed under *intentionality* [30.29]. One will remember *Brentano*'s [30.30] notion of psychic objects for which *intentional inexistence*, that is, mental immanence, obtains. According to Brentano, in an act of conceiving something is conceived as an object, in judgment something is judged (as true or false), etc. While *outer perception* effected by means of sensory organs leads to seeing certain colors or hearing certain tones, *inner perception* involves the act of hearing (of which we become conscious) as well as conceptualizing phenomena so that they are *evident*. In this respect, the German term for perceiving includes judgment: the term *wahrnehmen* literally means to take something for granted and *evident* that has been perceived properly. To *Husserl* [30.31], the manifold of inner perceptions we can bring about and the experience of *evidence* is an implication of intentionality. Husserl maintained that psychic phenomena thereby can be distinguished from physical phenomena.

Within a naturalist and monistic approach, one would argue that the brain realizes neural states that somehow represent mental states, and that neural states can in principle account for intentionality, and for mental acts such as thinking, desiring, imagining. Also, it is common to adopt a third-person approach to mental phenomena and to avoid, for reasons of scientific objectivity, a first-person perspective as was often adopted in works on the philosophy of mind as well as in psychology when dealing with *phenomenal consciousness*.

There are various models of how *phenomenal content* can be represented. An issue that has caused major controversy is that of subjective experience of certain things or states as evoking a specific *quality*. From a monistic and naturalistic view, the existence of *qualia* beyond *the sum total of all the innate and learned associations and reactive dispositions* has been denied [30.15, p. 388], or has been turned into a problem of representational states [30.22]. However, the tendency of many subjects to include properties of *qualia* into their experiences can be explained within the naturalistic framework by a dispositionalist higher-order theory of phenomenal consciousness [30.20].

Reductionism

Reductionism is a basic strategy in science aimed at understanding complex systems by reducing, for example, the number of variables operative in a model or the number of dimensions representing a system. In this way, in acoustics, vibration of strings often is treated as if the string is a one-dimensional continuum (where an *ideal string* is assumed to be of extreme or even infinite length and so thin that string diameter is negligible when compared to string length). Further, it is assumed that elongation of each mass point of the string is very small (so that the restoring force also is very small according to Hooke's law, and vibration amplitude is a linear function of excitation force). Similarly, a number of cochlea models have been constructed as one-dimensional, and very small deflections of basilar membrane (BM) structures are assumed in order to maintain linearity for certain parts and processes where in fact nonlinear behavior can be observed already for medium sound pressure level (SPL), and more so for high SPL.

Reduction of complexity is a necessary step to develop heuristics for solving certain problems. In some philosophical and neuropsychological approaches to perception and cognition, however, reductionism has gained a different status. Obviously not the least because of disappointment with perennial epistemological disputes in philosophy, and confessing *eroded confidence in 'the grand old paradigm', a framework derived mainly from Logical Empiricism* [30.32, p. 546] since the days of Hume, prospects that current scientific endeavors such as cognitive neurobiology and neural network models might hold for the reductionist epistemology were considered more promising than the continuation of traditional discourses. One has to remember, in this context, certain developments and debates in areas that, taken together, would make up *cognitive science* (for details, see [30.33]). To name but a few of the central issues, there had been the brain/computer analogy and the metaphor of the mind carrying out procedures similar to operations of a computer program that were of consequence for conceptualization and heuristics since about 1950 [30.34, Chap. I,2]. Further, findings in neuroscience according to which cortical areas and other brain structures are

said to work like task-specialized neural *modules* seems to have inspired concepts that suggested the *modularity of the mind* as a functional equivalent to the brain. Also, models of neural networks (comparable, at least in principle, to operations found in neurons, cell assemblies and similar substrates) soon proved the usefulness of the *connectionist* approach. These developments all had their impact on attempts at establishing *neurophilosophy* as well as philosophically oriented neuroscience that seeks to overcome the dichotomy of brain and mind [30.16, 18, 35, 36]. Common to such approaches is to explain perception and higher-order phenomena of cognition on the basis of lower-order phenomena, and to take into account facts and models available from biology and neuroscience as well as from computing [30.17]. Processes pertaining to perception and cognition are thus addressed *bottom-up* from their natural foundations rather than along abstract principles. Such approaches have been labeled *reductionist* insofar as cognition is investigated and explained largely from a biological and also from a computational perspective (whereby *mental phenomena* might be *reduced* to representations of neural brain states). In line with both naturalism and reductionism is the thesis stating *that the function of cognition is to enable the agent to deal with environmental complexity* [30.37, p. 3]. In order to adapt to the environment in an optimal way, humans (and other mammals) had to develop their cognitive skills.

There are several approaches to reductionism that differ, among other aspects, in the way the monistic perspective is implemented. While, in a more radical perspective, some claim identity of mind and brain so that mind states are nothing but brain states (taken to be observable as such), others admit there are mind states that can be experienced by subjects, but which are *epiphenomena* derived from brain states. Still others suggest the sheer complexity of brain structures and processes can result in *emergent experiences* that are difficult to trace in neural substrates (an excess of unpredictable, creative brain activity has also been accessed in theories of *autopoiesis* as well as in ideas pertaining to *radical constructivism*). However, concepts of *emergence* besides self-organization also include the aspect of complex interactions between systemic components [30.21, pp. 114–116] giving rise to salient patterns that seem relevant for, among other areas, auditory perception.

Empiricism

Empiricism in regard to perception and cognition evolved from several different angles in the 19th century. Among relevant sources one will have to reckon sensualism as proposed by John Locke and the belief that knowledge for the individual results largely from experiences that make up an aggregate. Further, association psychology (as sketched by James Mill) and inductive logic as developed by John Stuart Mill became of importance for scientists like Helmholtz and Mach who both advocated empiricism in the study of sensation and perception. The paradigm developed by Helmholtz can be described under the heading of *experimental interactionism*. To Helmholtz, acquiring experience starts from elementary sensations resulting from the input received from peripheral sensory organs. In regard to vision (which he uses for example), however, we can control what we actually see by moving our head and directing our eyes towards certain objects. Such movements are effected by means of innervations, which in turn can be activated through volitional impulses. Hence, the observer can select by innervations and motor control what he or she perceives, and what becomes *present* from a given object or from a range of different objects of which we have a sequence of sensations. According to Helmholtz, directed observation is an active process suited to realize that, by willful innervations, sensations can be turned into perceptions where certain aspects or features become clear. To Helmholtz, a lawful relation exists between (willful) innervation and perceptual focus. Taking the example of seeing objects in a space, *Helmholtz* [30.38, p. 237] argued that each willful movement of our head and eyes constitutes an elementary *experiment* since it leads to changing the phenomenal appearance of objects and permits us to check whether we have correctly realized its distinctive features.

We all perform many such perceptual *experiments* in ontogenesis in order to build up experience. Also, repeated perceptions that contain features *typical* of certain objects leave traces in our memory. Further, *Helmholtz* [30.38, p. 233] pointed to a cognitive mechanism he at times has called *unconscious inferences*. According to this concept, current sensation leads to a perception that makes use of a sum of previous experiences (resulting in, for example, *prototypes* or other typifications/generalizations) stored in memory. The sum of such experiences constitutes what, in modern terminology, would be *implicit knowledge*; *Helmholtz* [30.39, p. 85] distinguished between *Kenntnis*, i. e., knowledge accumulated through experience, and *Wissen*, that is, verbalized knowledge. For example, sensing the sound of a trumpet may evoke the instant and perhaps unconscious inference in a subject that it is a *brass instrument* one has heard. In regard to empiricist methodology, the concept of *unconscious inference* can be taken as applying inductive generalization to perception [30.40, Chap. 3]. Helmholtz' concept implies that, due to an ongoing process of acquiring

experience in each subject, sensory input is likely to *trigger* inferences (from categories, prototypes, learned schemata, etc. stored in memory) that influence actual perception. Hence, as has been discussed with respect to loudness perception and other areas, the perceptual response to physical stimuli, though based on peripheral pickup of sensory data and processing along specific neural pathways, typically involves also cognitive structures [30.41]. Of course, empiricism also had consequences in regard to methodology. In psychology (including psychophysics, [30.42]) and in the area that would later become psychoacoustics, experimental investigations aiming at *measurable* attributes of sensation and perception (Sect. 30.1.4) were, from the very beginning, deemed necessary.

30.1.2 Sensation, Perception, Apperception, Imagination

Historically [30.43], Thomas Reid perhaps was the first to make a clear distinction between sensation and perception. Summarizing his ideas, sensation is viewed as causing a change in experience, while perception is said to include a conception of an object or a relationship that is perceived, plus the immediate and irresistible conviction of the existence of such object or of a spatial organization [30.44, p. 88]. From Helmholtz's writings as well as from works by Wilhelm Wundt and other psychologists of the time, a useful distinction between concepts becomes evident:

1. Sensation
2. Perception
3. Apperception
4. Imagination.

A short summary of central features of these four concepts is given here that serves also as an introduction to the next section where a functional model of sensation and perception is outlined.

Sensation

By sensation (German: *Empfindung*) typically a process involving sensory organs and addressing *the senses* (vision, hearing, etc.) is understood, which starts at the periphery (skin, eyes, ears, tongue, nose) with some physical and/or chemical stimulus and leads to a mechanical (as in our ears) or other excitation that is followed by a physiological reaction that in turn results in a neural signal [30.45]. Such a signal can immediately trigger a fast response (subcortical, e.g., brainstem reflexes) that usually includes some form of motor behavior or other action suited to prevent damage from sensory organs or from other parts of the body, and to adjust to a new situation. Sensations, which may start also from within the body (e.g., visceral sensations, headache) can, yet must not, rise to some level of awareness depending on the conditions of the stimulus as well as on sensitivity of the sensory organ and the ascending neural pathway (for which a threshold is assumed; Chap. 31). Sensations, which somehow correlate to the neurally coded pattern of stimulation/excitation, often include emotive coloring (e.g., sensation of a very loud sound may go along with affright or even horror). Sensation can be regarded as based on a direction outward → inward, that is, from peripheral sensory organs used for *stimulus information pickup* to processes within the central nervous system. In general, for the emergence of perceptions, circuits comprising receptors (sensory organs) and neural transmission lines to the central nervous system (CNS) are required [30.46, Chap. 14]; such circuits also can include effectors whereby the system responds to sensory input [30.47, Chap. 5]. In psychology and psychophysiology, it has been customary for a long time ([30.48, p. 273 ff.], [30.49, p. 30 ff.]) to categorize sensations as to their quality, intensity, duration, extension, etc. If a subject notices qualities and/or intensities, his or her sensations must entail some elementary categorization process. It has been argued at times that subjects are likely to become aware of peripheral stimuli if the level of excitation exceeds a certain threshold (so as to bring the sensation to the subject's attention). In this respect, a certain level in intensity of a sensation would give rise to a perception while low-intensity sensations would remain unnoticed. In psychophysics, researchers since the days of Weber and Fechner have drawn relations between the physical intensity of stimuli presented to sensory organs and the intensity of sensations (Sect. 30.1.4, *Historical and Theoretical Background*).

Perception

Perception in this respect is directed towards the *content* of the sensation whereby the specifics of this content are interpreted in regard to certain properties or features (*what* is it that has been sensed?). In a straightforward *realist* approach, the content of what has been sensed should be explainable in an unambiguous way since, in such a perspective, sensation of *something* is causally related to the nature of the stimulus and the transfer function of the sensory channel. This aspect will be discussed in regard to pitch perception in more detail in Chap. 31.

The faculty to perceive, however, can also be understood as a general activity of interacting with the environment to which our senses are directed. For instance, walking in a natural or in a man-made environment (comprising spatial and temporal order) with eyes

and ears open implies that we see very many objects as they enter the field of vision, and we hear sounds as they appear in a sound field. At this stage, perceiving means that we distinguish objects on the basis of their phenomenal appearance where we may identify certain objects along some salient features. For the proponent of a *direct realism*, perceiving (seeing, hearing) generates

> *immediate knowledge* [...] *which is not inferred from, or suggested by, any further knowledge, or any ground or basis for knowledge.* [30.50, p. 191]

Such knowledge can, yet must not, be verbalized. Perceiving as a quasicontinuous process means things in a field of vision or in a sound field are captured in what could be called first-order approximation, where things become perceptual objects (often for a short time only, in kind of a *frame-by-frame* mode) and are categorized in a rough or global access with little if any attention to details. One can address such roughly categorized objects as first-order percepts. However, even rough categorization involves judgment (and probably also some *unconscious inferences*). The *theater* where judgment pertaining to properties of things that are perceived as features of objects takes place traditionally is *the mind*; in line with current debates [30.20, 22], some stage of *phenomenal consciousness* can be assumed to account for these tasks. It was argued long ago that perceiving, in particular of visual objects, involves operations that in certain respects are similar to geometrical measurement (or at least to making estimates of geometrical properties) as well as abstraction. For example, the observer, after noticing some objects, accomplishes perception of them by correctly identifying relevant properties under varying, and often poor, conditions [30.51]. Within this process, cognitive evaluation is needed to facilitate and to complete perception.

Apperception

According to a model outlined by *Wundt* [30.52], perceiving as an ongoing process involves a steady influx of things to become objects of perception as they enter the field of vision or as they emerge (as events in a temporal sequence as well as in some spatial coordinates) in a sound field. From the perspective of an average viewer or listener, following a brief and global categorization, most of such objects disappear from phenomenal consciousness with the influx of new things or events. It is only if things or events become the focus of attention as objects of perception that phenomenal consciousness gains a detailed understanding of their structural organization. In such a situation, objects are singled out of a quasicontinuous sequence of first-order percepts in an active process that *Wundt* [30.52, p. 244 ff.] has described as *apperception*. It requires the viewer or listener to focus on a perceptual object with due attention whereby its *content* becomes clear in regard to structural composition and functional aspects. For example, the relational structure of tones and intervals making up complex chords such as used by Wagner in his *Tristan* will hardly be grasped in a situation where a subject is listening to the music as it is performed in an opera house. One can analyze such chords though by attentive listening to portions of recorded music in several runs with the aim of determining as many intervals (representing the relations between tones in each chord) as is possible. The results of the analysis, i. e., the number and topological structure of tones in a given complex chord can be visualized mentally, for example, by means of a two-dimensional (2-D) or three-dimensional (3-D) tone net (as to tone nets, see [30.53]). Also, one can label certain chords according to their tone and interval structure (e.g., *underseventh-ninth chord*). Similarly, listening closely to a melody or to several melodic lines interwoven in a polyphonic setting results in perceiving a *melodic contour* or several such contours each of which contains intervallic (diastematic) and temporal information. Such contours that can be graphically presented in a 2-D format (with *pitch* and intervallic relations on the ordinate, and time on the abscissa) are apparently perceptual objects whereby subjects conceive of melodic structures. *Wundt* [30.52] would have addressed perceptual objects such as melodic contours derived from analytic listening as *formations* (*Gebilde*), indicating that, on the one hand, a melody in fact does have an intrinsic structural property of order in regard to pitch and time, and, on the other, a subject attentively listening to such a melody will build a perceptual object of which he or she becomes aware of as a *formation*. To facilitate apperception, a subject needs a *mental representation* of features distinctive of an object that is thus apprehended (one may regard this process as a second-order perceptual approach). A *mental representation* understood both as a process and an entity resulting from the process is essential for apperception as well as for other cognitive operations. It can be characterized in certain ways (see also [30.54]). First, a representation typically is achieved in an active process of perceptual analysis involving judgment and also knowledge stored in memory. Second, though the basis from which analysis starts in general will be sensations (in this case, auditory), the final representation is the result of abstraction of which subjects become *aware* as such. The *content* of the object that is represented is mental, and may have the format of an *image*. Though the semantic field of the term *image* is quite wide (covering or alluding to meanings

such as *idea*, *conception*, *metaphor*, *picture*; [30.55]), it is central to an *image* to present or to re-present something. In this respect, the image of a melodic contour that we abstract from listening to a tune (say, *We shall overcome*) is a useful *format* for (mental) representation and memory storage of musical structure (also [30.56]). Visual imagery has been addressed as an efficient cognitive tool employed in learning and memory [30.57]. One important aspect of *representation* is that it can bring back certain objects and their content that resulted from previous perceptions and have been stored in some format in memory. Such objects are retrieved from memory (typically, long-term memory LTM) and are re-presented in a *mental state* that of course rests somehow on neural states. Third, since the process of abstraction *strips down* the sensory input so that structural and relational features are left over and condensed into a perceptual object, the *content* of this object serves as a model that represents essentials of the sensory input, and which also can represent (depending on conditions, see Chap. 31) properties of the physical stimulus. Perception includes not just categorization yet to some extent an interpretation of sensory data and even a tendency to *extrapolate* from sensory data in that perception, though based on sensory input, may lead to constructing, for example, *illusionary* objects as percepts. In regard to auditory perception, the Risset/Shepherd sound constructs of seemingly constantly falling or rising pitch (Sect. 31.1.2) is a good case in point.

Imagination

Auditory perception can go along with visual imagery whereby skilled musicians may form, for example, images of the score of the music they actually listen to. Imagery also is essential in conceiving of objects that must not necessarily exist in the environment but which could be imagined to exist (like the enchanted mermaid singing in the sea or some giant trumpets suited to produce a sound level that causes town walls to collapse).

30.1.3 Functional Model of Sensation and Perception

The basic relations of sensation to perception outlined in Sect. 30.1.2 can be condensed into a functional model (sketched also in [30.58, Chap. 4] and [30.46, Chap. 14]) that combines bottom-up and top-down processes. The source always consists of the environment that offers a wide range of (physical, chemical) stimuli, and of the mammalian body with its sensory organs capable of picking up such stimuli. Sensory organs work when a stimulus transmits a minimum quantity and intensity of energy needed for excitation. This means a certain energy transfer into the sensory system is required beyond a threshold to yield, as in the case of the ear, a mechanical and then a hydromechanical excitation that in turn will result in a physiological and neurophysiological response in the inner ear (for details, see [30.8, Chaps. 2–5]). At the core is a generation of sensor potentials and of action potentials as the result of electrochemical transduction processes that lead to neural spike patterns in the auditory nerve (AN) suited to code auditory-relevant information. Such information is routed *bottom-up* along the AuP and brings about auditory sensations, and also may evoke early responses to stimuli such as brainstem reflexes even before reaching the level of cortical sensory areas. In regard to auditory stimuli, it is likely that integration of incoming information and analysis as to stimulus features starts on a subcortical level (for which thalamic nuclei, in particular the medial geniculate body (CGM), have been addressed). Analysis of neural information on the CNS level, in regard to binding parts into more or less coherent objects and segregating objects from each other, involves previous experience and memory, that is, elementary or more complex top-down processes. In this respect, even a rough (and preliminary) categorization of incoming information in regard to stimulus features that might be compared to certain templates and prototypes activates processing beyond mere sensation. This level often is addressed as perception, for which at least some *lower* mental processes such as elementary comparison and categorization are needed; according to the distinction of *lower* and *higher* mental processes, the latter apply to cognition and for many tasks involve explicit knowledge that can, yet must not always, be verbalized. Acts of classification, though directed to actual stimulus features (e.g., timbres of musical instruments one hears at a certain moment), are supported by experience and knowledge. Access to previously stored information can remain implicit, especially in situations such as listening to music in a concert, which means quasi-*real-time* processing of sensory input and fast formation of perceptual objects on the basis of prototypes, schemata, etc. However, subjects can also draw on explicit knowledge (of which a subject becomes aware when making decisions and judgments) especially if they are skilled musicians. Further, even elementary categorization as well as subsequent detailed formation of perceptual objects can be influenced by motivation as well as by expectancies. In addition, perception of sounds almost always includes some emotive component, which is also an element in categorization and classification. Single sounds and textures of sounds are experienced as loud, shrill, dull, or as harmonious, smooth, etc. but also as joyous or frightening, as pleasant, soothing, etc.

As one may study in many situations and contexts, humans do not always experience clear demarcation lines between sensation and perception, on the one hand, and between perception and cognition, on the other. Among the reasons for such a crossover one has to reckon both the sheer amount of information from a broad range of (visual, auditory, olfactory etc.) stimuli that can affect our senses while the information processing capacity of each sense modality or *channel* is limited. For the auditory modality, the channel information capacity has been estimated as $K = 40\,000$ bit/s. Conscious processing of (auditory, visual, etc.) information by the CNS, however, is much more limited and may be as small as 100 bit/s or less [30.59, p. 156 ff.]. In many situations related to music and sound, density of flow of (auditory and often also visual) information is very high, hence processing requires significant reduction of stimulus information relative to only a few features or dimensions to maintain perception. Dimensional reduction is a typical response in perception to keep up with a heavy processing load or even total overflow of information per time unit, or with a heavy load of information that needs to be processed in parallel (the limits being largely set by the capacity of the working memory [30.60]). Of course, the use of templates and schemata helps in forming perceptual objects and in perceiving the relations between them. While templates even support elementary auditory perception (as will be discussed in regard to pitch perception in Chap. 31), learned schemata apparently play a role in understanding musical syntax in the process of listening [30.61, 62].

The sequence of processing that relates sensation to perception and cognition can be tentatively sketched in a block diagram (Fig. 30.1). Since hearing is the sense modality that is of prime interest here, the stimuli will be sounds (that may be combined with visual, tactile, or olfactory stimuli), and the relevant peripheral sensory organ of course is the pair of our ears.

Hearing is a complex process in which feedback loops are essential, and in which bottom-up and top-down mechanisms closely interact. Feedback circuits such as implemented in the brainstem reflexes and in centrifugal pathways [30.8, Chaps. 6–8] lead to adjustment of transduction parameters such as motility of the outer hair cells (OHCs).

30.1.4 The Measurement of Sensation

Historical and Theoretical Background

Psychophysics is a field of scientific study investigating the relations between physical stimuli and the sensations as well as perceptions evoked in subjects. Such relations are subjected to measurement (if possible), and are thus given quantitative formulations. The idea that even the *strength* of conceptions is quantifiable goes back to Johann Fr. Herbart and to the mathematician and philosopher Moritz W. Drobisch, who laid the foundations for a discipline labeled *mathematical psychology* [30.63]. In regard to empirical studies, Ernst H. Weber, a physiologist, had carried out experiments aiming at just noticeable differences (JNDs) in sensations of weight and touch. He found ratios of 39 : 40 (weights of two bodies lifted by hand) and 29 : 30 (sensitivity for pressure two different weights exert on a hand; [30.64, p. 546 ff.]) as differential thresholds. Weber said he himself had registered *many different degrees of sensation* to conclude that we must test our *innate instruments of sensation* just as a physicist is testing the sensitivity of his measuring instrument. Taking concepts from both Drobisch and Weber, Gustav Th. Fechner, a physician and physicist, offered a comprehensive treatise on fundamental issues of psychophysics [30.65]. He took off from the basic ques-

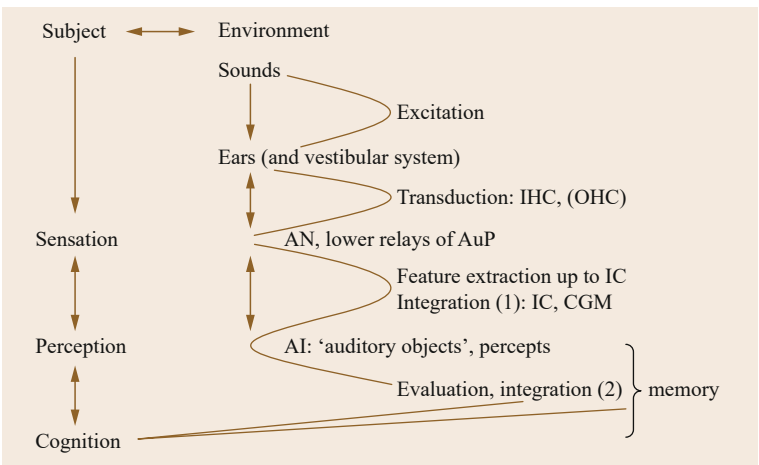

Fig. 30.1 Block diagram: main processing stages in hearing

tion: how does the human body relate to the *soul* (he still used this term), or, more specifically, how does the mind relate to our body? Fechner of course knew that the brain, like other parts of our body, is regulated by physiological mechanisms. However, as can be concluded from personal experience, human beings possess a *mind* capable of forming ideas and concepts, and of abstract thinking in general. Also, in addition to using our senses for whatever *information pickup* from the environment, we can perceive *certain* things as well as imagine things not observed so far (like the legendary unicorn). Such experiences led to the view of the mind being a sphere of its own; even if resting ultimately on brain functions, the *mind* is often regarded a superstructure based on, yet not reducible to, cortical functions [30.29]. This is the dualistic perspective that has been tackled by reductive approaches to the brain/mind gap (Sect. 30.1.1) leading to monistic theories [30.15]. Avoiding overt decision in favor of either *dualism* or *monism*, Fechner simply claimed a lawful relationship between physical stimuli, certain psychophysical functions (as embedded in the human body including the brain) and the sensations resulting from the stimuli. Hence, there is a tripartite relation of which stimulus and sensation are the endpoints that allow empirical investigation while the psychophysical operations (i. e., physiological and neurophysiological processes) activated by stimuli such as musical sound were not accessible to *direct inspection* (given the methodology and tools available to Fechner).

Fechner distinguished between outer and inner psychophysics whereby the former connects physical stimuli and sensations, and the latter would be concerned with specifics of the neural structures and activity underlying sensations and perceptions (as well as with a range of issues in regard to the fundamental relation of body and soul or body and mind Fechner was seeking to investigate). As part of inner psychophysics, *Fechner* [30.65, Vol. II] treats certain psychic conditions (e.g., attention, vigilance) and also memory phenomena such as after-images. Fechner's ideas on inner and outer psychophysics have been discussed in great detail, and have been used also for modern reformulations of psychophysics [30.66, 67].

The symbols ∩ and ◊ both denote measurement, however, of two different kinds. While physical stimuli in general can be measured in an objective way according to certain dimensions, parameters, and units that are well defined and accepted as such by the scientific community (as is, for example, the MKSA system), sensations are based on neural activity that, due to the complex distributed structure of the CNS, is difficult to measure. Accessible, though, are reactions of individual subjects that reflect their experiences relative to certain stimuli. What is measured, therefore, are stimulus parameters (∩) representing the physical *input* into a system that performs physiological and neurophysiological processing. The system output under certain conditions is accessible to measurement, or at least certain parameters can be measured and taken as indices of system performance; for example, the effect of very high SPL acting on dancers in techno discotheques can increase secretion of adrenaline as well as of acetylcholine that can be measured from blood samples. The extent to which sensations are measurable depends on modality, on the type of stimulus as well as on experimental conditions (as in measurement of pain, loudness, etc.). Quite often, the reaction of subjects is registered, which is taken to represent the sensation. The reaction itself can be measurable in a physical unit (e.g., pulse frequency (Hz) or skin resistance (Ohm) as in polygraphic recordings while a subject is listening to different types of music; also, reaction time (s) as an indicator of perceptual and cognitive processing complexity, etc.). Also, the sensation a subject might have, can lead to behavioral responses (e.g., facial expressions) recorded in an appropriate way. Further, reactions can be measured by asking subjects to mark the *intensity* or *strength* of a sensation using a scale offered by the experimenter. Such scales typically are ordinary, offering a number of alternatives that can be regarded as *degrees* of a sensation as experienced by a subject. Large samples of behavioral response data are gathered from such types of measurement (◊ in Fig. 30.2) that rest on subjective estimates and evaluations. Since, however, behavioral response data correspond in some way to the physical input it is possible to express the magnitude of sensation in terms of the input variables. For example, empirical findings demonstrate that, in techno discotheques, visitors scale subjective loudness into categories such as *moderate*, *loud*, *very loud* in correspondence with the increase of SPL measured in dB(A) or, more appropriately, dB(C). Hence, the scaling of relative loudness (Chap. 33) in this case can be tied to measurement of the *input* in a physical unit (indicated by an arrow from sensation to stimulus in Fig. 30.2). Expressing the *output* (magnitude of reactions of subjects) in terms of the

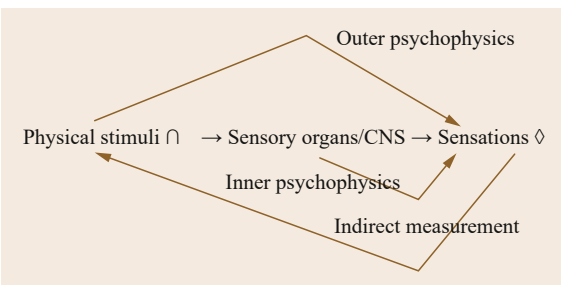

Fig. 30.2 *Outer* and *inner* psychophysics (Fechner)

input is one aspect of so-called *indirect measurement* of sensation.

Fechner foresaw difficulties inherent in the measurement of sensations [30.65, Vol. I, Chap. VII]. The main reason for concentrating on outer psychophysics was that stimuli and sensations are both accessible to empirical study. Fechner would have wanted to investigate neural brain states as well; however, there was no objective methodology available then (about 65 yr before human electroencephalogram (EEG) recordings, and more than a hundred years before positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) techniques were introduced). In a general form, outer psychophysics postulates that there is a lawful relation between a parameter S of a physical stimulus and a sensation E effected by S (via the receptor organs and internal processing) that can be expressed as a function $E = f(S)$. One parameter that had been studied even before Fechner was intensity (for the sense of touch, by *E.H. Weber* [30.64]). Applying $E = f(S)$, one could hypothesize that the sensation of loudness increases or decreases in proportion to the intensity of sound, which is defined as $I = p_{\text{eff}}\, v_{\text{eff}} = \rho\, c\, v^2$ ($p =$ sound pressure; $\rho =$ density of a certain medium, e.g., air; $c =$ sound velocity in this medium; $v =$ particle velocity). Hence, sensation of loudness can be expected to increase with rising sound pressure and increasing particle velocity. At least within the realms of classical physics, a common view is that exact measurement is possible for physical stimuli with parameters that can be varied along certain dimensions conceived as continua (so that, in theory, any value can be represented on a dimension between its minimum and maximum respectively). The notion of a *dimension* implies, in a strict sense, that such constructs must be quasicontinuous (consisting of differentiable elements), interval or ratio scaled, equipped with a well-defined or natural zero, and, as entities representing some acting parameter (e.g., a force of some kind), independent of each other so as to form orthogonal vectors in an n-dimensional metric space.

It has been argued that such conditions do not apply to sensations, since these would have to be treated as intensive and not as extensive magnitudes. Such a distinction points to *Kant*'s epistemology [30.68, pp. 202–205] where one of the axioms states that conceiving of phenomena in time and space implies extensive magnitudes (for instance, geometrical figures are conceived of in spatial dimensions). The notion of an extensive magnitude entails quantity (which in turn leads to operations of addition, multiplication, etc.). Sensations and perceptions resulting from real world phenomena, according to *Kant* [30.68, pp. 205–214], bear to intensive magnitudes, that is, they may represent different grades of the same basic quality. The distinction between quantifiable extensive magnitudes and intensive magnitudes that allow for a gradation of qualities has played a role also in the early debates concerning *Fechner*'s psychophysics (for essential arguments, see [30.66, 69–71]). The view according to which sensations can be graded (as subjects experience different degrees of phenomenal qualities) yet might not be accessible to true measurement as this would presuppose a sensory continuum plus a well-defined *unit* of measurement has had some consequences. One was to regard sensations basically subjected to *categorical* judgments and scalable on ordinal yet not on interval or ratio scale level (Sect. 30.1.4). Another was to call into question applicability of the concept of quantification to psychic phenomena, as well as comprehensive debates on what *measurement* entails in (a) the sciences and (b) in psychology and related fields. Such debates have been complex because they involve both fundamental principles as well as historical processes in scientific research.

Without going into details of historic background and theoretical argument, it is generally agreed that mathematics, including geometry, number theory, and even analysis, has played a significant role already in antiquity, and in particular in the so-called Pythagorean tradition of science [30.72]. In fact, Greek mathematical thought already included concepts such as the continuum and the infinitesimally small [30.73] that were elaborated on ever since, up to modern approaches (such as advanced by Dedekind, Poincaré, Hölder, etc.). Also, concepts of quantity, quantification, and measurement were discussed in Greek philosophy. *Aristotle* [30.74] defines quantity as a set of discrete elements that can be counted, while he regards magnitude as a continuous entity that can be segmented into parts. The elements that make up a countable quantum are numbers while magnitudes are realized in the length of lines, the width of a plane, and the depth of a body. Hence magnitudes rest fundamentally in geometric constructs, which are extensive, and comprise of continuous elements such as lines and circles. Therefore, length has been the paradigm of measurement from antiquity to the present (even in publications on theory and methodology of psychological measurement [30.75], and has served as an illustrative model to study fundamental principles (e.g., continuity, additivity) of measurement. In this context, one should remember developments in analytic geometry as well as efforts to provide a complete axiomatic-deductive foundation for geometry that have led to the treatment of geometry in terms of arithmetic, a development greeted as necessary to achieve utmost logical coherence [30.76, Chap. 2,3]. As one of the consequences, the concepts of *magnitude* and *measure* were subjected

to axiomatic justification. Though concepts such as *quantity*, *magnitude* and *proportion* of magnitudes are still related to geometric entities such as point and line, there is a clear shift to arithmetic reasoning whereby, for instance, the concept of *proportion* (known from Pythagorean tradition and systematically treated in Euclid's *Elementa*) is given a new treatment based on real numbers [30.77]). In effect, each magnitude can be represented by a (positive) real number (implying that a continuum of points forming a line can be represented by a continuum of real numbers). Also, distances between any pairs of points $(a, b, c, d, \ldots)$ can be expressed as *line numbers* (Hölder uses the German term *Streckenzahlen*) and can be given numerical treatment as real numbers.

Though Helmholtz played a significant role in modern approaches to analytical geometry (including non-Euclidean spaces and theory of manifold), he maintained that even complex geometrical constructs can be related to perception, and that geometry as well as measurement rests ultimately on our experience of forms and bodies in the environment (where we compare their sizes, assess their distance and location, observe motions of such bodies, etc. [30.78–80]). Hence, Helmholtz advocated an empiricist foundation of measurement, taking into account our ability of focused observation as well as to compare objects as they occur in the environment. Such comparisons may be directed to sizes, distances, weights (but may also include degrees of brightness and differences in pitch), and may lead to tentative estimates while precise measurement for Helmholtz requires *units* modeled close to natural objects or processes. Once such *units* are at hand, measurement of *magnitudes* is secured by operations such as counting, addition, and multiplication. Though Helmholtz viewed measurement in regard to physics in the first place, measuring was also defined in psychology as *comparing a magnitude with a fixed unit, and then counting how often the unit is contained in the magnitude* [30.81, p. 72].

In the 20th century, measurement theory has become a large field of its own, deeply rooted in mathematical and probabilistic foundations [30.82–84]. In one approach labeled axiomatic and representational, the basic idea is to *map* qualitative relations found between n empirical objects into a set of numerical relations (expressed, in most cases, as positive real numbers). Qualitative relations between objects may result from different *degrees* to which certain observable attributes exist in these objects (which implies an ontological statement), or which seem to exist according to our perceptions (including evaluation Sect. 30.1.2). The mapping of qualitative differences observed between objects into quantitative indices is homomorphic insofar as the resulting numerical structure represents the underlying empirical structure. The structure is defined in regard to identical empirical and numerical relations; it has been proposed [30.85, pp. 4–5, fn. 1] to use the term *isomorphic* for such cases. Under certain conditions (for which logical and mathematical definitions are given [30.86, Chap. 21], [30.75]) the mapping is regarded as isomorphic if each real number represents one (and only one) magnitude on a continuum.

In regard to empirical research such as is carried out in psychophysics, measurement has been given a rather broad definition as *the assignment of numerals to objects according to rules* [30.87, p. 677]. This definition, which Stevens himself saw as a generalized version meeting specific demands of the behavioral sciences, and of psychology in particular [30.88, Chap. 2] has been reiterated in quite many psychology textbooks and other publications, and thus has become kind of a standard. However, Stevens' definition as well as the concepts of measurement he has advocated in a range of publications [30.89–94], have been severely criticized on grounds both theoretical and empirical. Among the objections ([30.71, 95–97] and Sect. 30.1.4, *Loudness Scaling and Scaling of Pitch: Two Illustrative Examples*) that have been raised are these:

1. Stevens' approach where he, in numerous experiments directed to finding scales for attributes of sensation and perception, had subjects *assign numerals to objects according to rules*, is not compatible with established procedures of scientific measurement, which typically aim to find numerical relations between properties of objects that exist in this world (or, in regard to measurement in astronomy, somewhere *out there*). Measurement of such objects (or, rather, of magnitudes representing certain properties and attributes) thus often has led to the discovery of laws of nature; the relations found by way of measurement (most of all, in *classical* physics) are independent of the individual observer, and are largely invariant within a range of conditions. Relations can be expressed as ratios and proportions, as was done prominently in Greek mathematics and music theory, both of which seem to stem from Babylonian geometric traditions of rational division of straight lines as well as string lengths. The Pythagorean theory of proportions precedes Euclid by far [30.72, Part 2]; the legendary Pythagoras is said to have discovered that two strings of same length and tension yield harmonic intervals if divided in certain proportions based on small integer ratios such as $2:1, 3:2, 4:3, \ldots, m:n$ (where $m = n+1, n = 1, 2, 3, \ldots$). To be sure, *this was the first known example of a law of nature ruled by the arith-*

metic of integers ... [30.98, p. 138]. The theory of proportions was given systematic treatment in Euclid's *Elementa* (in particular, book VII and VIII), and again in *Hölder*'s [30.77] axiomatic approach to continuous magnitudes.

2. In regard to measurement, certain principles for defining a metric have been established; the principle of additivity (whereby $f(x \circ y) = f(x) + f(y)$; the sign $\circ$, known as *Hempel's operator*, indicates a well-defined operation to combine two physical objects into a new one) is perhaps best known. Also, the unit of measurement shall be defined by some standard object, which in turn should have some meaningful relation to natural objects or configurations as was the case with the meter (the *mètre des archives* of 1793), which represents – in good approximation – $1/10\,000\,000$ of the distance at sea level from the North Pole to the Equator. Also, the length of a pendulum that had a half cycle of exactly 1 s was very close to 1 m. Several of the units that Stevens employed for *subjective magnitude estimation* seem to be quite arbitrarily chosen; this holds true also with respect to anchor and zero points (we will address this issue below in Sect. 30.1.4, *Loudness Scaling and Scaling of Pitch: Two Illustrative Examples* in regard to the so-called *mel* scale of *subjective pitch*).
3. The methods of measurement Stevens was using in experiments with subjects in order to develop ratio scales and exponents for power law formulations (see below) have been challenged. Among the critical issues are some of the instructions given to subjects as well as the order and range of stimuli presented, which are regarded as factors having introduced a bias. Also, averaging applied to datasets from various samples (many of which differed in size as well as in regard to conditions) is viewed with some concern.

Stevens defended the work he and his co-workers had conducted at Harvard and maintained that measurement cannot, and should not, be confined to such variables for which the principle of additivity holds, for, in psychology and the social sciences, *there is a need to scale new kinds of variables and to measure the previously unmeasured* [30.88, p. 46]. One has to bear in mind that, in modern science from the Renaissance to the present, methodology directed to measurement, scaling, and to quantification of variables and magnitudes has been essential. This holds true also for musical acoustics and music theory [30.98, 99]. The quest to measure sensations, and possibly even complex mental properties (such as *intelligence* or *musicality*), therefore, fits into a general trend of modern science, which is looking for causality, lawful functional relations, and for exactitude (implying operations of *counting and measuring*, as was underpinned by [30.79, 80]). It might be added that, in psychology, there have been proposals for extended and alternative concepts of measurement [30.100–103]; some concepts either avoid the principle of additivity, or give it a broader meaning as was done by *Stevens* [30.89] when proposing a new scale of *subjective loudness* (Sect. 30.1.4, *Loudness Scaling and Scaling of Pitch: Two Illustrative Examples*). Also, attempts have been made at demonstrating that measurement for phenomena such as (musical) pitch and loudness in a form that adheres to the principle of additivity *by procedures essentially similar to those for length and weights* [30.95, p. 277] is feasible. These procedures were discussed in detail, however, with a view on proving the principle rather than providing a model that has practical relevance.

In his works on measurement, Stevens distinguished between two types of scales (prothetic and metathetic) and four scale levels (nominal, ordinal, interval, ratio). *Prothetic* scales are regarded to represent *intensity continua*. According to *Stevens* [30.94, pp. 371–372], intensity of sensations such as brightness or loudness can grow since there is *a physiological process in which excitation is added to excitation already there*. On the other hand, a sensation of a constantly rising pitch (as brought about by a sine sweep where the frequency is modulated so as to pass through a band (e.g., octave) per time unit) does not result from *added excitation but because new excitation has been exchanged for excitation that has been removed* [30.94, p. 372]. Hence, the assumption is that prothetic continua depend on physiological processes with additive patterns of excitation while metathetic continua would require a process of substitution. As paradigms for the two types of continua, Stevens himself has pointed to loudness and pitch respectively (though not exclusively; there are more examples for each type, [30.104]).

The term *continuum* as occurring in psychophysics and theories of perception implies that a random variable X can express very many values x_i; in principle and taking the mathematical concept of *continua* into account, any value x_i within the interval $x_{min} \leftrightarrow x_{max}$ is possible. However, while parameters of the physical stimulus can often be varied on a quasicontinuum (e.g., gain (dB) in an amplifier used for experiments in hearing), sensations are subjected to a discriminal process (Sect. 30.1.4, *Loudness Scaling and Scaling of Pitch: Two Illustrative Examples*, Sects. 31.1 and 31.7, Sect. 31.6.1), which leads to segmentation of continua. Though a continuum is assumed to exist for certain stimulus variables and for sensations corresponding to such stimuli (e.g., frequency of pure tones $\rightarrow$ pitch;

sound intensity → loudness), this assumption needs to be investigated on an empirical level. Consequently, one can segment such continua according to JNDs or other units that have empirical relevance in order to establish what is called a *sensory scale* [30.103, Chap. 3]. For such a scale to be valid and reliable, it would be requested that *it explains a large body of sensory data, collected with a variety of methods* [30.105, p. 131].

Basically, measurement and scaling as developed in the sciences call for certain conditions to be fulfilled: one may often start from (preliminary) observations that demonstrate that a number of objects or events differ with respect to some properties, or at least with respect to their phenomenal appearance. Differences can be viewed to exist in objects of the natural world (ontological and realist interpretation), or to be attributed to objects and events due to their phenomenal appearance to subjects (psychological interpretation made from a realist point of view). If differences among a set of objects are to be measured on a metric so as to capture differences precisely [30.106, pp. 16–20], one would need a gauge with a scale, which in turn calls for a proper unit as well as for a zero. Such a metric would be an interval or a ratio scale, for which additivity applies.

The well-known division of scale types into nominal, ordinal, interval and ratio [30.87, 90] includes the two metric scales as well as two that fall short of a strict concept of measurement. Scale types can be distinguished in regard to permissible transformations (such that do not affect the relational structure inherent in data, which is kept invariant) as well as other operations [30.101, Chap. 20], [30.86, 103]. Nominal scales often result from classification where a large number of objects is sorted into classes according to certain distinctive features (as is the case, for example, with musical instruments that can be classified with respect to the sound-producing element into idiophones, membranophones, aerophones, chordophones, electrophones). Within each class, all objects are regarded as equivalent with respect to the criterion defining the class. One can assign numbers to such classes; however, these numbers do not indicate a quantity or a magnitude, and can be chosen arbitrarily. With ordinal scales, a monotonous relation ($<$ or $>$) between elements is introduced as a number of objects or subjects are sorted so as to yield a rank order (like $A > B > C > D > E$). In case several objects have the same rank, there are ties that can be of relevance in statistical procedures (for statistical methods, see textbooks such as [30.107]). Ordinal scales, which are often used with variables representing subjective attitudes and performance, have been also employed in experiments directed to sensation and perception where ordinal scales can result from estimates of phenomenal differences that are experienced. For example, observers can be asked to judge the loudness of music examples they hear according to categories (which might have a range, with respect to loudness, from *very soft* to *extremely loud*). Though such estimates can be fairly consistent within samples of subjects, leading to a rank order that can represent *degrees* of sensational and perceptual qualities, an ordinal scale derived from rank order expresses relative differences not yet quantifiable in a well-defined unit. Such units as well as interval constancy are expected for an interval scale where the zero can be chosen at the discretion of the experimenter (who will, however, seek to anchor a scale at a zero that does have empirical meaning, e.g., a threshold of sensation). For a ratio scale, an *absolute zero* is requested (this is a theoretic postulate that can be difficult to attain in practice).

In regard to scale level, it has been argued that we cannot truly measure, for example, two different sensations of loudness resulting from two audio stimuli presented in succession since we have no *natural* unit of loudness at hand. Rather, we employ some comparison and may express that two sensations (A, B) are either *equal* ($A = B$, including $A \approx B$) or *unequal* (the latter implying $A > B$, or $A < B$). In case two sensations are found unequal, we may try to estimate their relative difference ($A \to B$ or $B \to A$), or may even guess what the ratio between A and B might be $(A : B)$. Subjective estimates as to *how much louder* A appears relative to B can be achieved on a scale comprising a number of categories ordered in accordance with a monotonous function and satisfying the criterion of transitivity. Judgments then involve assigning A and B to a certain category on an ordinal scale. However, true measurement of sensations, as already expressed by *Fechner* [30.65, T. I, Chap. VII], would require a unit derived from empirical investigation relevant to fundamentals of psychophysics. Measurement in the psychic realm to Fechner meant *summing so many times the same*, whereby *the same* in this respect means the same basic unit. The relevant unit for sensation was the just noticeable difference (JND) found in discrimination tasks.

To be registered as unequal by subjects, two sensations must differ by a certain magnitude, which depends on (a) the stimulus parameters and (b) the modality. *Weber* [30.64] found ratios for two stimulus magnitudes that led to just discriminable sensations; in these tasks, in which he acted as experimenter and as subject, sensation of course was registered in a situation of focused attention. Weber observed that the ratio of two stimuli just discriminable as to the intensities they produce in sensation is constant (or almost so) over a wide range

of stimulus settings. Taking one stimulus, of magnitude S, as a reference and the other that leads to a just noticeable difference in sensation as ΔS, the magnitude of ΔS in proportion to S denotes a differential threshold. The quotient $\Delta S/S = k$ ($k =$ constant) became known as the *Weber fraction* (and also as *Weber's law*). In case the quotient $\Delta S/S$ for a certain modality and type of sensation is constant within its range, there is but one value for k per modality (e.g., hearing) and type of sensation (e.g., pitch, loudness) relative to physical stimuli such as sine tones or other types of sound. For example, from empirical findings according to which most subjects can detect a shift in frequency for a sine tone from 1000−1003 Hz (at medium SPL), it has been concluded that for pitch of pure tones $k = 0.003$ (or $1/333$). Values for k of course differ from one modality to the next. One may start the process of determining JNDs from an absolute lower threshold, for example the minimum stimulus intensity applied to evoke a sensation of sound, which can be taken as a reference, S_0.

The *Weber fraction* can be viewed in terms of differentials since a small stimulus increment ΔS is needed to bring about a small change in sensation, ΔE, the just noticeable difference (JND) corresponding to a change of stimulus magnitude from S to ΔS. Hence, $\Delta S/S = k\,\Delta E$ and $\Delta E = 1/k\,\Delta S/S$. Fechner saw Weber's law as a basis for a differential equation [30.100, p. 37 ff.]. As a differential equation, Weber's law can be expressed thus

$$E = k\frac{\mathrm{d}S}{S}\,.$$

Fechner took

$$\mathrm{d}E = \frac{k\mathrm{d}S}{S}$$

as his *fundamental formula*.

From the basic $\Delta S/S =$ constant, one can expand its interpretation to conclude that *equal relative increases of the stimulus correspond to equal increases in sensation* [30.65, T. I, p. 64]. Hence, two stimuli that form a certain ratio with respect to a physical parameter (such as SPL) will bring about a *difference* in sensation corresponding to this ratio. As a particularly striking example, Fechner pointed to musical intervals, saying it is a simple and *notorious* experience to find, by way of hearing, that equal ratios of frequencies (of two pure tones) result in an identical *Tondifferenz* in various octaves [30.65, T. I, p. 181]. The term *Tondifferenz* as used by Fechner is a bit awkward as it includes arbitrary ratios while, at least for listeners familiar with music, it is the small integer ratio constituting a certain musical interval that leads to such *notorious* experiences; perceiving two pure tones as forming an interval of a perfect fifth always calls for a frequency ratio of $3/2$, no matter if this is realized in a rather low frequency region (say, 120 : 80 Hz) or at a high one (say, 4500 : 3000 Hz). Of course, thereby the *absolute* increase in stimulus frequency grows towards higher frequency regions. *Fechner* [30.65, T. I, Chap. IX] concluded that this peculiar sensation of musical intervals based on stimulus frequencies forming small integer ratios is unparalleled in other sense modalities. One can further argue that musical intervals are perceived as entities (or even as *Gestalten*) distinct in quality that do not fall under discrimination tasks and just noticeable differences (with the possible exception where subjects discriminate intonation deviations leading to perceivable differences in the quality of intervals (Sects. 31.6 and 31.7)).

Taking the Weber fraction as a differential, integration yields $E = k\ln S + C$ (where C is the integration constant and ln indicates the natural logarithm). Fechner's concept included the absolute minimum of stimulus intensity needed to evoke a faint sensation. For a very small stimulus S_0, sensation can be expected to vanish ($E = 0$) when $S_0 < b$, and to become just noticeable when $S_0 > b$. For $E = 0$ the equation is $0 = k\ln b + C$ and, hence, $C = -k\ln S_0$, which gives the threshold of sensation, S_0 (Fechner's *Schwelle*). *Fechner*'s [30.65, T. II, Chap. XVII] *Maßformel* then is

$$E = k\log\frac{S}{S_0}\,,$$

and the integrated formula is $E = k\ln S + C$. Fechner argued that the magnitude of sensation is not simply a function of the stimulus magnitude as such, yet is dependent on this magnitude in relation to the threshold. This is why the *Maßformel* contains the quotient S/S_0. It is only under certain conditions that the functional relation between stimulus and sensation simply obeys $E = \log b$ where b denotes the threshold, indicating that stimulus magnitude for every sensation must be measured from the lower threshold point. The concept is that the difference between an actual stimulus magnitude b and the threshold b can be measured like $E = k(\log \mathrm{b} - \log b)$, which equals

$$E = k\log\frac{S}{S_0}\,.$$

Fechner cautiously warned that strict proportionality of ΔE to ΔS holds only for very small increments. In order to turn the *Weber fraction* into a differential equation, and to use Fechner's *fundamental formula*, the increments would have to be infinitesimal and, hence, much smaller than the JNDs actually found in em-

pirical study of sensation. Fechner's approach led to the consideration of the difference between b and *b* as corresponding to a certain number of JNDs [30.65, T. I, Chap. VII]. In this way, measurement of sensation comes down to summing up or *counting* a number of JNDs to bridge the gap between b and *b*. As a result, the magnitude of sensation *E* corresponds to *n* times the JND counted from *b* to b ([30.103, pp. 106–108], who offers an algorithm for calculation of the number of sensation increments S_N/S_0 that fall between *b* and b). Judging the difference between b and *b* as a sum of JNDs (even if conceived as a series of concatenated JNDs) has been viewed as *indirect measurement* [30.108] as opposed to *direct measurement* where the difference b $\leftrightarrow$ *b* would be judged as one magnitude. (It has been mentioned above that, in Fechner's approach, *indirect measurement* refers also to another aspect, namely, measurement of sensation magnitude through measurement of the stimulus magnitude.)

Fechner originally (in 1851) had postulated that *psychic intensity* is the logarithm of the corresponding physical intensity; he subsequently modified his concept in regard to sensation. The general idea is that increases in the stimulus parameter must form a geometric series to bring about an arithmetic series of corresponding increases in sensation. Scaling of an attribute of sensation relative to a physical parameter typically starts from the lower threshold, which is *not* a discontinuity in the magnitude of sensation but the level of excitation where an observer notices a (sometimes very faint) sensation. Since the threshold is reached in small increments of stimulus intensity, starting from zero or a subliminal level, there have been considerations that one may regard the threshold itself as a JND (that marks the difference between *no sensation* and *minimal sensation*). For the threshold of sensation, the physical stimulus parameter must have a certain magnitude. For example, a sine tone of 200 Hz becomes audible for many persons at a SPL of $\approx$ 15 dB [30.109, p. 32]. If the threshold would qualify as a first JND, one would expect the next JND above 15 dB to be of similar magnitude. Fechner apparently did not make this assumption but argued instead that the JNDs above the threshold can be taken as equal provided both the JND of sensation and the stimulus increment are very small.

Fechnerian scaling of a sensory attribute yields a logarithmic function for which the graph would have a shape similar to that shown in Fig. 30.3.

The Weber fraction has been generally accepted as empirically proven within certain limits; observations near a threshold of intensity sensation may indicate a *near miss* to the *Weber law* that must be slightly modified accordingly [30.110, pp. 121 ff.]. Fechner's assumption that a sensation magnitude can be measured as a sum of JNDs has been rejected by many. The main argument (also in regard to the *Weber fraction*) is that the JNDs are not constant in size over the range of measurement. Some of his critics [30.111, Chap. 4], [30.112] denied measurability of sensations as magnitudes at all and instead held that sensations must be viewed in a qualitative rather than in a quantitative way.

As an alternative to Fechner's approach, a concept in psychophysics advanced in particular by Stanley S. Stevens et al. at Harvard in the decades from 1940–1970 has gained prominence. Relating stimulus magnitudes to subjective magnitudes, Stevens claimed *that equal stimulus ratios produce equal subjective ratios* [30.92, pp. 153, 172]. In short, the concept is *that the sensation* Ψ *is proportional to the stimulus* S *raised to a power* n [30.92, p. 162]. Hence, Stevens' power law is $\Psi = kS^n$. Leaving aside constants depending on the choice of units, the formula simply is $\Psi = S^n$. What needs to be determined, then, is the exponent *n* relevant for a given sensory modality as well as certain classes of stimuli. Different from Fechner's approach, which was based on *indirect* measurement (Fig. 30.2), Stevens proposed a methodology of *direct* measurement that includes four types of experiments all designed to achieve ratio scaling of sensory attributes [30.92]:

1. Ratio estimation (including direct judgment of ratios)
2. Ratio production (by either fractionation or multiplication)
3. Magnitude estimation (with or without a modulus prescribed by the experimenter)
4. Magnitude production.

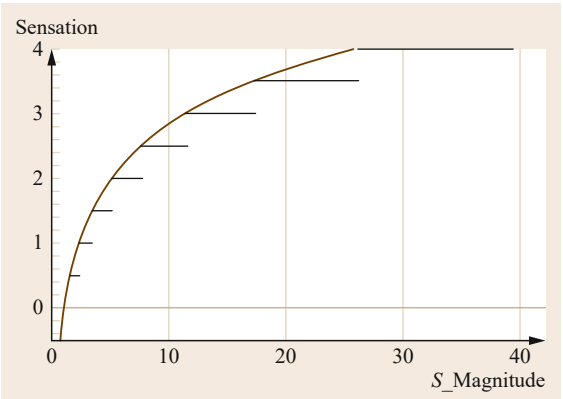

Fig. 30.3 Graph illustrating *Fechner's law* (increases in stimulus intensity corresponding to subsequent JNDs indicated by *horizontal lines*)

This scheme was somewhat expanded later on to include cross-modality matching and cross-modal ratio matching [30.93]. Stevens' approach to ratio scales and to establishing the power law deserves special notice because it led to two scales proposed as being of relevance to the sensation and perception of sound, namely, the so-called *mel scale* of pitch [30.113] and the *sone scale* of loudness of which several versions were published [30.104, 114]. We will examine both scales in detail below after briefly looking into some of the experimental methods.

The idea to have subjects insert a stimulus R_m between pairs of stimuli R_1 and R_2 so that R_m is right in the middle, and the distance $R_1 \leftrightarrow R_m$ is of the same size as $R_m \leftrightarrow R_2$, has played a role already in Wundt's lab at Leipzig; *Merkel* [30.115], working with visual stimuli, reported that R_m was significantly closer to the arithmetic mean than to the geometric mean (with the latter to be expected due to Weber's law and Fechner's law). In 1890, Wundt and Stumpf engaged each other in a famous controversy concerning sensation of *tone distances* [30.116, Chap. III.1], and Stumpf later had his coworkers Abraham and von Hornbostel perform experiments on *tone distances* (where the magnitude of a tone distance is defined as the difference of two frequencies [Hz]: $f_2 - f_1$). The results in particular for a large distance ($74 \leftrightarrow 4115$ Hz) showed that a tone intended to bisect the distance had a frequency close to the geometric mean (which is 551.8 Hz) and far from the arithmetic mean. Moreover, in several experiments directed at fractionation of a *tone distance* into equal appearing smaller distances, estimates were not independent of musical intervals (which apparently served as categories and perceptual *yardsticks*; [30.117]). Observations reported by *Pratt* [30.118, 119], on a small sample of subjects, also indicate that frequency distance estimates interfere with musical intervals (in particular for tone distances smaller than an octave), and that subjects with some musical background tend to bisect distances by a frequency corresponding to the geometric mean rather than the arithmetic mean.

Stevens started his experiments on sensation of loudness and pitch (as well as on other sensory attributes) in the 1930s. In a number of ratio estimation experiments, subjects had to judge the ratio of pairs of stimuli presented to them in succession. In ratio production experiments, subjects typically were asked *to adjust a stimulus to produce a certain ratio to a standard*. With respect to fractionation, subjects might be asked to adjust a tone or noise so that it appeared to them as *half as loud* as a standard. Conversely, multiplication might be done by adjusting a pure tone from a sine generator so as to produce a pitch *four times as high* as that of a standard. The method of magnitude estimation did not employ ratios yet

> *requires the subject to assign numbers to a series of stimuli under the instruction to make the numbers proportional to the apparent magnitudes of the sensations produced.* [30.92, p. 165]

Complementary to magnitude estimation, subjects were engaged in magnitude production where *the experimenter might name various magnitudes and ask the subject to adjust stimuli to produce proportionate subjective values* [30.92, p. 165].

From a broad range of experiments addressing several modalities and sensory attributes [30.104], *Stevens* [30.92] came to the conclusion that the relation of stimulus to sensation almost always can be scaled according to a power function of the form $\Psi = S^n$ (with an appropriate exponent for each attribute). Taking the range of modalities and attributes where a power function seems to apply, he made a generalization towards *the* psychophysical law (labeled *power law*, and also *Steven's law* or *Plateau–Stevens law*).

Scaling according to a power function $\Psi = S^n$ would yield a graph of the form shown in Fig. 30.4 where both the y-axis and the x-axis are logarithmic. Displayed is the sensation of loudness (in sone; Sect. 30.1.4, *Loudness Scaling and Scaling of Pitch: Two Illustrative Examples*) as a function of sound level (dB). In a log–log plot, the resulting graph is a straight line (in this case, the loudness function is very much idealized).

The quest for ratio scales favored experimental operations such as fractionation, multiplication, ratio estimation and ratio production. Stevens' attempt at building a *new psychophysics* based on what he called a *schemapiric* approach, combining experimental manipulation and measurement done mostly by *assign-*

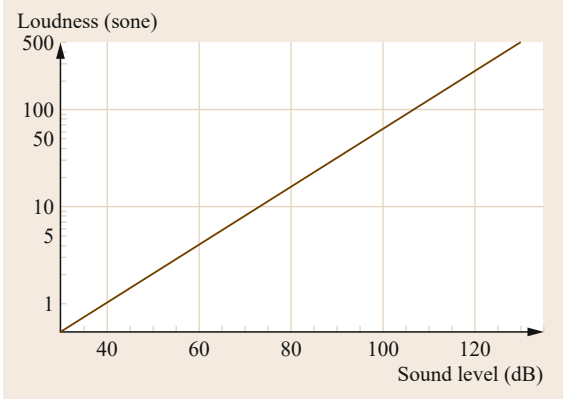

Fig. 30.4 Graph illustrating *Stevens' power law* (for loudness)

ment of numerals to objects [30.88, 91–93], has been met with skeptical reservation. Critics objected that the instructions given to subjects were not neutral and that, typically, *power law data are generated by inducing subjects to assign an approximately geometric distribution of numbers to a geometric series of stimuli* [30.97, pp. 183, 191]. Analysis of the model employing mathematical tools and scrutiny [30.97, Chap. 11] reveals that, given the methodology used by Stevens for experimental design and procedures, the chance to end up with the power law is very high. In this respect, the outcome appears as a consequence of assumptions and modeling rather than of empirical investigation. Even the logical and mathematical concepts of Stevens et al. have been attacked as flawed [30.96]. Other objections raised in the literature were directed against specifics of experimental procedures, data acquisition, and interpretation of data in regard to finding ratio scales as well as to generalize findings to the power law [30.95, 97, 120–123].

Loudness Scaling and Scaling of *Pitch*: Two Illustrative Examples

To illustrate the problems, two scales established by Stevens et al. shall be examined in more detail. One is the sone scale for *subjective loudness*, the other is a scale for *subjective pitch* known as the mel scale. The sone scale was regarded a paradigm for scaling of a prothetic continuum, the mel scale a paradigm for scaling of a metathetic continuum [30.88]. Again, the development in particular of the *sone* scale must be viewed against a background of previous research (see also [30.124]) since there are quite many experiments on loudness sensation antedating Stevens' own contributions to scaling.

To begin with, it was long known that the sensation of loudness relates to the amplitude of vibration of a (periodic or nonperiodic) signal. The source of such a signal may be, for instance a mass of air enclosed in an organ flue pipe in which resonance results in a standing wave. Energy from this pipe emitted into the sound field ([30.125, Chap. 6], [30.126, Chap. 6]) leads to periodic changes of pressure. Though static pressure under normal conditions is quite high (about $1.013\,\mathrm{hPa} = 101.300\,\mathrm{Pa}\ (\mathrm{N/m^2}) = 1.013\times10^6\,\mathrm{dyne/cm^2}$), our ear, which has gained its specific morphology and functions in the evolution of pressure-sensitive organs, is capable of detecting even extremely small pressure changes. In regard to sound, periodic changes of the static pressure are sensed from a threshold for hearing that is as low as 0.00002 Pa.

The intensity of sound, which can be defined as the mean density of the energy flux in a given medium with density ρ (for details, see [30.4, Chap. 4], [30.127]) can be expressed as

$$I = \frac{\rho}{2} c (2\pi f)^2 \hat{A}^2 \,,$$

where $\hat{A}$ is the peak value, c is the wave velocity in air ($\approx 340\,\mathrm{m/s}$ at $20\,^\circ\mathrm{C}$), and ρ denotes density in air, which is $0.00121\,\mathrm{g/cm^3}$. In a more practical view, the intensity of sound equals the product of the root mean square (rms) value of the sound pressure and the rms value of the particle velocity, that is

$$I = p_{\mathrm{eff}}\, v_{\mathrm{eff}} = \rho\, c\, v^2 \,.$$

Since sound pressure is the field quantity that is most decisive for loudness perception, intensity relates to p like $I = p^2/\rho c$, which can be expressed, in the cgs system, in erg ($\mathrm{g\,cm^2/s^2}$).

The characteristic acoustic impedance of air is quite small ($\rho c = 42\,\mathrm{g/(cm^2\,s)}$) so that, approximately, $I \approx p^2$. The reference point for intensity of sound usually is $I_0 = 10^{-12}\,\mathrm{W/m^2}$, which is taken as 0 dB intensity level. The sound pressure correspondingly is $p_0 = 20\times10^{-5}\,\mathrm{Pa} = 0.00002\,\mathrm{Pa}\ (\mathrm{N/m^2})$. Some correspondences of sound pressure (Pa(rms)) and sound intensity to the decibel (dB or db) scale are given in Table 30.1.

Since the range of pressure the ear can deal with spans seven magnitudes, a logarithmic measure is more apt.

It was known from experience that the intensity of a sound emitted from a source decreases with distance if a listener moves away from the source. An early experiment, taking perceived intensity as a function of distance (mm) from the source (a pocket watch placed in a wooden frame with a hole towards the ear of the observer that could be opened and closed for periods

of time), reported that two intensities were discriminable with certainty if their ratio was 100 : 72, and hardly discriminable (the number of correct and incorrect judgments being almost equal) if the ratio was 100 : 92. Though several hundred observations were made by the two experimenters [30.128], they abstained from fitting a *curve* to their yet preliminary data. Another study (also from Tübingen) underpinned that we tend to perceive stronger stimuli as closer to our sensory organs, that is, intensity is correlated with perceived or imagined (if the sound source is not visible) distance [30.129, p. 8]. This is the core of what much later became the *physical correlate* theory of loudness [30.121, 122]. The relation of intensity to distance depends on the nature of the sound source (point or line [30.130]) and can be given as

$$I \sim \frac{1}{r^2}$$

for point sources and

$$I \sim \frac{1}{r}$$

for line sources.

In the 20th century, among the aspects studied were differences in the sensitivity of the ear with respect to tones of different frequency [30.131]. Progress in experimental setups and procedures was made when electric signal generation, reproduction and measurement equipment became laboratory tools for hearing research. *Fletcher* and *Wegel* [30.132] found a minimum range for the lower threshold at 1–4 kHz where the pressure variation needed to evoke a sensation was 0.001 dyne/cm^2. *Wegel* [30.132, p. 156] published a sketch of the auditory sensation area as defined by curves for the lower and upper limits of hearing respectively. The threshold has its lowest point at about 3 kHz with an rms pressure of ≈ 0.0007 dyne/cm^2 (which is very close to actual threshold values); the peak of the upper limit is located at ≈ 4000 dyne/cm^2 for frequencies of ≈ 0.5–1 kHz. *Fletcher* and *Steinberg* [30.133] investigated how the energy contained in complex sounds might contribute to the overall loudness and suggested this *may be obtained by summing up the contributions throughout the frequency range* [30.133, p. 316]. *Steinberg* [30.134] continued this early approach to loudness summation and gave a formula to calculate the loudness, L, as a function of the energy spectrum of a sound and its level above threshold. To this end, his formula included a weighting of components to make sure that, with increasing intensity of a complex sound, low frequency components contribute increasingly more to the loudness sensation. He used logarithms to define sensation level as

$$S = 20 \log_{10}\left(\frac{P}{P_0}\right),$$

where P is the rms pressure of the sound wave and P_0 the minimum audible pressure for subjects with normal hearing. Steinberg employed the *transmission unit* (TU) customary in telephone technology and defined as $10 \log_{10}(P_1/P_2)$ (where P_1 and P_2 are two powers). *Kingsbury* [30.135], in *behavioral* experiments with 22 observers (11 male, 11 female) established equal loudness contours for pure tones that were compared to a standard at 700 Hz. Since he conducted behavioral experiments, Kingsbury presented statistics of his data and discussed the variability found therein. Still inclined to a JND approach in the realm of Weber and Fechner, Kingsbury employed a *loudness unit* that *expresses the ratio of the smallest perceptible difference in the energy of a tone to its total energy*, and he derived loudness functions for various pure tone frequencies from a function established for a 1 kHz standard. For the JNDs, Kingsbury used data published by *Knudsen* who had suggested that

> *under favorable circumstances, the normal ear can distinguish about 400 gradations from threshold to a painful intensity 10^{12} times as loud.* [30.136]

Knudsen argued that, from his data, a modification of the Weber and Fechner law (as had been proposed by Nutting for light sensation) would be apt for audition. A few years later, *Riesz* [30.137], also from empirical data (12 subjects), concluded that the Weber fraction for differential intensity sensitivity ($\Delta E/E$) of pure tones was, from a certain level above the lower threshold onwards, almost constant ($\Delta E/E = 0.05$–0.15, depending on frequency). In regard to frequency position, the minimum $\Delta E/E$ was found at about 2.5 kHz. Riesz calculated that, at about 1300 Hz, the number of JNDs for loudness would be 370.

Parallel to scholars in the USA (in particular, Harvey Fletcher et al. at Bell labs), Heinrich Barkhausen, a physicist working in electronics and electroacoustics, began to explore loudness sensation and scaling of loudness in the 1920s. One of the issues was how the power of a signal (e.g., a tone from a generator fed into headphones) relates to the loudness sensed by subjects. While the electrical signal could be defined using physical magnitudes (voltage, current, gain), a scale for loudness had yet to be established. Taking a tone of 800 Hz, Barkhausen, with the aid of a *sound meter* (built to detect intensities whose ratios are 1 : 2 : 4 : 8 :

16 : . . .) established a scale from the lower threshold (where the signal fed into earphones was barely audible) to a sensation experienced as painful. The unit he proposed was *Wien* (to honor the physicist Max Wien), where 1 Wien would be the threshold and the upper limit would be at about 16 000 Wien. According to this scale, the difference from 2–4 Wien would be sensed as equally large as that between 2000–4000 Wien. To meet practical demands, *Barkhausen* [30.138, p. 601] offered a logarithmic scale (with the logarithm at base 2) for which the unit would be *phon*. He tabled the two scales, adding some dynamic levels used in music for comparison (Table 30.2).

The unit *phon* is still in use (though with some modifications). In a modern definition (DIN 45630), the loudness level of a sound is n phon if this sound is judged, by observers with normal hearing, as being of equal loudness as that evoked by a pure tone of 1000 Hz, which is sensed as a plane wave incidental normal to the listener, and which has a SPL of n dB (reference sound). If the threshold at 1000 Hz is taken as 0 dB, calculation of loudness can be done according to

$$\Lambda_{1000} = L = 20 \log_{10} \frac{p}{p_0} = 10 \log_{10} \frac{I}{I_0} \text{ [phon]} .$$

From Table 30.1 it is clear that, on the decibel scale, an increase of 10 dB means that the pressure amplitude rises by a factor of about 3.16 while intensity rises by a factor of 10 (as it should to make p^2 equal I). *Kingsbury* [30.135] also addressed the issue of a *direct* comparison of two tones (B, C) in regard to loudness without reference to a standard (A). *Barkhausen* and *Tischner* [30.139] found that comparisons of complex tones (and noise signals) with a standard (pure tone) of varying frequency and intensity were possible within an error margin of, in most trials, ≈ 10%. *Richardson* and *Ross* [30.140] had their observers ($n = 11$) make *numerical mental estimates* of the loudness of tones varied in intensity and frequency relative to a standard (for which the loudness was declared unity). The intensity in many experiments of the time being controlled by the current fed into a telephone receiver, it was fairly easy to determine the ratio of currents used for different intensity levels and to see whether the corresponding loudness levels did yield a similar ratio. *Ham* and *Parkinson* [30.141], stating that, in the previous experiment of Richardson and Ross, on average *the logarithm of the mental estimate ratio of loudness was directly proportional to the logarithm of the current ratio in the phones*, had their (in total, more than 175) observers estimate (1) the percentage (%) to which a stimulus seemed to have decreased in intensity relative to a standard; then, observers were asked (2) to record when a (decreasing) stimulus appeared to evoke 1/2, 1/3, or 1/5 of the loudness of a standard, and, conversely (3), when the loudness of an (increasing) stimulus was two, three and five times as great as that of the standard. From quite many (≈ 4500) observations, *Ham* and *Parkinson* [30.141] concluded that observers can make reliable judgments with respect to the relative loudness of sounds according to a function

$$mL = \mathrm{a} + \mathrm{b}e^{nx} ,$$

where mL denotes the multiple change in loudness, a and b are constants, and x is the difference in the levels of the sound expressed in decibels. Struggling (as many researchers of the time) with *the Weber–Fechner law*, they inferred

> *that the increase (or decrease) of sound energy measured in decibels is a logarithmic function of the increase (or decrease) in loudness.*

Judgments on loudness

> *appear in all cases to be made as a per cent, fraction, or multiple of the original level. In no case did the judgments indicate that the loudness change was an additive or a subtractive function.* [30.141]

The state of affairs reached in loudness measurement and scaling was summed up by *Fletcher* and *Munson* [30.142] with definitions of basic concepts such as intensity level (number of dB above reference intensity) and loudness level (loudness of any sound measured as intensity level of the equally loud reference tone of 1 kHz relative to a threshold). For pure tones, loudness as a sensory magnitude depends on both frequency and intensity. The basic function for loudness,

N, thus is $N = G(f, I)$, where f is the frequency in Hz and I is the intensity ($I = p^2/\rho c$).

From comprehensive measurements and analyses of data, *Fletcher* and *Munson* [30.142, pp. 90–91] derived their famous loudness level contours (also known as equal loudness curves or Fletcher–Munson curves), which reflect the fact that the sensitivity of our ears is different for (pure) tones of different frequency (an important factor being the transfer function of the outer ear and middle ear respectively [30.8]). One can combine the equal loudness-curves with the *phon* unit (modern definition) to yield *isophones* (curves of loudness level for different frequencies expressed in phons). The latest version of equal loudness contours/isophones as described in ISO 226 (2003, 2008) is shown in Fig. 30.5.

The loudness of a pure tone presented at arbitrary frequencies and with varying SPL can be judged by comparison to the loudness of a reference tone at 1 kHz; in many experiments subjects had to adjust the stimulus (a sine tone of a certain frequency) in SPL so that the stimulus and the reference seem to evoke equal loudness. The SPL of both the stimulus and the reference can be measured in dB. At 1 kHz, phon scale and dB scale converge for various levels (or nearly so) while they differ significantly at very low and very high frequencies. To appear as *equally loud* as a 1 kHz reference tone of 40 phon (= 40 dB), a pure tone of 50 Hz must be presented with a SPL of ≈ 75 dB. The flattening of contours at higher levels probably is due to a nonlinear compressive loudness function in hearing (Chap. 33). The JND for loudness sensation of pure tones found in a number of experiments has been 1 dB or 1 phon respectively.

The phon scale can be used to measure loudness levels, though measurement in practice is laborious because it involves two parameters per stimulus (energy, frequency) even for simple sounds like sine tones as well as comparison of a stimulus to a reference sound [30.143, Chap. 4]. Therefore, a method of *direct* measurement as offered by Stevens seems attractive for reasons of simplicity. It is of interest to note that, in his article introducing the *sone* as a unit for measuring *subjective loudness*, *Stevens* [30.89] discusses concepts of measurement including the criterion of additivity (Sect. 30.1.4, *Historical and Theoretical Background*). Being a strong proponent of operationism [30.144, pp. 656–658], [30.145], *Stevens* outlines his concept in terms of operations stating that

> *the attribute of sensation to which the number 10 is assigned should appear to be half as great to the experiencing subject as that to which the number 20 is given,*

he concludes that, with a scale derived from such relations,

> *the operation of addition consists of changing the stimulus until the observer gives a particular response which indicates that a given relation of magnitudes has been achieved.* [30.89, pp. 406–407]

The loudness scale thus established is one based on *assigning numerals* to sensations that appear *half as loud* or *twice as loud* as a reference stimulus. A sine tone of 1000 Hz at 40 dB SPL above threshold heard with both ears served as the anchor point of the scale and was defined as 1 sone. A tone of 1 kHz heard *twice as loud* thus had the loudness of 2 sone, a tone heard *half as loud* 0.5 sone, and so on. The plot of the loudness function obtained for the 1 kHz stimulus [30.146, p. 118, Fig. 43], indicated a decrease in intensity of nearly 20 dB for a drop of loudness from 1 sone to 0.1. Stevens later revised his loudness scale on the basis of averaging data he and others had obtained in experiments. He [30.114, p. 820] concluded that, for the 1 kHz sine tone stimulus, the appropriate increase in intensity would be 10 dB for a loudness ratio of 2 : 1. The exponent of the power function then is $\log_{10} 2 = 0.3$ so that $L = kI^{0.3}$ (with $k =$ constant). The intensity I is taken as the density of energy flux and as proportional to p^2, $I \sim p^2$. If I is measured in units relative to the reference level of $10^{-16}\,\mathrm{W/m^2} = 0\,\mathrm{dB}$, then for $40\,\mathrm{dB} = 1$ sone, $k = 0.06$ (the threshold for loudness being $L = 0.06$ sone, which corresponds to 0 dB). The power function for loudness thus is $L = 0.06I^{0.3}$. For

sound levels > 50 dB, Stevens assumed loudness L to grow by a factor of two per 10 dB also for a range of continuous noise signals.

Taking the 10 dB increase or decrease of intensity as appropriate for producing loudness ratios of 2 : 1 and 1 : 0.5, respectively, the sone scale for the 1 kHz tone (where 1 sone = 40 dB = 40 phon) turns out nicely (see also Fig. 30.4) like in Table 30.3. The loudness function corresponding to this scale of 10 dB steps is at odds with a principle of sound radiation, which states that pressure and particle velocity in the sound field decrease with growing distance from a point source like p, $v \approx 1/r$ where r is the radius (however, in the nearfield $v \approx 1/r^2$ applies).

In practice, by doubling the distance from a source (e.g., a loudspeaker radiating constant sound in one direction), a decrease in SPL by −6 dB can be measured with a sound meter. In experiments, Warren et al. found that, to most subjects, estimates of half-loudness of a sound are equivalent to twice the distance from a source, where doubling distance means 1/4 of the intensity or a reduction by 6 dB. Absolute values for half-loudness equivalent to doubling the distance varied from about −6 to −8 dB depending on stimulus and source conditions, however, with a clear tendency towards −6 dB [30.122], [30.123, pp. 111–122]. In his later studies, *Stevens* [30.147] adopted a step of 9 dB as equivalent to a doubling or halving of loudness. As a rule of thumb, for sine tones in a convenient frequency and intensity range (say, 200−1000 Hz, 40−80 dB SPL) most observers will agree that *somewhere between* 5−10 dB *difference in intensity is twice as loud* [30.148, p. 76].

Judgments obtained from subjects on what is *twice as loud* or *half as loud* depend on physical parameters (the frequency, level, and duration of pure tones; spectral energy distribution, level and duration in complex tones; the center, bandwidth, spectral and phase structure, level and duration of noise bands) as well as on experimental conditions (use of loudspeaker(s) or headphones, quality of audio and test equipment, monaural or binaural presentation, order of stimuli in the presentation, etc.). The variability inherent in the data sets used by *Stevens* [30.114] to derive the 10 dB equivalence to doubling or halving loudness is considerable. Analysis of sample sizes and of the distribution of mean and median values shows that the 10 dB median finally chosen for doubling or halving loudness seems problematic [30.149, pp. 46 ff.]. Moreover, there were objections that the experiments Stevens et al. had conducted were biased in regard to instructions, the range of stimuli presented to observers as well as the range available for responses and other effects [30.97, 121–123, 149]. However, *Stevens* [30.150] seems to have foreseen such objections as he tried to assess effects of stimulus range, level, context, etc. Proposing methods such as direct magnitude estimation or cross-modal matching he believed to reduce or even prevent possible biases, Stevens in many publications up to his final book [30.88] maintained the validity of the power law as applying to loudness as well as to other sensory attributes. Other researchers agreed that the power law *appears to have a general validity for prothetic sensory continua* [30.151, p. 82]; see also [30.110, Part IV, Chap. 3].

One important aspect to justify the assertion simply is that increasing the intensity of a stimulus fed into a system such as a sensory organ coupled to a neural pathway suited to processing sound or light should reasonably also increase the *intensity* of the respective sensation. This was the assumption already made by Fechner (Sect. 30.1.4, *Historical and Theoretical Background*). Stevens regarded prothetic continua as such where *excitation is added to already existing excitation*. The term *excitation* is central to modeling of pitch and loudness perception [30.152, 153] where a correspondence between parameters of the sound stimulus (typically, amplitudes and frequencies of spectral components, bandwidth and level of noise bands) and places or areas of excitation on the BM are considered. Assuming a tonotopic organization for the BM taken as a chain of (slightly overlapping) bandpass-type auditory filters (AF), one can expect certain frequencies to produce excitation at certain places on the BM (Sect. 31.4, Fig. 31.4 and Fig. 31.5). Also, a correspondence of sound intensity to the area of excitation is reasonable since, in an elastic mechanical and hydromechanical system such as the cochlea [30.154, 155], the area of excitation on the BM should spread in proportion to the intensity of energy supplied (Chap. 33). It has been suggested that, at least for simple sounds (pure tones and similar stimuli), sensation of loudness *is likely to be closely associated with the physical vibrations of the BM* [30.156, p. 100]. In this respect, a close correspondence between BM vibration amplitude and loudness sensation could be expected. However, it has been argued from observations in animal experiments that, even for pure tones, *no one location in the cochlea can encode the entire auditory dynamic range of sound intensities* [30.157, p. 178]. The *loudness code*, therefore, must cover the activity from an area of neurons. The magnitude of the sensation of course should relate, in a lawful manner, to the intensity of the sound stimulus as well as to the corresponding pattern of excitation. While BM excitation is accessible to measurement, neural processing that leads to the sensation of loudness in humans has become a topic of research just recently [30.158–160]. In the 1940s and 1950s when

Table 30.3 Relation of subjective loudness (sone) to loudness level (phon)

Stevens conducted most of his experiments, *inner psychophysics* of loudness was difficult to investigate so that *outer psychophysics* – having observers *assign numerals* to stimuli according to the apparent strength with which sensory attributes were registered – seemed a viable option. In addition, since many observations on loudness sensation could not be satisfactorily explained in terms of Fechner's law, seeking an alternative was certainly justified. The question seems whether the *new psychophysics*, which deems magnitude estimation experiments and attempts at *direct measurement* as well as scaling of sensory attributes in general essential [30.161], has led to significant results in regard to factual evidence and methodology.

One has to remember the *psychophysical law*, which claims that *equal stimulus ratios produce equal subjective ratios* ([30.92, pp. 153, 172]; Sect. 30.1.4, *Historical and Theoretical Background*). Attributes of sensation hence are ratio-scaled so that subjective magnitudes relate to the physical stimulus by a power function [30.70, Chap. 3]. *Luce* [30.162, Theorem 1] has demonstrated that the only function that will preserve physical intensity ratios is of the form $u(x) = \mathrm{a}x^{\beta}$ where x is a typical value of the independent variable, $u(x)$ is the value of the dependent variable, and the exponent $\beta > 0$ is a constant independent of both the unit for u and for x. Consequently, in regard to loudness [30.110, p. 136], the function is $L(I) = AI^{\beta}$, where I denotes intensity of sound and A and β are positive constants.

To facilitate such neat formula, assumptions have to be made. One of the most fundamental assumptions is *that stimuli and responses both form continua*. If this assumption cannot be justified, this *would mean casting out much of psychophysical theory* [30.162, p. 92]. In fact, many textbooks on psychophysics as well as on psychology in general seem to take it for granted *that stimuli and responses both form continua* while empirical data quite often do not support this assumption. Judgments received from subjects in many experiments conform to an ordinal scale (at best), and this is also found in experiments on loudness in particular when stimuli are chosen from real music ([30.163] and Chap. 33). But also in laboratory experiments observations were made that indicate that subjects might use a single (ordinal) scale for either ratio or difference estimates of loudness [30.164]. Moreover, it has long been noted that *scales based on direct judgments of subjective differences are linearly related to those based on subjective ratios* [30.165, p. 203], and that a logarithmic transformation of a (prothetic) magnitude scale often corresponds closely to a category scale [30.100, p. 56 f.]. In regard to the power law, *Stevens* [30.147, p. 586] himself noted that, *at frequencies below* 400 Hz *there is a dramatic change in the exponent of the power function that governs loudness*. *Stevens* [30.88] maintained, however, that notwithstanding necessary corrections, the basic approach (largely based on magnitude estimation and magnitude production tasks leading to ratio scales) was sound, and that the power law applies to sensation of loudness.

To assess matters properly, one has to recall that the search for a loudness function that relates the intensity of a (pure or complex) tone to the sensation of loudness had begun in the 1920s. Attempts at fitting data to functions corresponding to the laws of Weber and Fechner [30.141] met with great difficulties. In addition, *Newman* [30.166] had argued, against Fechner's approach, that the JND is not a unit suited to measure the loudness of tones of different frequency. One might object to his conclusion, though, since the differences in the number of JNDs he calculated (largely from data taken from [30.135]) for six frequencies {80, 200, 400, 1000, 1900, 4000 Hz} to fit in between the lower limen and a loudness level of 70 dB are probably due to the lower limen varying with frequency. In principle, observers might attempt to estimate the difference between two sensory magnitudes (A, B) by imagining the size of the relevant JND, and then *summing up* the number of JNDs corresponding to the difference A $\leftrightarrow$ B; such a process might work if the difference between A and B is rather small (so that the JND appears as a fraction of the difference A $\leftrightarrow$ B, and can also be regarded as of constant size within this range). Though a Fechnerian process of *indirect* sensory measurement cannot be precluded always (depending on the type of stimulus and experimental conditions as well as on the observer's strategy to deal with magnitude estimation), it became clear from many experiments that subjects could estimate the magnitude of two stimuli (in terms of either *difference* or *ratio*) by *direct* comparison.

Several versions of *corrected* loudness functions have been issued previously [30.167, 168]. In regard to the striking variability of data reported in many publications on loudness, it seems questionable that a single loudness function could account well for a very broad range of possible stimuli (from sine tones to full orchestra, and from distant traffic noise to types of sound loaded with impulses such as produced by machinery

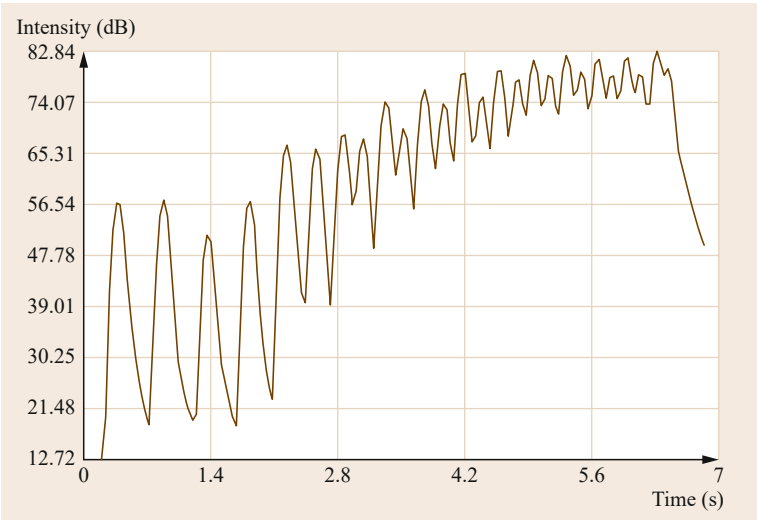

Fig. 30.6 Sequence of strokes on a snare drum; increase of intensity (dB)

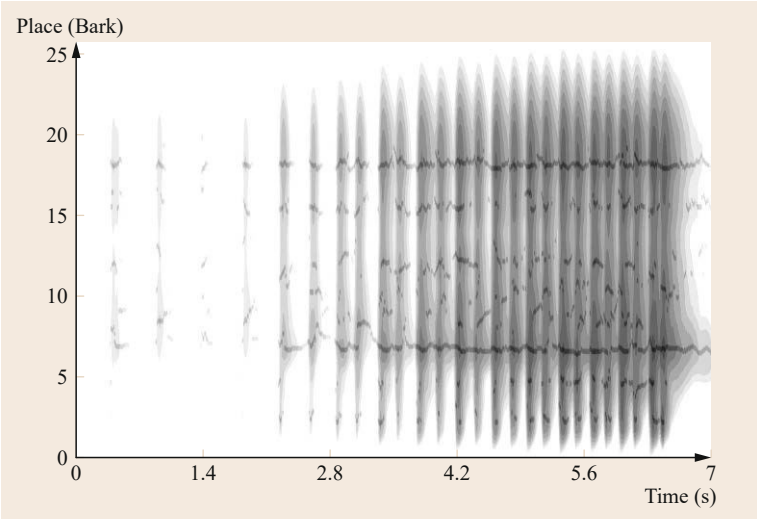

Fig. 30.7 Cochleagram, sequence of drum strokes on a snare drum

or, for that matter, techno music). One aspect that might possibly explain, at least in part, the extreme variability of data on loudness is that sound stimuli comprise more than one physical dimension (and, correspondingly, more than one parameter), which in turn address more than one sensory attribute. To illustrate the case, we take a sequence of strokes applied to a snare drum with different force. Of course, intensity (dB) of the sound (recorded with a single condenser microphone from ≈ 50 cm above the upper drum skin) rises with increasing force as input variable (Fig. 30.6).

Because the force applied increases, more modes of vibration are elicited. From the cochleagram of the same sequence, it becomes evident that spectral energy also increases so as to involve more of the Bark filters at the low end as well as the high end (Fig. 30.7). Thus, there is a *spread of excitation* in that more critical bands (CBs) are activated at higher levels of intensity; consequently, there is significant energy in most of the 25 (Bark) filters representing the BM. According to models of *loudness summation* [30.152, 153, 169], sensation of loudness increases in proportion to the number of CBs activated (Chap. 33).

However, there is more than an increase in loudness. As more modes in the drum are elicited due to an increase in the force applied, spectral energy both at low and at high frequencies increases and the sounds in the sequence are perceived as developing both more *depth* (the relevant sensory attribute being *volume* at low frequencies) and more *edge* (the attribute being *sharpness* due to amounts of energy at high frequencies). Since spectral energy increases both at low and

at high frequencies, the spectral centroid (a weighted mean of spectral energy [30.9]) does not vary much from one stroke to the next (its position stays close to 3–3.2 kHz). However, especially in brass instruments (trumpet, trombone, etc.), increasing physical parameter values (pressure of blowing, which affects also velocity of the particles) at the input also will excite more of the higher modes, which typically leads to a shift of the spectral centroid towards a higher frequency. A higher spectral centroid is sensed as an increase in brightness, and may be experienced also as an increase in sharpness (Sect. 32.2.2, *Semantic Attributes of Timbre*). In sum, by changing a single stimulus parameter more than one sensory attribute may be affected.

Stevens of course knew this problem (even from his early work; [30.170, 171]). *Stevens* [30.88, p. 54] argued that, in experiments, *the subject has the help of instructions designed to direct his attention to a single attribute of a stimulus*. To direct a subject to act this way means he or she must suppress information contained even in seemingly simple stimuli (such as pure tones, which can contain information relevant to sensation of *pitch* and *loudness* as well as to phenomenal attributes such as *brightness*, *volume*, *density*, and *vocality*; [30.116], Chap. 32). Though it is possible to focus attention on a single attribute, there are *integral* dimensions of sensation and perception [30.172, Chap. 5] so that one dimension implies the existence of the other. Experiments have shown that sensation of *pitch* is not totally independent of *loudness* (since a change in SPL can influence the *pitch* of pure tones to some degree; Sect. 31.1, Sect. 31.6.1) and that both *pitch* and *loudness* relate to a dimension of *brightness* [30.173, 174]. Since *brightness* plays a significant role also in vision, there are intermodal correspondences (accountable to neural networks connecting input from different sensory channels). Given the often intricate interrelation between *dimensions* and *attributes*, an approach comprising combinations of variables to study cross-modal information integration and multimodal effects has been proposed, with the aim of establishing a *psychocognitive law* [30.175]. The multimodal and multidimensional paradigm (that is necessary to understand, for example, timbre perception; Chap. 32) may be suited to overcome limitations of *classical* psychophysics where, in quite many experiments, single attributes and dimensions have been investigated. There were certain reasons to proceed this way, among them technical issues as is evident also in many publications on loudness from the years 1920–1950. In general, experimental designs and theoretical frameworks quite often relate to current information and communication technology (as the setup of later and more advanced theories such as signal detection shows [30.176, 177]).

In retrospect, *Stevens* [30.89, 146] took the quest for *summation* and *additivity* of sensory magnitudes from the research on loudness undertaken by *Fletcher* and *Munson* [30.142, Chap. 3], [30.178]. He probably also found inspiring the aspect of a physiological explanation of magnitudes of sensory attributes that had been pursued since the 19th century, and had been adopted by Fletcher early on [30.179]. We will explore this issue, to some degree, by taking a look at the so-called *mel scale* [30.113, 180] devised to study *melodic pitch*. The English-American term *pitch* has many different meanings (only some of them relating to sensation and perception). A well-known definition tells us pitch is *that attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from low to high* (ANSI 1973, after [30.181, p. 267]). Traditionally, the physical parameter considered most relevant to determine the sensation of pitch, especially of pure tones, was frequency.

While loudness of pure tones was found to depend on both intensity and frequency, the point of departure for research that led to the *mel scale* apparently was that the pitch of a pure tone of given frequency (Hz) as sensed by observers can be changed to some extent by manipulating intensity. Experiments to this effect were undertaken by Stevens and some other researchers in the 1930s, and have been repeated (with some modifications) thereafter. The effect of SPL on the pitch of pure tones is small at medium frequencies (400–1000 Hz) and medium SPL (60 dB) yet increases at both low and high frequencies with SPL where the pitch shift exceeds 1% [30.152, p. 114]. *Stevens* et al. [30.180, p. 185] argued that, because of the effect intensity can have on sensation of the pitch of pure tones, pitch cannot be simply equated with frequency. Therefore, a new scale for pitch would be apt to account for *the perceiving organism*. This scale, taking a reference loudness of 40 dB, should consist of *numbers whose values are directly proportional to the magnitude of the perceived pitch*. The scale was derived, analogous to loudness scaling, from fractionation involving the *half as ...* task (in this case: *half as high*), and resulted in a pitch function. However, in regard to difference limen (DLs), the experiment yielded that *all DLs for pitch, at a constant loudness level, are of equal subjective magnitude* [30.180, p. 189]. This finding was interpreted in regard to the structure of the BM such that the DLs are associated with *the location of stimulation on the BM*, that is, in terms of a place theory of pitch (comprehensive summaries of pitch theories are given by [30.6, 182–185]). Consequently, the pitch scale as devised by Stevens et al. should closely correspond to BM tonotopicity (from Greek tonos = tone and topos = place). Finally, in regard to musical intervals, *Stevens*

et al. [30.180, p. 190] concluded that, *throughout the useful musical range, intervals increase in subjective magnitude with increasing frequency of the stimulus*. They believed to have thereby proven a hypothesis expressed by *Carl Stumpf* [30.186, p. 250], according to which *the same interval represents, with rising pitch up to about* c^3 [C_6 in US octave designation]*, an increasing distance in sensation*. However, Stumpf considered this but an assumption, and was rather critical of so-called *distance comparisons* of pairs of tones [30.186, pp. 247 ff.] since he had found that observers with a musical background would almost *go crazy* if forced to estimate *tone distances* while at the same trying to suppress perception of musical intervals. As an example, he said that three pure tones having frequencies of 71 : 97 : 111 Hz would be perceived as a somewhat detuned fourth (71 : 97 ≈ 540 cent) and as an enlarged whole tone (97 : 111 ≈ 233 cent), and not as tone distances per se.

The mel scale was issued in a revised version [30.113] based on additional experiments where subjects had to segment large frequency distances (200–6500 Hz, 40–1000 Hz, 3000–12 000 Hz) into *four equal pitch distances*. This is a complicated task since, for example, the interval 200–6500 Hz in fact spans more than five octaves (Table 30.4). The task thus implies dividing an interval of 6027 cent into four equal parts. If this interval is segmented into four *tone distances*, each such distance would be ≈ 1507 cent wide, and each pair of tones would need a frequency ratio of $f_i/f_j = 2.388$. The five tones framing four *equal tone distances* thus would have frequencies close to

200 477.61 1140.56 2723.71 6500 Hz

As can be expected, the data obtained from subjects show a huge amount of variability caused by the experimental design, and even averages are far from the correct values. For Stevens, the mel scale was meant to demonstrate that the sensation of pitch (of pure tones) is a *function* of frequency, yet cannot be simply equated with frequency. As an anchor point, Stevens chose the sensation of pitch corresponding to a sine tone of 1000 Hz presented at 40 dB SPL to have a *melodic pitch* of 1000 mel. The pitch function for the mel scale is shown in Fig. 30.8.

Here, frequency is kept linear to indicate how large an *octave* expressed in mels would be in corresponding frequency. For conversion of mel to frequency, several algorithms have been proposed [30.187, 188], like

$$\text{mel} = 1127.01048 \times \log\left(\frac{f}{700+1}\right);$$

$$\text{also mel} = \left(\frac{1000}{\log(2)}\right)\left(\log\left(\frac{f}{1000+1}\right)\right)$$

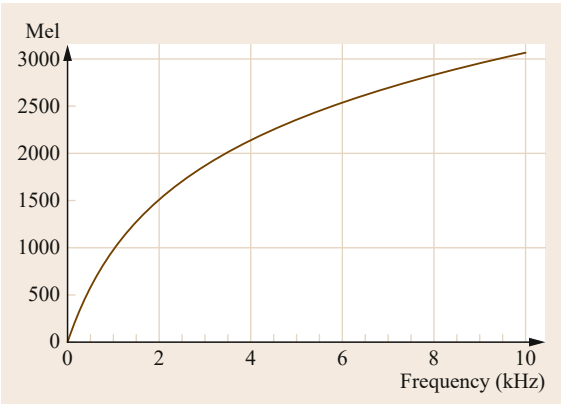

Fig. 30.8 *Mel pitch* as a function of frequency (Hz)

For example, doubling 800–1600 mel corresponds to a *tone distance* of 723.57–2195.07 Hz, which is much more than an octave, namely, in excess of an eleventh (expressed on a logarithmic scale relevant to psychoacoustics and music, the *tone distance* equals 1921.27 cent). Conversely, the octave 800–1600 Hz would yield a *tone distance* expressed in mels like 853.94–1340.674, that is, a ratio of merely 1 : 1.57, which is much less than a musical octave (the ratio 1.57 equals 781 cent, implying a musical interval of a minor sixth). With frequency given on a logarithmic scale, a graph for the mel pitch function results as shown in Fig. 30.9.

After using fractionation and equisection, Stevens later extended his experiments to magnitude estimation of pitch distances. He admitted that *many of the observers registered some degree of protest* [30.104, p. 407] when called to make such estimates. Also, experiments involving piano tones as well as pure tones showed the influence of musical intervals, in particular of the octave, on pitch magnitude estimates [30.189].

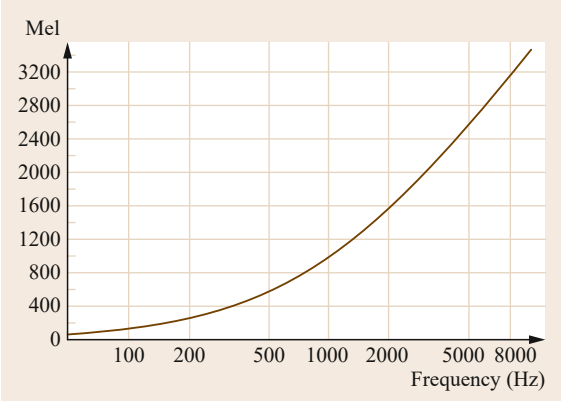

Fig. 30.9 Mel pitch function for a frequency range from 50 Hz to 10 kHz

Table 30.4 Structure of frequency distance 200–6500 Hz

200		400		800		1600		3200		6400		6500	Hz
	1200		1200		1200		1200		1200		27		Cent

Indelible effects of musical interval perception were discussed in terms of *response biases*, but empirical data indicated that the mel pitch function would not remain invariant. However, it was held that the mel scale was *fairly well established* from empirical data, and moreover was supported by *the simple relationship it bears to JNDs, critical bands, and other auditory parameters* [...] *as well as to anatomical and physiological findings* [30.151, p. 47]. Stevens was of the opinion that the mel scale of *subjective pitch* or *apparent pitch* [30.88, p. 165 ff.] had deep anatomical and physiological foundations, in that it mapped frequency to the BM, and was suited to describe basic psychoacoustic concepts such as the CB and the JND in terms of the *mel* unit. According to *Stevens* [30.88, pp. 165–67], there is a correspondence between *equal distances along the BM and equal pitch differences in mels* so that *the pitch function [in mel] provides a linear map of the BM*. Also, he believed the smallest resolvable difference between two pitches to be *about one mel*. In comparison, *Zwislocki* [30.151, p. 50] had calculated 1 JND $\approx$ 4.5 mel at $\approx$ 80 dB SPL. Finally, the size of the CB was assumed to comprise 100–180 mel (depending on frequency range), with an average somewhere around 137 mel [30.190, p. 557] or, rather, 100 mel [30.88, p. 167]. Ideas expressed by Stevens on CBs relating to the BM and data published by *Georg von Békésy* [30.191] and other researchers relating stimulus frequency to place of maximum excitation on the CP led to a cochlear map and a formula proposed by *Greenwood* [30.192]. From the hypothesis that CBs (without any overlap) represent equal distances on the BM, the position x of a frequency f on the BM (apex to base) can be calculated like

$$f = A \times (10^{ax} - k) \,,$$

in which A, k, and a are specific for certain species, among them humans [30.192, 193]. The graph of the pitch function (Fig. 31.4 and Fig. 31.5) shows that, *over most of the BM, and most of the frequency range, log frequency versus basilar position is nearly a straight line* [30.193, p. 2602]. However, this is not the case for low frequencies ($f < 500$ Hz) where the curve flattens markedly towards the apex (Fig. 31.4).

In regard to an anatomical and physiological interpretation of the mel scale, *Zwislocki* [30.151, p. 55] concluded *that equal distances on the pitch scale correspond to equal numbers of peripheral neurons*. He gave the following correspondences

$$1 \text{ mel} \mathrel{\widehat{=}} 12 \text{ neurons},$$
$$1 \text{ JND} \mathrel{\widehat{=}} 52 \text{ neurons},$$
$$1 \text{ CB} \mathrel{\widehat{=}} 1300 \text{ neurons}.$$

Zwicker et al., who had carried out experiments on *ratio pitch* independent of Stevens, yet had employed the method of fractionation (*half as ...*) and established a scale centered at 125 Hz where ratio pitch nearly converges with frequency up to about 400 Hz. For higher frequencies, the increase in frequency to produce same ratios is similar to the *mel scale* [30.109, pp. 57 ff.]. *Zwicker* and *Fastl* [30.152, p. 162, Table 6.2] relate the scale of 24 CBs (expressed in Bark(z)) to the length of the human BM (about 32 mm), the number of JNDs, mels, and the number of hair cells. From this table, the following correspondences are given

$$24 \text{ Bark} \mathrel{\widehat{=}} 32 \text{ mm} \mathrel{\widehat{=}} 640 \text{ JND} \mathrel{\widehat{=}} 2400 \text{ mel} \mathrel{\widehat{=}} 3600 \text{ hair cells}$$
$$1 \text{ Bark} \mathrel{\widehat{=}} 1.3 \text{ mm} \mathrel{\widehat{=}} 27 \text{ JND} \mathrel{\widehat{=}} 100 \text{ mel} \mathrel{\widehat{=}} 150 \text{ hair cells}$$
$$0.01 \text{ Bark} \mathrel{\widehat{=}} 13\,\mu\text{m} \mathrel{\widehat{=}} 1 \text{ mel}$$
$$1 \text{ JND} \mathrel{\widehat{=}} 3.8 \text{ mel}$$
$$1 \text{ mm of BM} \mathrel{\widehat{=}} 20 \text{ JND} \mathrel{\widehat{=}} 75 \text{ mel}$$

Questions concerning the validity of the *mel scale* must have started when observations from the experiments of *Stevens* and *Volkmann* [30.113] could not be replicated in another laboratory [30.194]. In 1956, experiments performed at Stevens' lab led to effects that gave even more concern in that observers, when asked to divide a *tone distance* of 400–7000 Hz into four equal appearing parts, did not choose identical frequencies in ascending and in descending order (different from what Stevens had expected; [30.120]). Also, hypotheses Stevens had formulated with respect to equal pitch differences (in mels) corresponding to equal distances on the BM could not be confirmed, while the actual data supported models of the cochlea map where distance on the BM relates to log frequency as well as to musical intervals ([30.120] and Sect. 31.3). *Stevens* [30.88, p. 168] maintained that musical intervals based on frequency ratios such as 2 : 1 or 3 : 2 would not be perceived as identical in different registers, and instead *increase in perceived pitch extent with increasing*

stimulus frequency. Seeing that musicians tune their instruments (e.g., the strings of a violin) to musical intervals, Stevens dispraised them for tuning *to the musical scale, not to the scale of subjective pitch*.

The claim that a scale of *subjective* or *apparent* pitch would exist independent of musical pitch scales has been refuted, from various angles. First, there is sufficient empirical evidence to conclude that, at least for subjects with some musical background, *equal ratios of frequency give rise to approximately equal intervals of pitch* [30.195, p. 412]. Second, experiments involving transposition of tonal patterns showed that both subjects with and without musical training carry out transpositions in a log frequency medium, which is suited to represent as well as to preserve melodic and other tonal patterns as invariant under transposition [30.196].

While the musical scale based on log frequency is form-bearing (*morphophoric*), in that melodies can be shifted up and down the scale, the *mel scale* as proposed by *Stevens* and *Volkmann* [30.113] is not. The very term *melodic scale* thus is a misnomer. The only finding that may support ideas connected with the *mel scale* is that, above 5000 Hz, in particular subjects lacking musical training tend to perform *tone distances* (when asked to realize a tonal pattern) that do not conform to the size of musical intervals. Explanations for such performance include mechanisms of pitch perception where an upper limit of temporal coding seems to exist at about 4–5 kHz (Sect. 31.4) as well as unfamiliarity with the sensation of pure tones or even small noise bands [30.109, pp. 557 ff.], which were used for pitch production in a high frequency range in order to avoid musical allusions. *Stevens* has pointed to difficulties reported by observers to deal with *those high pitchless tones* [30.104, p. 408]. A third argument against the *mel* concept was that, in a cross-cultural perspective including *Western* music, the logarithmic musical scale accounts for octave identity (a *universal* or at least *near-universal* auditory *and* musical phenomenon; Sect. 31.1.2) as well as for the representation of modal structures and melodic contours based on a hierarchy of pitches [30.197]. Finally, the inadequacy of the *mel scale* becomes fully apparent if a piece of music is realized with this scale (for compelling melodic and harmonic examples, listen to demonstration no. 49 provided by [30.198]).

Though *Licklider* [30.199, p. 1003] had characterized the *mel scale* as representing *the ordinary type of pitch perception*, this is not quite correct. The experiments conducted by Stevens (as well as by Zwicker) evidently are directed to but one of the dimensions constitutive of pitch perception, namely *tone height* while *tone chroma* (the property of tones to be part of a scale organized in intervals that can be identified as meaningful entities; see Sect. 31.1) was disregarded. Stevens himself wasn't even sure whether *subjective pitch* would conform to a metathetic continuum, or if the low end (frequencies below, perhaps, 200 Hz) should be viewed as prothetic [30.104, pp. 406–409]. He saw clearly that *pitch* is a sensory attribute that does not lend so easily to scaling outside and independent of musical pitch [30.88, pp. 164–69]. Though concepts of *ratio pitch* and the *mel scale* continued to be outlined in books on psychophysics [30.152, Chap. 2] and [30.1, pp. 354–356] and [30.4, pp. 295–297], and the *mel pitch function* also has been used in signal processing of speech (where cepstral coefficients are calculated on the basis of the *warped* mel scale [30.200]), the attraction such constructs as the mel scale had in the heyday of *operationism* is certainly lost.

Though scaling of sensory attributes has continued (and is inevitable, if only for practical reasons such as sound and noise control), attempts at establishing *the* psychophysical law applicable to a range of modalities and sensory attributes might be met with some reluctance. However, there have been alternative approaches to formulating general laws with respect to perception and cognition. One such law evolved from concepts of multidimensional scaling and was directed to perceptual generalization, viewed as *a cognitive act, not merely a failure of sensory discrimination* [30.201, p. 1319]. The concept of similarity, basic to our experience and, therefore, at the core of various methods of unidimensional and multidimensional scaling, has been employed in formulating a general recognition theory [30.202, 203].

Another approach stems from information theory. Regarding perception as a choice between alternatives, *Norwich* [30.204] has offered a *fundamental equation*

$$F = kH\,,$$

where F is a perceptual variable, $k > 0$ is a constant, and H is the entropy. From the *fundamental equation*, an equation called *the entropy law*

$$F = \frac{1}{2}k\ln(1+\gamma I^n)$$

is derived with I = intensity and γ being a constant (the value for γ as well as for the exponent n need to be determined from experimental data), which is said to embrace both the *laws* of Weber and Fechner as well as of *Plateau* and *Stevens* [30.204, Chap. 10]. The entropy function can be fitted to empirical data from, for example, experiments on loudness.

Sensations Briefly Re-viewed

Concluding the chapters on measurement of sensation, an issue that has been brought up since Fechner will

be briefly re-viewed, namely, the nature of *sensations*. It should be recalled that, in the 19th century, psychology as a discipline largely developed from two angles, one being sensory physiology, the other philosophy (for much of the historical background, see [30.144]). Sensations had to be treated, on the one hand, in regard to sensory organs, their anatomy, physiology, and specific functions. In addition, characteristics of physical stimuli had to be investigated to see how peculiar sensations would relate to properties of the stimulus. On the other hand, the *content* of the sensations as providing the substrate for perceptions was of interest. In this regard, sensations have been viewed as *elementary processes of consciousness* [30.49, p. 30] dependent on the stimulus input as well as the function of the respective sensory channel from periphery to center. The concept of sensation in this way comprises aspects beyond the physiological level, in that a sensation can convey a *quality* or express an *intensity*, and leads to further categorization of the input involving previous perceptual experience and memory. This is the framework that underlies much of Helmholtz's *Tonempfindungen* (as well as his writings on physiological optics).

From an empiricist and realist perspective, it can be argued that sensory data, which result from peripheral stimulation such as sound waves and a transduction process of physical energy into neural code, contain information that is analyzed at a number of stages of the (auditory) pathway up to the cortex, to yield percepts that can be further processed in various ways. A functional view thus adopted of course needs to go into (anatomical, physiological, psychophysical) detail provided, for the most part, by empirical research. Such research reveals that sensory input is analyzed, in the auditory system (as well as in other sensory channels) with respect to stimulus features, with the purpose of identifying *what* the input represents [30.45]. Parallel, and in specific neural pathways [30.8, Chap. 6], the input is analyzed as to *where* it comes from. Information from both streams (identification, localization) then is combined into some code representing an (auditory or visual) *object* at higher levels where further perceptual processing as well as motor responses may be started.

The nature of sensation and perception has also been an issue in philosophy where, for example, extensive debates concerning the status and purposes of *sense-data* have taken place [30.205, Chap. 7] long before major camps in philosophy took a monistic turn in regard to the time-honored mind-body problem. From a monistic point of view inspired by neuroscience, there is no question that musical sound we hear is transformed into *sequences of electrochemical pulses streaming up the axons of neurons* [30.15, p. 49], and that, even though these pulse sequences as such are *toneless signals*, they can be analyzed in the CNS so that we perceive a sound by noticing at least some of its attributes. What we perceive by hearing a sound (say, the opening chord of an electric guitar in *A Hard Day's Night*) of course is not the *toneless signal* of neural pulse trains but a representation of the physical stimulus. Representation in this respect means that spectral and temporal features of the sound are transformed into an auditory image (Sect. 31.5), which permits further analysis into constituents that are perceived as phenomenal attributes. From a logical point of view, the relation between sensation and perception in principal is hierarchical (having a *sensation* is a necessary condition for *perception*; [30.205, Chap. 7]) though a gradual transition is possible (Sect. 30.1.2). For example, it can be said that, on the level of sensation, a set of tones of nearly equal sound level and almost identical onset time is heard as a complex sound while, on the level of perception, it is categorized as a chord or sonority [30.206, p. 208]. Even a phenomenologist like *Husserl* [30.207] acknowledged that comprehension often starts from *outer perception* (conceived as a basically receptive mode of becoming aware of things), but is soon turned into acts of judgment and predication, from which generalized empirical concepts (such as the *type*, perceived as a recurrent combination of certain features) and finally notions on higher levels of abstraction result. Hence, sensing things in the *world out there* can be regarded the initial step in a process leading to perception that includes more detailed categorization of the sensory input; still one step further, a subject may possibly achieve apperception (apprehension), which, in general, calls for conscious analytical access [30.206].

Part of the argument leveled against Fechner had been that measurement of the intensity of sensations is impossible since this would require measurement of intensities inside the organism. In that *inner psychophysics* could not be pursued to much effect in those days, the opposition concluded that *outer psychophysics* only performed measurement of the physical stimulus, and that Fechner's approach to *indirect* measurement of sensation in fact meant not measuring sensation at all. By the time Stevens set to work on psychophysics, factual knowledge of anatomical structures and physiological processes relevant to hearing had grown significantly [30.146]. Correlations between properties of auditory stimuli and response patterns in the AN had been reported [30.208]. In this respect, *inner psychophysics* including measurement of intensities on the neural level had become feasible. Some findings obtained from electrophysiological recordings of cortical potentials yielded a correspondence

of stimulus intensity and amplitude of potentials that seemed to corroborate several of Stevens' power law exponents [30.209, 210]. The amplitude of potentials recorded as a function of stimulus intensity was interpreted as *strength of sensation*. Notwithstanding such attempts at introducing objective methods into psychophysics from neurophysiology, much of the research kept a focus on behavioral studies where responses to stimuli were obtained from methods such as fractionation, magnitude estimation, and cross-modal matching. The main reason why psychophysics often was constrained to investigations of (in many experiments, unidimensional) stimulus–response patterns perhaps is that, in an era when behaviorism and operationism were leading paradigms, observation of *public* behavior was deemed scientific. Even in his final book, *Stevens* reconfirmed this position:

> *What science means by sensation is a construct, a conception built upon the objective operations of stimulation and reaction. We study the responses of organisms, not some nonphysical mental stuff that by definition defies objective test.* [30.88, p. 51]

Sensations thus were taken as *behavioral reactions*, not the psychic processes Fechner seems to have envisaged.

For the purpose of this chapter, sensations are regarded, in general, as processes induced by physical stimuli that lead to specific patterns of excitation of sensory organs as well as to corresponding specific patterns of neural coding (for a recent overview of relevant facts and models, see [30.45]). For example, sensation of tonal roughness and beats has been explained, from *Helmholtz* [30.211] to the present, with respect to spectral and temporal features of sound stimuli giving rise to peculiar BM excitation patterns that in turn are transformed into neural code reflecting modulation. By inference, a certain code pattern found at some of the relays of the AuP indicates a corresponding *sensation* is likely to occur in the organism. From a similar perspective, current research seeks to trace certain stimulus features as encoded in neural spike trains along the AuP up to the cortical level (Chap. 31). According to rate-place concepts of neural organization, activation of certain areas of the brain, and in particular of cortical areas, would be viewed as a token for *perception* to take place.

30.2 Types of Sound and Sound Features Relevant for Hearing and Music Perception

Music comprises a broad range of sounds that can be characterized with respect to their temporal and spectral features. Both interact to yield dynamic *shapes* observable for single sounds as well as for compounds of several sounds that are layered (as in many types of actual music). The production of complex sounds can be effected by means of musical instruments including the human voice; of course, complex sounds are also generated and sensed by other mammals as well as by various vertebrates and invertebrates (for an overview, see articles in [30.212, 213]). In regard to sound generation and sound radiation, there are (physical and biological) systems capable of undergoing periodic or nonperiodic vibration, which can result in audible sound under suitable conditions. A detailed account of relevant facts and models (which entails stochastic and deterministic vibration, linear and nonlinear vibration, etc.) is found in textbooks such as [30.4, 125, 126, 214–217]. For the purpose of the present chapter (where only deterministic vibration is of interest), it suffices to distinguish between (a) periodic vibration, (b) quasiperiodic vibration, and (c) nonperiodic vibration. Periodic vibration, in a physical system such as the undamped oscillator, results in constant period length, $T(s)$, so that $f(t) = f(t+T)$. A single periodic vibration defined as a real-valued sine or cosine function with (peak) amplitude, A, and zero phase angle, φ

$$f(t) = A\sin(2\pi ft + \varphi),\ f(t) = A\cos(2\pi ft + \varphi)$$

can be represented in an amplitude spectrum by a line of length A at frequency f. Several periodic functions (which we assume to represent vibrations of a mechanical or electronic system) can be superposed so as to yield, according to Fourier's theorem [30.4, 217], a complex vibration pattern, where amplitudes, frequencies, and phase angles can be chosen at will. If individual vibrations have different phase angles, these can be plotted in a phase spectrum in addition to the amplitude spectrum. In the following example (Fig. 30.10) five simple vibrations defined by real-valued cosine functions have been superposed.

Note that the frequencies form a harmonic series where $f_n = n \times f_1$ (for $n = 1, 2, 3, \cdots, k$) and that the amplitudes decrease from one component to the next like $A = 1/n$. Also, all components are phase-locked at $\varphi = 0$. It is easy to see that Fig. 30.10 contains ten periods of vibration covering 0.1 s; hence, $T = 10$ ms, which is the inverse of the frequency with which the complex pattern of vibration repeats. Since $T = 1/f$,

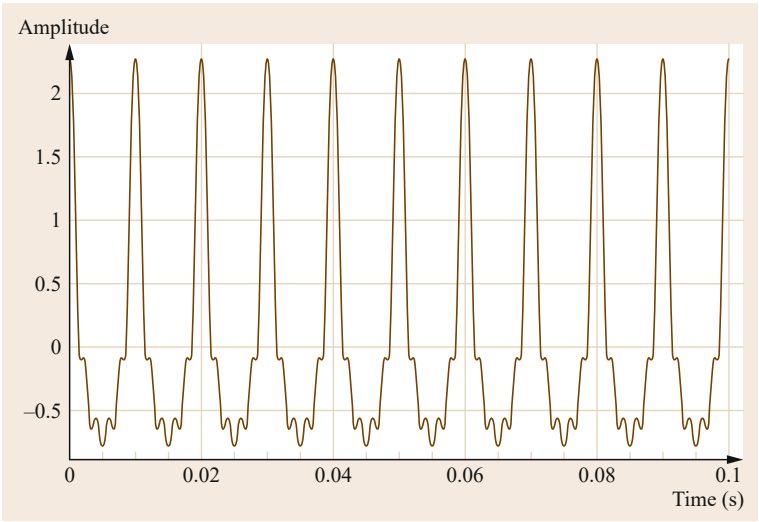

Fig. 30.10 Periodic vibration composed from five harmonic components Cos[2Pi100t] + 0.5Cos[2Pi200t] + 0.33Cos[2Pi300t] + 0.25Cos[2Pi400t] + 0.2Cos[2Pi500t]

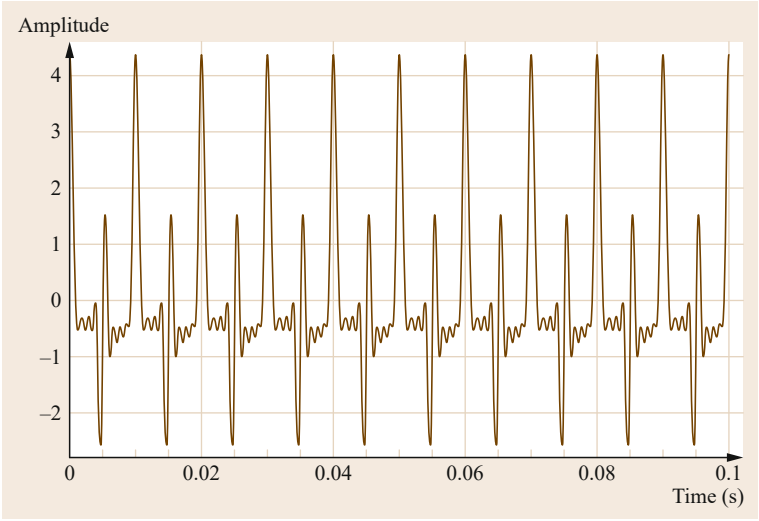

Fig. 30.11 Superposition of nine harmonic components Cos[2Pi100t] + 0.9Cos[2Pi200t − 10Degree] + 0.8Cos[2Pi300t + 20Degree] + 0.7Cos[2Pi400t − 30Degree] + 0.6Cos[2Pi500t + 40Degree] + 0.5Cos[2Pi600t − 50Degree] + 0.4Cos[2Pi700t + 60Degree] + 0.3Cos[2Pi800t − 70Degree] + 0.2Cos[2Pi900t + 80Degree]

also $f = 1/T$ is obtained. The frequency with which the complex vibration or waveform repeats per time unit in this chapter will be indicated as f_0. Since f_0 refers to a complex vibration or sound (as might be displayed on an oscilloscope), it has also been labeled the *oscillatory frequency* [30.3, p. 87]. In the case of the complex vibration shown in Fig. 30.10, f_0 equals the frequency of the lowest harmonic, $f_1 = 100\,\text{Hz}$ so that here $f_0 = f_1$. If the signs $(+, -)$ and the phase angles are used to manipulate the relations between harmonics, a more complex pattern can result. Figure 30.11 shows superposition of nine harmonics, however, the amplitudes are now decreasing like $\{1, 0.9, 0.8, 0.7, \cdots, 0.2\}$, and all components have different phase angles.

Inspection of the graph reveals that there are still ten periods of $T = 10\,\text{ms}$ defined by the strong peaks, however, a second periodicity is now visible with smaller peaks in between the main peaks. From a comparison of Fig. 30.10 and Fig. 30.11, one may infer that the phase relations between harmonic (and also inharmonic) components have a significant effect on the resulting shape of a complex vibration. The patterns shown in Fig. 30.10 and Fig. 30.11 of course can be put into digital sound synthesis so that the waveshapes become audible as complex tones.

Nearly periodic vibration can be observed in the waveshapes of many sounds generated in analogue and digital synthesizers but also in aerophones such as organ flue pipes. For example, the tone C_4 played with the stop Prinzipal 8′ on the historic organ of Hollern (near Hamburg, built by Arp Schnitger 1688–1690, fully restored 2010, tuned to $A_4 = 462.65\,\text{Hz}$) in its steady

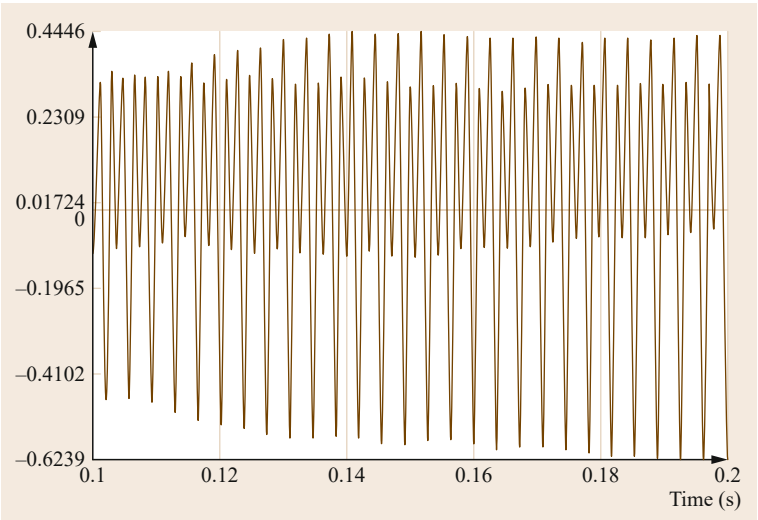

Fig. 30.12 Schnitger organ at Hollern, Prinzipal 8′, tone C_4, periodic waveshape, 100 ms

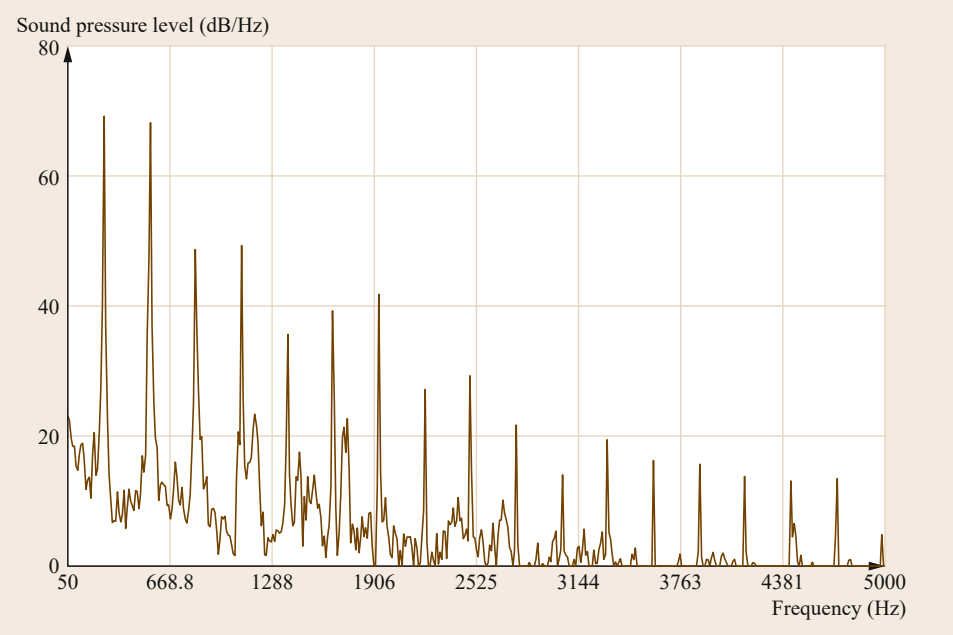

Fig. 30.13 Spectrum (LTAS), organ sound (Prinzipal 8′, tone C4, $f_1 \approx 276.5$ Hz)

state (after transients) has an almost perfect periodic waveshape, of which 100 ms (section 0.1–0.2 s of the sound) are displayed (Fig. 30.12).

Single periods have durations of ≈ 3.63 ms corresponding to ≈ 276.5 Hz, which is the fundamental frequency (f_1) of the first harmonic in the spectrum; 17 harmonic components are shown in the long-term average spectrum (LTAS) in Fig. 30.13.

The correspondence between a periodic (or nearly so) vibration or waveshape and a harmonic spectrum is covered by the Wiener–Khintchine theorem, named after seminal works published by *Wiener* [30.218] on generalized harmonic analysis and by *Khintchine* [30.219] on correlational analysis of stationary random processes. Khintchine proved that the correlation function, $R(t)$, of a stationary random process $x(t)$ can be spectrally decomposed, and that a mean exists for such a correlation function. Wiener demonstrated that, in a time series $s(t)$, the single statistical independent parameter is the autocorrelation function (ACF), $\Phi(\tau)$, which permits calculation of an expected mean [30.220, 221]. The practical implication is that a period or at least a *quasiperiod* of length T can be determined for time series where a high rate of fluctuation is evident

and periodicity is unclear because the *quasiperiod* – if it exists for a given time series – can be much extended (there of course is a limiting value at $T \to \infty$; [30.219]) or *hidden* in data due to a noisy and/or inharmonic signal. Areas where the approach outlined by *Wiener* and by *Khintchine* can be applied include extraction of periodicities from noisy signals such as EEG recordings with which Wiener worked later on to explore possibilities of ACF techniques [30.221]. In regard to music, there are idiophones such as some of the gongs found in Javanese and Balinese *gamelan* where periodicities in the sound signal are difficult to determine due to spectral inharmonicity and spectral density; analyzing such sounds with ACF can help to reveal quasiperiods.

The Wiener–Khintchine theorem, which plays an important role in signal processing [30.4, Chap. 14], [30.222], states that the power spectrum $W(\omega)$ of a stationary time function $f(t)$ equals the Fourier transform of its ACF, $\Phi(\tau)$. The Wiener–Khintchine theorem thus substantiates the role of two principles fundamental to acoustics and hearing: periodicity and harmonicity. ACF analysis (performed with the algorithm for *enhanced ACF*; [30.223]) of the organ sound displayed in Fig. 30.12 and Fig. 30.13, the tone C_4 recorded from the Prinzipal 8′ stop, yields the fundamental, f_1 (3.6 ms ≈ 276 Hz) and shows strong peaks also at lags (ms) corresponding to subharmonics of f_1 (e.g., 10.8 ms ≈ 92 Hz). The fact that the fundamental of a harmonic complex sound as well as its subharmonics can be determined by means of ACF is important also for pitch perception (Sects. 31.4–31.5).

Sounds from natural instruments as well as from the human voice are not always strictly periodic, though. Deviations from strict periodicity can be caused by various factors, among which are:

1) Fluctuations resulting from playing or singing techniques, for instance use of vibrato as is common in violin, cello and flute playing as well as in belcanto singing style.
2) Spectral inharmonicity which corresponds to (often complex) patterns of vibration.
3) Transient onset behavior as observable in sounds of many musical instruments.

In the following, some examples for these three groups will be discussed.

1) Vibrato implies a modulation of period length and, correspondingly, of frequency (FM). The notion *frequency*, in this context, changes its meaning. According to $f = 1/T$, the frequency of a stationary sinusoidal indicates the number of periods per second. However, if the period length is continuously varied with time (whereby, in the most simple case, the variation in the parameter again is periodic and corresponds to a sine or cosine function), so is the frequency of a sinusoidal, which thus becomes the *instantaneous frequency*. In terms of signal and systems theory [30.217, Chap. 6], [30.4, Chap. 19], the instantaneous frequency in an frequency modulation process can be calculated from the instantaneous or local phase $\varphi(t)$, which is a real-valued function for the complex-valued signal $\boldsymbol{x}(t)$. The instantaneous angular frequency can be determined as the derivative of the phase:

$$\omega(t) = \varphi'(t) = \frac{\mathrm{d}}{\mathrm{d}t}\varphi(t) \; ;$$

the instantaneous frequency then is

$$f(t) = \frac{1}{2\pi}\varphi'(t) \; .$$

In a practical perspective applicable to musical sound, one can say that the instantaneous frequency is that calculated for any single period of a quasiperiodic signal fluctuating more or less regularly up and down in pitch (see [30.224], with an example from Near-Eastern melismatic singing). For a number of periods, each of which differs in length (or duration as measured in *ms*), a mean period length can be calculated, to which a mean frequency corresponds as its inverse. Again, in a practical perspective, such quasiperiodic signals where the period length of any period deviates from the mean within certain limits, can be expected to evoke an *average pitch* corresponding somehow to the mean period length as well as to the mean frequency calculated for an interval relevant to auditory perception (Chap. 31).

One can easily build FM sounds from sine and cosine functions using the basic equation

$$y(t) = \sin(2\pi f_c t + \Delta f \cos(2\pi f_m t)) \; ,$$

where f_c is the carrier frequency, Δf is the peak deviation from the carrier and f_m is the modulation frequency. For example, in Mathematica code, the input

```
Play[Sin[2Pi 500t + (20 Sin[2Pi 5t]/5)], {t, 0, 10},
    SampleDepth → 16, SampleRate → 44100]
```

results in a FM sound object with audible pitch shifts up and down (similar in quality to singing a vowel such as /a/ with vibrato). If represented as a spectrum (Fig. 30.14), this FM sound reveals why the concept of *frequency* for such signals needs further consideration.

It is obvious that there are major spectral components symmetric to the center frequency, which is

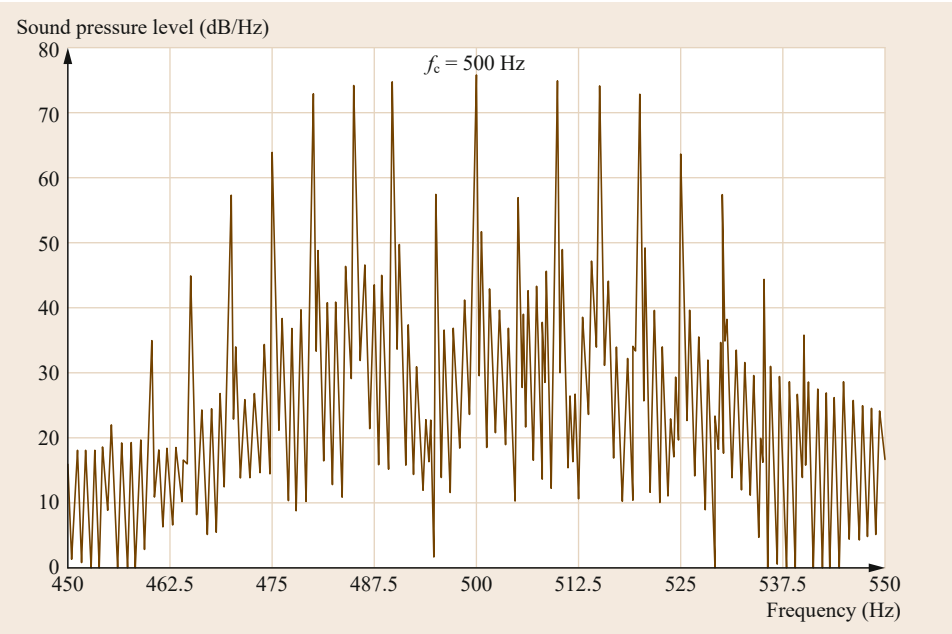

Fig. 30.14 Spectrum for FM sound Sin[2Pi500*t* + (20Sin[2Pi5*t*]/5)]

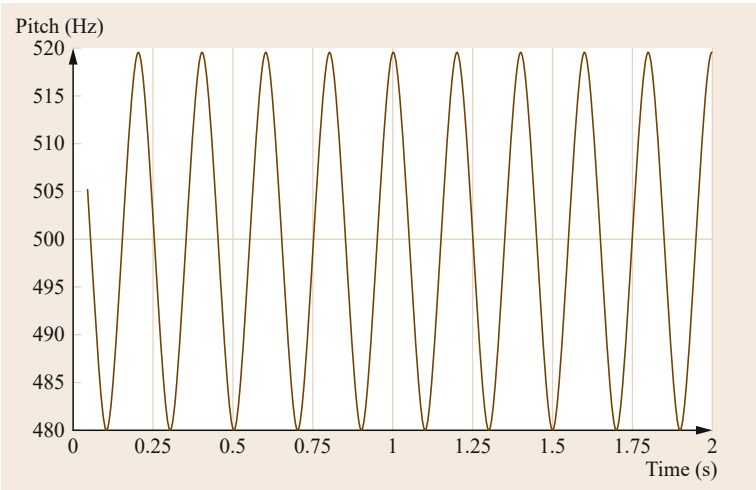

Fig. 30.15 Pitch track (f_0) for FM signal calculated from ACF

$f_c = 500\,\text{Hz}$ and represents the carrier of the FM sound. The other spectral components are at multiples of the modulation frequency, $f_m = 5\,\text{Hz}$ relative to f_c. The frequency spectrum, because of averaging frequencies over time for a certain interval (defined by the length of the fast Fourier transform (FFT) window; [30.4, 217, 222]) does not reveal specific temporal information any longer as to when exactly the period of the signal did correspond to one of the frequencies shown as peaks in the spectrum. Conversely, when the pitch track representing f_0 of the signal is calculated from the ACF (Fig. 30.15), it becomes evident that f_0 varies steadily over time; consequently, there is an instantaneous frequency for any time point. From a practical perspective, one can take a frequency f_0 corresponding to each single period to find the pitch track for a musical signal that includes FM such as a piece played on a violin *con espressione*, that is, with finger vibrato (Chap. 32).

2) Another factor responsible for the existence of quasiperiodic sounds is inharmonicity of spectral components. Inharmonic spectra are found, due to vibration patterns and wave propagation in solids [30.116, 215, 225], in almost all idiophones such as xylophones of West and Central Africa and metallophones (gongs, gong chimes, keyed metallophones comprising thick

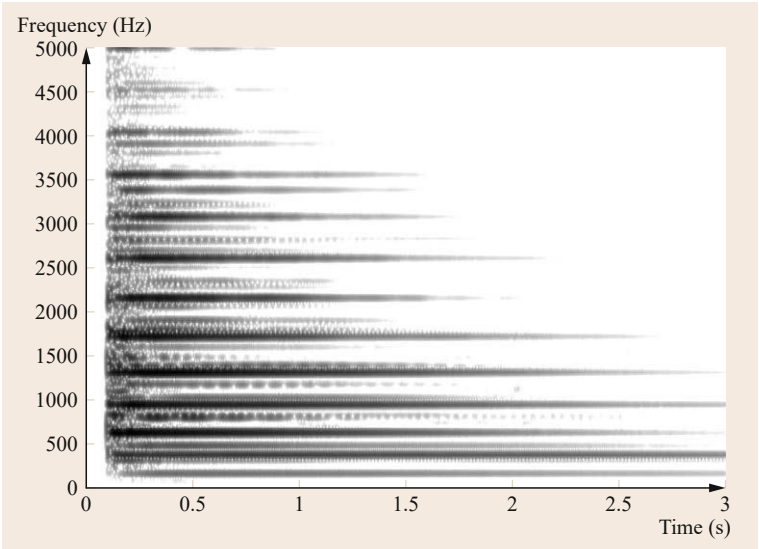

Fig. 30.16 Bell no. 7, Brugge carillon, spectral components 0–5 kHz

bronze or iron bars coupled to resonators) prominent in ensembles of South East Asia (e.g., Javanese and Balinese *gamelan*). Spectra of sounds recorded from vibration in solids are inharmonic because phase velocity of transversal as well as axial bending waves is dependent on frequency, that is, roughly, $c_B \propto \sqrt{f}$. Spectral inharmonicity of xylophone bars can be reduced by optimizing the geometry as well as by the use of synthetic material such as *palisono* (which resembles wood in certain features but is much more homogeneous and isotropic in structure). Similarly, the body of swinging and carillon bells can be shaped so that an almost harmonic spectrum results instead of the traditional spectral structure of *Western* bells where, typically, a minor third is found in one octave and a major third in the next (the frequency ratios of strong bell partials within the lower octaves are, typically, close to 1 : 2 : 2.4 : 3 : 4 : 5 : 6 : 8.1). Because of this peculiar inharmonicity (and additional inharmonic components), also the time series of sound signals recorded from bells is, at best, quasiperiodic; typically, there is no simple repetition pattern observable so that the length of the period τ is difficult to determine (for instance, by ACF methods). Sounds recorded from bells are often quite complex in regard to temporal and spectral features (attack, buildup of modes, sometimes also AM due to inharmonicity and spectral density [30.226, 227]), and hence are not easy to analyze by ear. As an example for a fairly complex spectral structure, bell no. 7 of the famous carillon of Brugge (cast by J. Dumery in 1744), shall be examined. Figure 30.16 is the spectrogram of the bell sound (displayed is the frequency range from 0–5 kHz for 3 s) where at least a dozen or so strong components can be identified plus a number of components carrying smaller amounts of energy. The main spectral components of this bell sound in the range up to 1 kHz are at the frequencies presented in Table 30.5 (for which approx. ratios and cents are given).

Interval (1) expresses the relations from one component to the next while Interval (2) indicates only large framing intervals relative to the lowest component labeled *fundamental* in this scheme (bell founders and campanologists like to use a nomenclature based on *bell partials*). From the frequency ratios it is evident that, except for the minor third, most of the components are nearly harmonic relative to the fundamental; however, the cents reveal that, already in the second octave above the fundamental, the major third is too sharp (to

Table 30.5 Brugge carillon, bell no. 7, main spectral components and bell partials

No.	Hz	Ratio	Cents	Cum.	Interval (1)	Interval (2)	Bell partial
1	153	1		0	Fundamental	Fundamental	Hum
2	306	2	1200	1200	Octave	Octave	Prime
3	367	2.4	315	1515	Minor third		Tierce
4	470	3.07	428	1943	Major third	Twelfth	Quint
5	617	4.03	471	2414	Fourth	Double octave	Nominal

7	935	6.11	287	3151	Minor third		

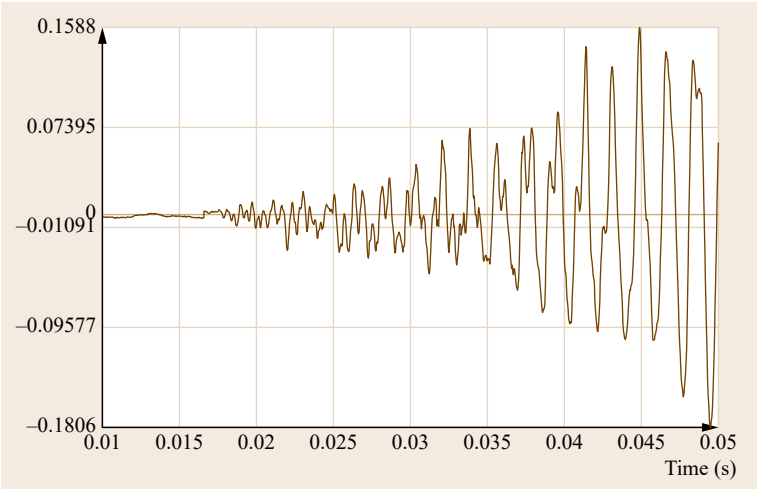

Fig. 30.17 Transient part of organ sound, Prinzipal 8′, C_4, time series for 50 ms

the effect that the twelfth relative to the fundamental is sharp) while the fourth completing the double octave is flat. Such deviations rather tend to increase in higher octaves. Moreover, in bell spectra the main partials often are found interspersed with smaller inharmonic components suited to complicate the waveshape resulting from the sum of all components, on the one hand, and to diminish its periodicity, to the other. The overall perceptual effect of spectral inharmonicity in bells is ambiguity of *pitch* (Sect. 32.2.4).

3) As a third group of sound phenomena lacking clear periodicity, transients have to be mentioned. One has to see that sound production in many instruments is effected by means of an impulse (like in percussion instruments as well as in plucked strings), or by a sequence of pulses like in aerophones where either a valve (for instance, a double reed as in the oboe or bassoon, or two lips pressed against each other, as is done by players of brass instruments) opens and shuts (completely or partly, depending on blowing pressure), or a jet stream is deflected and interrupted when hitting the sharp edge in the mouthpiece of a flute or in the labium of an organ flue pipe (for details, see [30.215]). Both the valve mechanisms (reeds, lips, also the vocal folds of the glottis) and the edge tone generator operate in a basically periodic process (or duty cycle). However, viewed in detail, these processes are quite intricate, and include nonlinearities in several, if not many parameters (for details, see [30.228, Chap. 7] and Part A of this volume). To understand fundamentals of the transient process of sound generation in an organ flue pipe, it is sufficient to see that excitation of modes of vibration in the mass of air enclosed in the pipe must be achieved against the input impedance of the system and the inertia of the mass before standing waves are established, and a steady-state sound is radiated from the pipe. Before that, with a particular key of the organ pressed, a valve opens and air (*wind* in organ terminology) starts streaming from a reservoir into the pipe. Before a certain pressure level is reached and the edge tone generator comes into action, *wind* in fact streams through the length of the pipe (in long and wide pipes such as the 16′ or even 32′ diapason pipes, this process can last for more than 50 or even more than 100 ms). Vibration then sets in for individual modes but, typically, there are several cycles where first only a few modes are established that are not yet well synchronized, leading to a pattern of vibration that lacks clear periodicity. The onset for individual modes can be very soft (with pressure amplitudes rising smoothly) or more sudden, resulting in a somewhat plosive transient (a sound phenomenon known as *spitting*). The transient sound from organ flue pipes therefore often is noisy and only partly tonal (in regard to pitch and timbre, both viewed according to the Wiener–Khintchine principle, that is, temporal periodicity corresponding to spectral harmonicity).

The transient portion of the organ sound recorded from the Prinzipal 8′ (tone C_4) is shown in Fig. 30.17. It takes about 30 ms to establish periodic vibration firmly where the overall amplitude rises due to increasing locking of modes and, accordingly, more effective superposition of harmonics.

Looking into the first 200 ms of the same organ sound with short-time Fourier transform (STFT) spectrum analysis so that the frames (2048 pts, Hanning) highly overlap (Fig. 30.18), one can follow the transient process from one spectrum to the next. It is obvious that partials 1 and 2 appear first, however, with rather flat spectral lobes that become narrower and steeper with time. Partial no. 3 starts at about 40 ms after onset, and higher partials even later. Also, there are considerable fluctuations in partial frequencies within the first

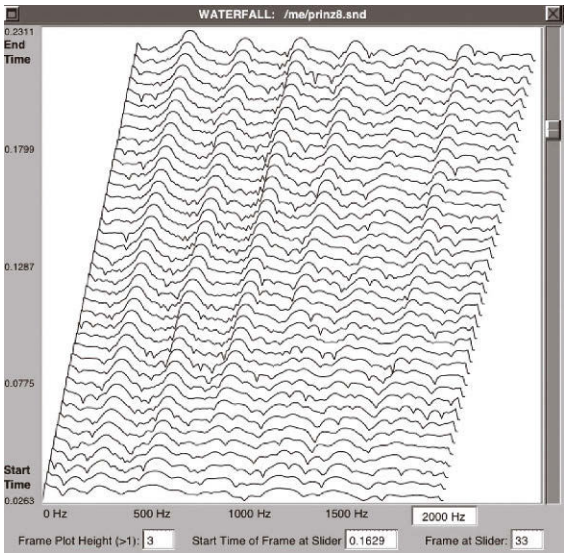

Fig. 30.18 Organ (Hollern), Prinzipal 8′, tone C_4, transient onset, 39 spectra representing ≈ 205 ms of sound

150 ms. Typically one finds the frequencies and amplitudes for each spectral component representing one of the modes of vibration to change from one frame of analysis (FFT window) to the next. Spectral flux (SF) is a parameter to measure the magnitude of such change, which can be expressed as an onset function, *SF* ([30.229] and Chap. 32).

Another method suited to analyze transients is the harmonic-to-noise ratio (HNR), which measures the degree of periodicity in the signal by either ACF or cross-correlation function (CCF) [30.230]. In the measurement presented here, the parameter actually calculated by CCF is periodicity-to-noise. The ratio is expressed in dB (a HNR of 0 dB means there is equal energy in the harmonics of a complex tone and in the noise). For the organ flue pipe, the HNR measured for one second is shown in Fig. 30.19.

As a consequence of the noisy transient, the spectral centroid (calculated with a phase vocoder algorithm; [30.9, pp. 45 ff.]) jumps to ≈ 7 kHz immediately after onset, where it peaks for ≈ 20 ms and then rapidly falls to 700 Hz and stays there for the time the sound is in its steady state (Fig. 30.20). The spectral centroid usually is calculated according to

$$C = \frac{\sum_{k=1}^{K} A_k f(t)_k}{\sum_{k=1}^{K} A_k}$$

where A_k are the partial amplitudes and $f(t)_k$ are the partial frequencies.

The spectral centroid [30.228, pp. 27 ff.] indicates the point (expressed as a frequency in Hz) of the spectrum where half of the energy is above this point, and the other half is below. The spectral centroid can be calculated for each frame of analysis (also labeled *window* in FFT algorithms; the size of the window typically is 2^n sample points, where $n = \cdots, 8, 9, 10, 11, 12, \cdots$). Taking the centroid for each frame, and having frames

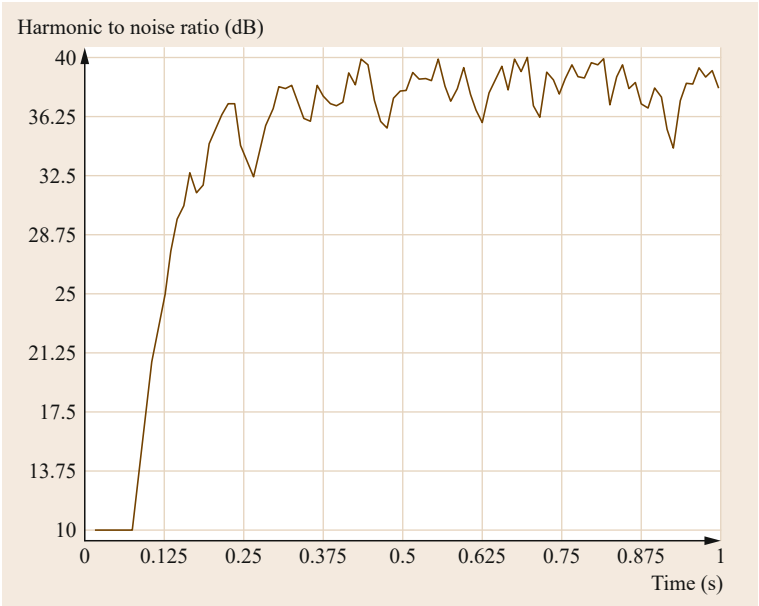

Fig. 30.19 Harmonic-to-noise ratio (HNR), onset of organ flue pipe, 1 s

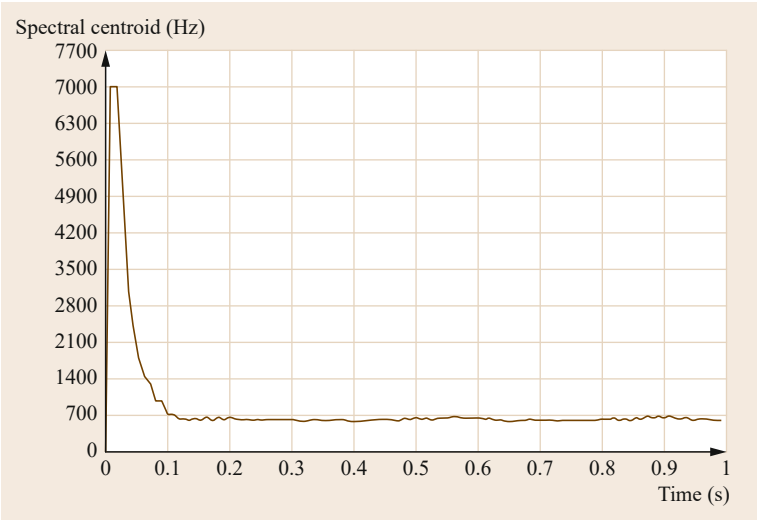

Fig. 30.20 Graph of spectral centroid plotted for 1 s of organ sound, Prinzipal 8′

overlap by at least half of the window size, the spectral centroid then can be plotted as a (quasicontinuous) function of time.

Such curves are of interest since the spectral centroid is a signal parameter that is closely related to the psychoacoustic dimension of *brightness*. Increasing spectral centroid means a shift of energy in the direction of higher frequencies (towards the *treble range*).

A useful parameter to describe the temporal evolution of a particular sound is its envelope. Musicians know to shape the envelope of sounds on a synthesizer by setting values for attack time, decay time, sustain and release relative to level (so-called ADSR envelope; Fig. 30.21).

As a scheme, an ADSR envelope looks like Fig. 30.21; one often can find a similarity between the envelope of a sound derived from intensity (as a measure of energy flux) over time and the curve of its spectral centroid. If the envelope starts with a rapid attack and rises to high amplitude, it is very likely that the sound has been elicited by an impulse or by some other rapid transfer of energy into the system that leads to a similar effect. Concentration of energy at the onset means that, for example in a *natural* instrument such as a swinging bell where the energy is transmitted from the clapper to the bell in, on average, 1 ms or less [30.231], very many eigenmodes are elicited almost at once. Consequently, the overall amplitude of the sound rises fast to a peak but in general also soon decays because many of the higher modes die away from damping. A similar behavior can be observed in, for example, sounds recorded from single strings of harpsichords, which are plucked with considerable elongation of the string (relative to its rest position) followed by a sudden release of the string from the plectrum. Both the bell and the thin

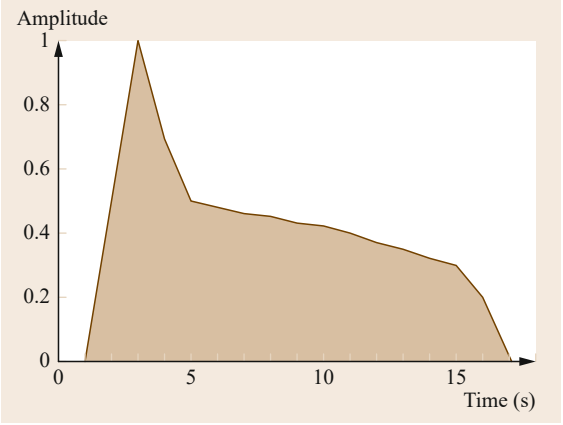

Fig. 30.21 Schematic shape of ADSR envelope (amplitude or level over time)

strings of the harpsichord exhibit a rapid attack, a fast decay, and a long sustain.

To conclude this section, there are sounds from idiophones (such as gongs, xylophones, cymbals) and membranophones (various types of drums), which are quite short and percussive, and which mostly also have an inharmonic spectrum. A number of instruments may even exhibit a quasicontinuous spectrum within a certain bandwidth similar to a noise signal. For example, if a snare drum is played with the snares applied, the modes of the upper head are mixed with the noisy sound of the lower (resonant) head to which the snares are attached. Of course, the actual sound produced depends on the type of drum as well as on the heads and snares used, the tension of both membranes and the force applied to the upper head, the place of excitation, etc. Figure 30.22 is a spectrogram of a snare drum played

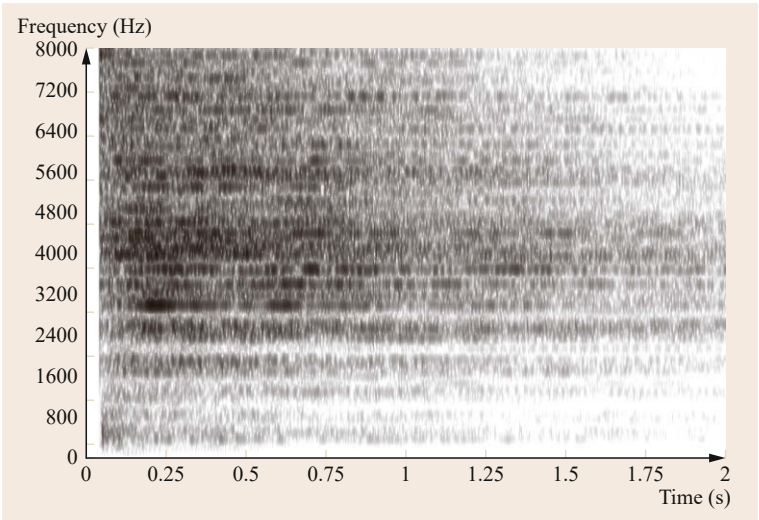

Fig. 30.22 Snare drum, single stroke with stick, spectrogram 0–8 kHz, 2 s

with a single stick for one stroke suited to illustrate the case where spectral energy distribution is close to quasicontinuous. The sound was recorded with a single condenser microphone placed in a position where a player sitting at a drum set would be expected to have his or her left ear.

The spectrogram reveals a fast attack, with much of the energy radiated from the drum within the first second. In fact, the SPL within 0.7 s drops by about 40 dB.

In many musical contexts, a range of complex sounds occur at the same time (or nearly so). This can lead to extremely variable waveshapes and, correspondingly, to abrupt changes in spectral energy distribution within short spans of time (consider, for example, symphonic works by Mahler or Stravinsky's *Sacre du printemps*). Perception of musical sound, therefore, requires that our sense of hearing is capable of fast adaptation to changing sound patterns from which relevant features must be detected.

30.3 Some Basics of Sound in a Sound Field

A sound field is an (ideally) homogeneous medium filled with molecules (*particles*); in a medium such as air, sound waves propagate at a speed, c, which in air at a temperature of 20 °C is about 343.2 m/s. Sound waves are generated from forces leading to movements of particles around their resting positions (leaving aside Brownian molecular movement). Field quantities relevant for sound waves and wave propagation in a given sound field are wave speed, c, pressure, p, particle velocity, v, and density, ρ. Also, temperature can be of relevance (since density and, consequently, wave speed change with temperature). Sound waves [30.126, Chap. 6] can be viewed as disturbances changing the equilibrium in the sound field. Changes of pressure, p, of particle velocity, $v = \partial\xi/\partial t$ (ξ = displacement) and density, ρ in a given medium are closely interrelated as expressed by Euler's law

$$-\frac{\partial p}{\partial x} = \rho_0 \frac{\partial v}{\partial t} \,.$$

A local change in pressure thus leads to particle motion. Assuming pressure and density in a medium like air to consist of a normal component (p_0, ρ_0) and an alternating component ($p_\sim$, $\rho_\sim$), we have $p = p_0 \pm p_\sim$ and $\rho = \rho_0 \pm \rho_\sim$. Pressure is a scalar while velocity is a vector, $\boldsymbol{v}_\sim$. According to the principle of continuity, density of air (which at sea level and 15 °C temperature is $\approx 1.2041\,\mathrm{kg/m^3}$) can be assumed to change but little in a sound field. The acoustic impedance,

$$Z = \frac{p(x,t)}{\boldsymbol{v}(x,t)} = \rho_0 c \,,$$

in air at 20 °C is $413.3\,\mathrm{N\,s\,m^{-3}}$. The magnitude of changes occurring in a sound field appears to be quite small [30.232, Chap. 2]. A SPL of 100 dB means the rms pressure amplitude is $2\,\mathrm{N/m^2}$ as compared to an average resting pressure at about $100\,000\,\mathrm{N/m^2}$ (or 1000 hPa). In a plane wave propagating in air (density $\approx 1.2\,\mathrm{kg/m^3}$) at 340 m/s the rms particle velocity

($\boldsymbol{v} = \mathrm{d}\xi/\mathrm{d}t$) is 5 mm/s at 100 dB, and the displacement, ξ, of a particle from resting position for a pure tone of 1000 Hz is just 1 μm. However, acceleration of particles can be impressively high, since, for a SPL of 100 dB and a pure tone of 1000 Hz, one obtains an acceleration of $\approx 30\,\mathrm{m/s^2}$, which is the threefold of acceleration of gravity.

The modified Euler equation (which expresses the conservation of impulse) valid for gases is

$$\rho_0 \frac{\partial \boldsymbol{v}_0}{\partial t} = -\frac{\partial p_0}{\partial x} .$$

The equation of continuity (which expresses the conservation of mass) in the gas is

$$\rho_0 \frac{\partial \boldsymbol{v}_0}{\partial x} = -\frac{\partial \rho_0}{\partial t} = \frac{1}{c^2}\frac{\partial p_0}{\partial t} \text{ where } c^2 = \frac{\mathrm{d}p}{\mathrm{d}\rho}(\rho_0)$$

is the speed of sound in air and ρ_0 is the normal density at rest. The wave equation for a plane wave traveling into one direction (along the x coordinate) can be derived thus

$$\frac{\partial^2 p_0}{\partial x^2} = \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} .$$

Solutions to the wave equation in one dimension are of the form $p(x,t) = f_1(x-ct) + f_2(x+ct)$ where f1 and f2 in general are functions that can be differentiated twice. The two functions express that two plane waves are propagating from the point of excitation in opposite directions along the coordinate x as in a string conceived as a one-dimensional continuum. For undamped harmonic plane waves, a possible solution is of the form

$$p(x,t) = A\cos\left[2\pi\left(\frac{x}{\lambda} \pm ft\right) + \varphi\right],$$

where A denotes the peak amplitude, λ denotes the wavelength and φ is the phase angle. Such a simple wave would have a spatial period of $\lambda = c/f$ and a temporal period of $T = 1/f$. In the harmonic wave described by the formula, sound pressure changes periodically as a function of place and time. The solution for spherical waves can be simplified to that for plane waves, except for the near field defined by the wavelength where both velocity and wave impedance are more complicated terms [30.216, pp. 100–102].

A wave transports energy through a given medium. The intensity of a sound, I, represents the mean density of the energy transported in a wave

$$I = \frac{1}{T}\int_0^T p\, v \sin^2\left[\omega\left(t - \frac{x}{c}\right)\right]\mathrm{d}t$$
$$= \frac{1}{2} p\, v = p_{\mathrm{eff}}\, v_{\mathrm{eff}} = \rho\, c\, v^2 .$$

In this formula, p and v denote peak values, and p_{eff} and v_{eff} indicate rms values. Energy density

$$w = \frac{p^2}{2\,\rho_0\, c^2} + \frac{\rho_0\, v^2}{2}$$

sums potential energy (first term on the right side of the equation) and kinetic energy (second term); w is a periodic function for both time and place. The sound energy contained in a volume V of a medium then is the potential and the kinetic energy integrated over that volume. A simple harmonic wave of wavelength λ, traveling in one direction (along the coordinate x) with a frequency of f at a phase velocity of c contains a certain amount of energy per period. If the wave goes through a plane, S (the size of which may be taken as $1\,\mathrm{m^2}$), the energy flow in a short time interval Δt will be

$$\Delta W = wSc\Delta t .$$

The ratio $\Delta W/\Delta t = J$ is the power (or strength) of the energy flux, and the ratio $J/S = j$ is the flux density, which again is a periodic function of time, implying that a wave traveling through a plane S in fact carries a sequence of energy pulses. It should be mentioned that the frequency of energy pulses is twice the frequency of a given wave (there are two energy concentrations per period as expressed by wavelength). As is evident from Table 30.1, the energy ($\mathrm{W/m^2}$) at the threshold of hearing is extremely small, indicating the fine sensitivity of our hearing organ. However, small changes in local pressure in the air are in fact the signal parameter with which sound waves are transmitted to the ears of mammals. All relevant information is contained in the fluctuations of the pressure amplitude that can be registered over time with a (suitably sensitive) microphone, and can be stored as for analysis in an analogue or digital format (e.g., as a time series of samples).

31. Pitch and Pitch Perception

Albrecht Schneider

This chapter addresses sensation and perception of pitch mainly from a functional perspective. Anatomical and physiological facts concerning the auditory pathway are provided to the extent necessary to understand excitation processes resulting from sound energy in the middle ear as well as within the cochlea. Place coding and temporal coding of sound features is viewed in regard to frequency and period as two parameters relevant for pitch perception. The Wiener–Khintchine theorem is taken as a basis to explain the correspondence between temporal periodicity and spectral harmonicity as two principles fundamental to perception of pitch and timbre. The basics of some models of the auditory periphery suited to extracting pitch from complex sounds either in the time or in the frequency domain will be outlined along with examples demonstrating how such models work for certain sounds. Sections of this chapter also address tone height and tonal quality as components of pitch as well as the rather dubious nature of the so-called tone chroma. Issues such as isolating tone quality from height (as in *Shepard tones*) and an alleged preference of subjects for stretched octaves are covered in a critical assessment. A subchapter on psychophysics includes just-noticeable difference (JND) and difference limen (DL) for pitch, the concept of auditory filters known as critical bands, the sensation of roughness and dissonance as well as special pitch phenomena (the *residue* and the missing fundamental, the concept of virtual pitch, combination tones). Another section covers spectral fusion, Stumpf's concept of *Verschmelzung*, and the sensation of consonance. Further, there are sections on categorical pitch perception as well as on absolute and relative pitch followed by a brief survey of scale types, tone systems and intonation. The chapter closes with a section on geometric pitch models and some basic features of tonality in music.

31.1 Pitch as Elementary Sensation and as Perceptual Quality

The English-American term *pitch* that is used, most of all, in physics and engineering as well as in psychoacoustics and music has many meanings. A major aspect of *pitch* semantics is to denote a spatial relation such as a distance, an interval, a rise or inclination. In regard to certain types of sound (such as described in Sect. 30.2 above), sensory processing triggered by the acoustic input leads to perception of a quality that is labeled *pitch* in English, *hauteur du son* in French, *Tonhöhe* in German, *altura del tono* in Spanish, *Wysota tóna* in Russian, and *yingāo* in Chinese. The terms used in French, German, Spanish, Russian (and many more languages) are equivalent in that they all express a particular sound quality in regard to a spatial dimension ranging from low to high (in some cultures, the direction rather is from high to low, but still referring to a dimension imagined as vertical in space). It seems that, at least for a range of natural sounds found in the environment (such as animal calls, birdsong, speech) human listeners almost involuntarily tend to categorize such signals with respect to qualities pertaining to *pitch* as well as to *timbre*. Pitch hereby includes at least two different spatial and also two different qualitative aspects. In regard to spatial ordering, subjects usually can distinguish various sounds as they appear to have a different height relative to a dimension low–high. Of two sounds, one can be judged to be higher or lower than the other, or both may appear equal in height (some may appear indiscriminable in this respect due to ambiguous sound structures; Sect. 31.1.2). If sounds appear different in height this must not imply that they also have a definite pitch since such differences can be evoked, for example by bands of filtered noise distributed around different center frequencies. If the noise bandwidth is wide enough, two or more such stimuli presented one after another give rise to sensations of only a relative difference in *height* that, typically, goes along with a relative difference in *brightness* (these two attributes are inextricably connected in normal sensation and can be dissolved only by some manipulation in the lab; Sect. 31.1.2). However, one can narrow the bandwidth to such an extent that each sound attains an almost *tonal* quality so that one can even play simple melodies making use of narrow-band noise with different center frequencies [31.1]. Already *Külpe* [31.2, pp. 108 ff.] argued that, besides a sensation of *tone height* resulting from periodic tones, a corresponding sensation of *noise height* can be experienced. Narrowing such noise bands further and further in the end would leave just one spectral component per sound (typically, the center frequency), and playing the same simple melody (say, *Frère Jacques*) then would result in sensations of definite pitches. *Definite* in this respect means the tones now occupy a very small segment or even a precise spot on the dimension low–high, which can be defined in an appropriate physical parameter (like log frequency). The shift from relative distances as produced by a sequence of noise bands to tones each of which are defined (in the most simple case) by exactly one frequency position also activates a peculiar perceptual quality, namely that of distinct intervals between several tones. Perceiving a sequence of tones in regard to pitch involves an estimate of their relationships, which in part are spatial (in terms of distances and intervals between them and/or a *contour* such tones establish in a pitch/time space) and in part have to do with *affinity* and *similarity* (Sects. 31.7, 31.8, 31.9, 32.2). *Houtsma* [31.3], exploring pitch perception with a range of different sounds (pure tones, harmonic *residue* complexes presented either diotically or dichotically, amplitude-modulated broadband noise, clicks), concluded that noise bands can evoke sensations suited to discriminate them on a dimension low–high in an ordinal way, whereas genuine pitch perception is restricted to those sounds that realize intervals as ratios that can be correctly identified. To be sure, noise signals that can be discriminated as to their relative *height* when presented successively may still suggest kind of a rough scale (up or down) or a melodic contour though lacking definite, identifiable pitch ratios [31.3]. Hence, pitch perception in a strict sense depends on sound signals that are quasiperiodic and comprise a more or less harmonic spectrum. As has been confirmed in a range of experiments, resolvable spectral components are essential in pitch perception (apparently predominating temporal information [31.4]). In regard to temporal processing of pitch that is extracted from complex sounds, one has to take reaction time and integration constants of the auditory system into account [31.5, 6], [31.7, Chap. 5]. From data concerning the time needed to establish a stable pitch sensation for pure tones, factors that seem of influence are the period duration and frequency as well as the sound level. Since the periods relevant for music can range from 33 ms (at 30 Hz) to 0.067 ms (at 15 kHz), the time needed to reliably detect a pitch (where an estimate of the pitch obtained from a sample of subjects reaches a percentage of correct answers clearly beyond chance) should be roughly proportional to the stimulus period and frequency. Some early investigations found 60−100 ms for very low frequencies (50 Hz), about 30 ms for 300 Hz and ≈ 15 ms for the frequency range from 0.5−5 kHz [31.8]. An average value of 66 ms for arbitrary pitch estimates has been suggested more recently [31.9, p. 205], with

possibly less time (20–40 ms) needed if subjects have information beforehand about the likely pitch range of the stimuli. For complex tones with only resolvable harmonics a time window of 20 ms has been suggested [31.10] while integration time is probably extended for complex sounds comprising only unresolved higher harmonics. From published data one can assume that about 5–8 periods of a periodic sound stimulus are sufficient for a stable pitch sensation.

The most basic stimulus known to elicit a perception of a distinct pitch is the sine tone. It can be taken as the reference for pitch perception [31.11, Chap. 11.1.2] since a sine tone of medium intensity, at least in the midrange from about 200 to 1500 Hz, usually evokes a single pitch, which is regarded as both salient and unambiguous. The main reason for this effect is that such a sine tone constant in frequency stimulates in a precise way a very small section of the basilar membrane (BM) and leads to a neural response pattern in the auditory nerve (AN) that reflects both the frequency (place code) and the period (time code) of the acoustic stimulus (Sects. 31.3 and 31.4). In a frequency range well suited to human listeners (say, between 250–1000 Hz), a sine tone presented at a level just 3–6 dB above threshold already evokes a clear pitch. It has been observed in various experiments that subjects usually can match a sine tone in frequency to a test sound such as a harmonic complex tone with but little variance if the fundamental of the complex tone is in the range of many sounds known from speech and music (that is, between about 200 and 800 Hz), and the sound level is also convenient (40–60 dB). Also, many subjects are able to sing or hum a sound at, or close to, the same audible pitch after listening first to a sine tone of, say, 440 Hz, presented for 2 s at a sound pressure level (SPL) of 50 or 60 dB by means of loudspeakers to their ears at a distance of 1–3 m. *Pitch strength* as measured by magnitude estimation increases for sine tones at medium frequencies with SPL (from 20 to 80 dB) as well as with duration (up to 300 ms [31.12, Chap. 5.7]). However, a sine tone is hardly a natural stimulus while many sounds we hear in the environment (from birdsong to human speech and, of course, music) have harmonic spectra comprising several or many partials. It has been found in some mammalian species that the DL for harmonic complex tones was lower than for sine tones presented at the same frequency [31.13, p. 63]. If a harmonic complex tone is presented to human listeners in a range where f_1 is between $\approx$ 130 and 800 Hz (roughly C_3–G_5), there are several partials besides f_1 that can be *resolved* by the BM–CP filter bank (Sect. 31.3). Pitch information can be derived in the frequency domain from f_1 as well as from such partials that directly reinforce f_1 (the octaves at f_2 and f_4). Other resolvable partials also contribute to the perceived pitch of harmonic complexes [31.4]. Moreover, the periodicity of such a signal as encoded in the complex waveshape (Figs. 30.10 and 31.6a) provides another cue. Therefore, a harmonic complex with partials phase-locked (as sine or cosine components) and with amplitudes decreasing with harmonic number offers several cues (or clues) for perceptual determination of pitch. There are auditory models that derive pitch estimates either from matching partials to a harmonic template or from periodicity analysis (Sect. 31.5).

In general, sounds with harmonic spectra are stronger or more *salient* in regard to pitch perception than are sounds with inharmonic spectra; sounds comprising continuous spectra such as noise bands usually give rise to weak or ambiguous sensations of pitch. Pitch sensations can also be evoked from amplitude modulation (AM) of noise bands and even from repetitions of a sound reflected from hard surfaces with a period of several ms between reflections indicating that periodicity is an important factor. However, a sensation of pitch can be elicited also from sharp edges in spectra in broadband signals [31.4, 14] as well as from a range of other phenomena (briefly reviewed in [31.15]). From a large number of experiments and observations it is clear that there are both spectral and temporal cues relevant for sensation and perception of pitch (for overviews see [31.9, 11, 16]).

31.1.1 Pitch as Dependent on Frequency and Period: A Brief Review

Historically, the concept of *pitch* as connected to that of *frequency* dates back to the late 16th and the first half of the 17th century (with contributions notably from both Vincenzo and Galileo Galilei, Isaac Beeckman, and Marin Mersenne [31.17, 18]). Mersenne came close to calculating the absolute frequency of a vibrating string according to

$$f = K\frac{1}{l}\sqrt{\frac{P}{\rho}}\,,$$

where K is a constant, l is the string length, P is the tension and ρ is the density of the string. Mersenne succeeded in finding, in a fair approximation to correct numerical values, fundamental frequencies for both strings and organ pipes. He and some of his contemporaries also noticed that the sound of a vibrating string of given length contains harmonic partials (an issue investigated in detail by Sauveur around 1700). In early acoustical theory, vibration of strings was modeled after the pendulum, whereby each very small segment Δl of a string can be viewed to perform the same motion as

that of a pendulum [31.18]. Taking a string segment Δl as a point mass accelerated by some force, its displacement from equilibrium over time describes a sinusoidal trajectory per period of vibration. Insofar as pitch is considered a function of the frequency of vibration, it is also a function of the number of vibration cycles conceived as periods completed per time unit since $f = 1/T$ and $T = 1/f$. Knowing that the basic pattern of vibration in strings is sinusoidal, one could surmise that sensation of pitch is dependent on sinusoidal vibrations. However, there were also experiments carried out by Robert Hooke (around 1681) and much later by Félix Savart where they found that a pitch sensation can be evoked from a periodic process such as pressing a strip of brass or card against the teeth of a revolving toothed brass wheel [31.19, p. 42]. This was also an elegant method to determine the absolute frequency (which equals the number of teeth on the wheel times the number of revolutions of the wheel per second [31.18, p. 32]). By about 1820, Charles Cagniard de la Tour invented the siren consisting of rotating discs perforated with equally spaced holes [31.20, p. 30]. Such a siren produces regular sequences of puffs of air suited to evoking a pitch sensation. *August Seebeck* [31.21] followed these experiments, using a siren as sound generator. In a number of conditions he found that a periodic time signal composed of isochronous pulses is sufficient to produce a salient pitch. *Seebeck* [31.22, p. 453] concluded that a (steady) tone results from the repetition of patterns of vibration whereby the duration of the period defines the *height* (German: *Höhe*) of the tone. Seebeck was severely criticized by *Ohm* [31.23] who claimed that, for a steady tone to become audible and to have a certain *pitch*, a vibration of the form $A \sin 2\pi(mt + p)$ would be necessary either in a direct form (i. e., a sine wave of frequency mt as stimulus) or as a *real component* that can be *precipitated* from a regular sequence of impulses (the German text has *Eindrücke* for impulses). Though the Seebeck–Ohm dispute is fairly well known [31.16, 24–26] and several of Seebeck's experiments have been explained as well as repeated by *Schouten* [31.24], it is still worth recalling some of Seebeck's observations and the arguments that followed from both sides. *Seebeck* [31.22, 27] reported in particular that for the condition where the holes on the rotating disc of the siren were spaced equidistantly, there was one clear tone (a *Hauptton* heard as a salient pitch) plus a number of harmonic partials (addressed as either *Beitöne* or *Obertöne*), which he perceived as *very weak*. This statement is repeated several times [31.22, p. 454, 456, 463], [31.27, p. 362]. *Ohm* did not deny that a siren could produce a series of impulses; he [31.23, p. 518] insisted that such impulses had to follow one another at intervals of the length $1/m$, and that p had to be constant for each pair of successive intervals to allow a steady tone to become audible. Ohm's argument in part addressed the ratio of the duration of each impulse relative to the pulse period (the pulse duty factor τ/T, where τ is the duration of the pulse and T is the pulse period). By assuming τ to cover almost T, Ohm imagined a sequence with broad pulses that could have resulted in one *real* sinusoidal at frequency $(mt + p)$ plus a few weak *Beitöne* (which Ohm admitted could be included in the complex sound). *Seebeck* [31.22, pp. 455–57] rejected Ohm's interpretation as unrealistic since, under the condition of equidistant holes fed with air by one pipe, τ had to be much smaller than T, and certainly like $\tau < 1/2\,T$. *Seebeck* [31.27] has stressed that Ohm's concept, which relates pitch to a fundamental frequency f_1 strong enough to be heard as a single *tone*, was just the narrow formulation of a much wider principle; like Seebeck, Ohm of course saw the reciprocity of frequency and period, to conclude that the repetition of a vibration at a period of $T = 1/f$ is the fundamental condition for steady tones to occur. However, while Ohm demanded a single strong sinusoidal vibration $A \sin 2\pi(mt + p)$ or a complex reducible to such a pattern to be present in each period, *Seebeck* [31.22, 27] stressed the importance of the period $T = 1/f$ as such, and argued that periods could be filled with various waveshapes of the general form $f(\cos 2\pi mt)$, that is, a superposition of cosine terms. He [31.22, pp. 474 ff.] went even further when arguing that, on the basis of series expansion applied to building complexes from series of cosine terms, complex tones might have a f_1 partial with a rather weak amplitude, a_1, so that this component $(a_1 f_1)$ could not be the sole source of the clearly audible tone (with a pitch sensation corresponding to f_1). Rather, the tone sensation might result from the combined effect of successive partials ($a_2 f_2$, $a_3 f_3$, $a_4 f_4$, etc.) because these partials, when *taken together*, *result in the same period* as that covered by $a_1 f_1$. Thereby, a weak $a_1 f_1$ component would be reinforced (in hearing) by a group of successive higher partials. Seebeck even saw the possibility (from his mathematical considerations rather than from his experience) that the first terms in a series of harmonic partials might be so weak in amplitude that they could not contribute in any significant way to a complex tone while a number of higher partials *combined* could express the motion pattern equivalent to $A \cos 2\pi(mt + p)$. Finally, *Seebeck* [31.22, p. 479] speculated that several partials of the form $a_s \cos 2\pi(smt + p)$ could produce a tone (in sensation, a pitch at f_1) even *if no term* of the form $a \cos 2\pi(mt + p)$ *is present*. This of course is the case of the *missing fundamental*. Hence, the important factor Seebeck brought into play was that various waveshapes, representing different spectra, can share

the same period, and that their repetition at $f = 1/T$ can give rise to a very similar or even identical sensation of *tone height* (*Höhe des Tones*). In this respect, Seebeck advanced a concept later known as *repetition pitch*, *periodicity pitch*, or *low pitch* (including the pitch of complex harmonic sounds with a *missing fundamental* [31.16, 24, 25]).

Helmholtz [31.28, Chap. 4] advanced the concept that our ears will sense only a *pendulum-like* (i. e., sinusoidal) vibration as a simple tone, and will dissolve complex sounds into a series of sinusoidals that are sensed as a series of tones. This concept (following Fourier and Ohm, respectively) must be viewed in regard to Helmholtz's model of the BM as a chain of tuned resonators; from anatomical data he assumed 600 *radial fiber* resonators to be available for each of the seven musically relevant octaves, which makes 50 for each semitone [31.28, pp. 241–242]. A mechanical resonator of course will be excited if a spectral component carries energy at the resonance frequency. Hence, it was natural for Helmholtz to postulate that sensation of a simple tone is effected by a sinusoidal whose frequency matches that of a resonator. Harmonic partials thereby would engage different resonators, and would give rise to respective sensations, which were combined into one percept representing a complex tone (e.g., the note G_4 played on a violin) on a higher neural level. According to Helmholtz, we become aware of only the percept (while sensations may trigger *subconscious inferences*, see Sect. 30.1.1).

With the Ohm–Seebeck dispute and Helmholtz's BM resonator model, the stage was set for pitch theories that had a focus either on the ear as frequency analyzer [31.29–31] or on the hearing system viewed as performing periodicity detection [31.24, 25, 32–35]. To be sure, both aspects have been combined in various ways to account for actual observations obtained from both physiological investigations and psychophysical experiments (for overviews see [31.9, 16, 36]). Also, both frequency analysis and periodicity detection have been implemented into a range of auditory models. Essential features of such models will be discussed in Sect. 31.5 (below) following a sketch of the auditory pathway (AuP) in which some functional characteristics relevant for pitch processing are outlined (Sects. 31.2 and 31.4).

31.1.2 Tone *Height* and Tone *Quality* as Components of Pitch and the Dubious Nature of *Tone Chroma*

In the previous sections, pitch sensations were considered to be largely dependent on either frequency, or period, or both. The characteristic of pitch to be the perceptual correlate of simple or complex tones that differ in either f_1 or f_0 refers to one dimension usually termed *tone height* (see above) that has two poles at *low* and *high*. Using a tone generator that outputs a sine wave into an amplifier and headphones (of suitable quality), one can easily explore both the range of audible frequencies and the smallest frequency differences that can be detected as pitch JNDs. However, when sweeping in a quasilinear fashion through a wide frequency range, one will notice changes in *brightness*, which increases with rising and decreases with falling frequency. Evidently, the sensory quality experienced as brightness covaries with frequency as well as with *tone height*. Hence, in a first approximation, both *tone height* and *brightness* can be viewed as a function of frequency. For this reason, it has been argued that sequences of pure tones especially in high frequency regions elicit sensations of different degrees of brightness rather than evoking *pitches* (the latter imply assignment of tones to locations sufficiently *distinct* to permit an estimate of intervals between them). The *mel scale* (see above, Sect. 30.1.4), which did not consider the perceptually relevant *octave equivalence* of pairs of pure or complex tones that conform to a frequency ratio of 2 : 1 on the one hand, and stretched into high frequency regions far beyond musical register on the other, has thus been classified as a *brightness scale* [31.26, p. 158].

A factor most relevant for music perception is that most subjects report strong *similarities* between pitches evoked when frequencies have doubled or halved in rising or falling direction respectively. Two tones presented at frequency ratios of 2 : 1, 4 : 1, or 0.5 : 1 between their fundamentals are perceived as equivalent not in height but in their quality; a tone an octave above or below the reference tone appears as a repetition in regard to quality [31.37]. *Rameau* [31.38, p. 16], in discussing the nature of complex harmonic tones, had already remarked that we know from experience that the octave is nothing but the replica of a certain tone, and that we easily can confuse two tones an octave apart (*je sçavois que l'Octave n'est qu'une replique, combien il y a d'identité entre les sons et leurs répliques, et combien il est facile de prendre l'un pour l'autre, ces sons même se confondant à l'oreille.*). The effect is usually addressed as *octave equivalence* whereby a musical interval spanning eight tones (whole steps) is taken to express the perceptual similarity. However, besides musical experience there are facts from acoustics and neurophysiology suited to address the phenomenon.

In regard to acoustical features, two sine tones of frequencies 200 and 400 Hz and equal amplitude, when presented simultaneously and with synchronous onset, match perfectly as two periods of the higher tone equal

one period of the lower tone; together, they result in a simple symmetric waveshape that repeats steadily at a period of 5 ms. If the same octave is formed from two harmonic complex tones (each having six partials with amplitudes $1/n$), the waveshape in Fig. 31.1 results.

It is easy to see that the main period is at 5 ms and a second periodicity is established at half of that value. Subjects may hear two tones clearly separated by an octave; however, with the 5 ms period much stronger in amplitude, the complex with f_1 at 200 Hz is prevalent. *Helmholtz* [31.28, Chap. 10] advanced an explanation for *octave equivalence* in which he emphasized two harmonic complex tones like those represented in Fig. 31.1 have partials that coincide with their respective frequencies, and no partials to interfere with each other:

200 400 600 800 1000 1200
400 800 1200 1600 2000 2400

Hence, several pairs of partials reinforce each other while roughness of such a two-tone interval is negligible in regard to *critical bands* (CB, Sect. 31.6.2 below). Also, one can consider the partials from both tones as belonging to one harmonic series starting at $f_1 = 200$ Hz. This would explain the high degree of uniformity that octaves such as depicted in Fig. 31.1 elicit in perception. It has been reported already by *Stumpf* [31.39, 40] that subjects lacking musical training (and not used to analytical listening) tend to take two tones presented at an octave as one.

Besides acoustical cues for what *Helmholtz* [31.28] labeled *Klangverwandtschaft* (affinity of complex tones due to common harmonic partials), there are such from neurophysiology. As is well known, pure tones and complex tones evoke neural discharge patterns that, in single AN fibers, can be measured with microelectrodes and usually are represented as either a poststimulus time (PST) histogram or as an interspike interval histogram (ISIH). In such diagrams (abscissa: time in ms, ordinate: rate of intervals measured) one sees peaks not only at the period of the pure tone but also at multiples [31.41]. In addition, ISIH often exhibit a slight dispersion around spike periods (ms) corresponding to the period of the acoustic stimulus (and its multiples). A possible explanation is the probabilistic nature of neural response patterns (including spontaneous activity and relative as well as absolute refractory period of neurons); in a single AN fiber, spikes must not occur at every period of the stimulus and also phase-locking of discharges is not always as strict as one may expect from the stimulus (e.g., steep wave crests at the onset of each period as in Fig. 31.1). In regard to ISIH being composed of multiples of the period corresponding to the stimulus, two pure tones an octave apart can give rise to neural responses that are quite similar. The phenomenon that two tones an octave apart appear similar and consonant has been attributed to common stimulus and neural periodicities already by *von Hornbostel* [31.42, p. 713] from observations on binaural (dichotic) hearing. More recently, experiments involving dichotic fusion indicated evidence for internal octave templates [31.43]. For complex tones, consonant intervals show few competing periodicities and have clear peaks in ISIH obtained from AN fibers whereas dissonances show many competing periodicities [31.44–46]. The most coherent periodicity pattern is that of the octave.

The factors referred to will be less efficient or even missing when two tones an octave apart are presented in succession. If two pure tones are one or even two

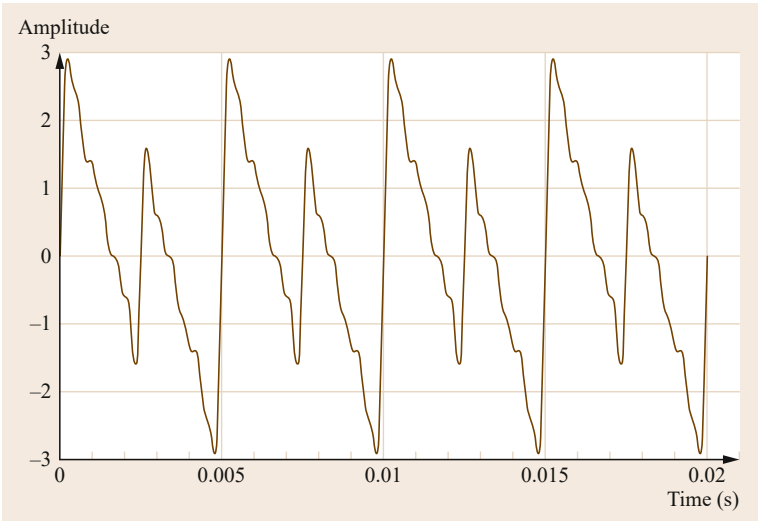

Fig. 31.1 Octave 200 : 400 Hz formed of complex tones (six partials each, $A = 1/n$)

octaves apart, there of course is no coincidence of partials, yet still most subjects with some musical experience will identify the interval correctly by making use of echoic and short-term memory as well as interval categories stored in long-term memory (LTM) (Sect. 31.7). Even in a condition where subjects listen to a slow sine sweep starting at a certain frequency (say, 100 Hz), they will take the starting point as an *anchor* and will register whenever the sweep reaches octaves at 200, 400, 800 Hz, and probably also at 1600 and 3200 Hz, respectively. At frequencies above ≈ 4 kHz, interval recognition deteriorates due to neurophysiological limits of periodicity coding (Sect 31.4) though some well-trained musicians manage to identify intervals at low error rates even above that limit [31.47]. However, the effect of increasing error rates for tones and intervals presented above 4 kHz has been reported for subjects with so-called *absolute pitch* (AP [31.48] and below, Sect. 31.7).

Perceptual octave equivalence is a basic condition for converting the dimension low–high from relative distances (sensations differ with respect to *tone height* and *brightness*) to musical scales and intervals. If tones that are an octave apart are perceived as having the same *quality*, this constitutes a cycle that repeats every octave. Theoretically, the number of elements within (or rather on) the cycle could be infinite. *Brentano* [31.49], pondering the problem of gradation of *tonal qualities*, considered the JND as a possible unit of discretization of the octave. In regard to the very small JND for frequency differences in the middle octaves, he dismissed these *simple elements* in favor of *saturated elements* (his reasoning was by drawing parallels to vision and color perception, see below), which can be identified as the tones in a musical scale. The point of course is that *tonal qualities* must not only be discriminable (as are JND) but identifiable as such to become meaningful units in regard to perception as well as musical composition and performance. Hence the number of *saturated elements* within one octave must be considerably smaller than the number of JNDs that fall into the same interval. The number of tones per octave used in music and the number of *pitches* relevant for performance as well as listening differs among cultures. In *Western* music theory, the number of tones usable per octave according to notation (taking sharps, flats, double sharps, double flats into account as they occur in many works) is 31−35 [31.50, pp. 183 ff.]. In systems of just intonation (JI), the number of tones may be as high as 53 [31.51] or even 171 per octave [31.52] in order to implement a huge set of diatonic, chromatic, and enharmonic tonal relations with deviations no greater than the DL for pitch in humans. However, the number of pitch categories per octave that can be identified in perception and cognition is much smaller than the number of pitches that can be distinguished both in performance and listening. For example, a shift from a-flat to g-sharp in a chord progression A^b major–E major in JI is well audible, yet it is in doubt whether average music listeners could also identify the two different tones (by naming them while listening) or could explain which pitches/tones have been exchanged in the two chords. Recognizable tonal relations (scale steps, intervals, chords, other sonorities) in part depend on acoustic and psychoacoustic features (offering cues for perception) and in part are internalized, in each musical subject, in a process of learning and practice. In many textbooks for elementary music education and music psychology, the number of so-called *pitch classes* per octave relevant for practice is given as $n = 12$ (by analogy to the number of keys available on a standard *Western* keyboard), which seems a superficial view not only in regard to professional musicians engaged in, for example, madrigal or barbershop singing, or performing in string or saxophone quartets, but also because of confusing concepts. The notion of *pitch class* is applicable to, and has been used in, mathematical models of scales based on set theory where a reduction from n pitches to m *pitch classes* ($m \ll n$) is feasible [31.53]. The notion of a pitch category, though, should be reserved for perceptual and cognitive issues as are relevant for *categorical perception* (Sect. 31.7).

Tones identifiable as pitches within an octave may have a distinct tonal quality; a minimum requirement is that such tones are periodic (or nearly so) and last for enough time to be sensed. Tones having a *tone quality* with their pitch are the basis for perceiving scale steps and intervals, and in turn the function of each tone is largely defined by structural relations within a scale as well as by their *contact* to adjacent tones (for a detailed discussion see [31.54, 55]). The tonal quality of tones identifiable as musical pitches within an octave (and recurring in each octave) has been distinguished from tone height by *Geza Révész* [31.37, 56], who also experimented with separating *tonal quality* from *tone height*. In elaborating on a concept known as *two-componential theory of pitch*, Révész distinguished two principles of similarity relevant for the perception of tones, one being the proximity of tones differing only slightly in frequency and in pitch (as sensed by subjects), the other the similarity of *quality* between tones an octave apart. Contradicting earlier approaches, which had held that similarity in pitch decreases linearly as the frequency distance between two tones increases (implying that the fifth above a given tone would be more *dissimilar* than a minor and a major second), Révész argued that frequency distance between tones alone cannot be a decisive factor for judging their similarity. Obviously,

that distance is small for two tones that differ by only a JND in pitch and still appear quite *similar* in this respect, while the distance is large for two tones an octave apart where similarity again is very high. However, it is a different kind of similarity than that based on distance estimates. *Lotze* [31.57, p. 212], among many scientists, had pointed to the singular experience of *octave equivalence*; he described hearing two tones an octave apart as *an undefined fusion of sameness and raise*. *Lotze* [31.58, p. 465] also assigned the same *tone character* to tones an octave apart. In line with these qualifications, *Révész* [31.37, p. 15 f.] regarded *quality* as a phenomenal characteristic that tones an octave apart have in common (in this respect, all notes with the same tone name but located in different registers have the same *quality*). In his 1913 treatise, he presumes that a scale of tones exists (as he used his piano for some experiments) that repeats within each octave. A more precise yet somewhat different statement is found in *Révész* [31.56, p. 67]: *The 'tone qualities' of the chromatic and any other scale form a recurrent series the members of which are complete within one octave*. Evidently, there is a shift here of *quality* from tones an octave apart to 12 chromatic scale tones. He elaborates further that *interval quality* and *tone quality* are phenomenal attributes *that do not appear isolated since their existence is based on the musical tone series* [31.56, p. 85]. In this respect, the two attributes become distinguishable in perception because musical scales constitute a series of sounds where different tone qualities go along with different degrees of *tone height* (and brightness). In a strict sense, *tone quality* without *height* is an abstraction. *Révész* [31.37, p. 131 f.] argued that, from a phenomenological point of view, one can conceive of a series of pure qualities as well as of a series of pure *heights*. He concedes that, in reality, only a musical scale provides both components in an audible and perceivable form. *Révész* [31.37] took the musical scale (the European chromatic scale in ET12) as given. A separate issue is how such *tone qualities* come into existence, in ontogeny of subjects as well as in a historical and cultural perspective.

Stumpf [31.59], recognizing the merits of Révész's two-componential concept of pitch but seeing also a host of problems involved with this approach, called the 12 chromatic tones of the scale now common in European music *historical qualities*. He [31.59, p. 323] distinguished these from what he labeled *arch qualities* (*Urqualitäten*), the fundamental property of tones within one octave to be sensed as different in pitch. Stumpf agreed to Brentano's view that small increments in pitch (the size of a JND) constitute a change in quality (and not just in *brightness*). He [31.59, pp. 317 ff.] argued the attribute of *tone quality* is lost, as observed in experiments conducted by, in particular, his doctoral student, *Catharina von Maltzew* [31.60], more and more above C_8 (≈ 4186 Hz) while we still sense relative differences in *tone height* (conveyed as *brightness*). Since in this range perception of *qualities* (conceived as discrete, identifiable pitches) deteriorates, so does perception of intervals. This is in line with more previous observations concerning the upper limits of pitch perception as based on periodicity ([31.61] and Sects. 31.4, 31.5).

In his report on current research, *Stumpf* [31.59] addressed the role not only of *tone height*, *brightness*, and *quality*, but also of attributes such as vocality (that had been investigated, in a range of experiments, by Stumpf's doctoral student, *Wolfgang Köhler* [31.62, 63]). *Rich* [31.64] then tried to determine the DLs for those attributes including *quality* (which is called *tonality* in his work). The goal was to manipulate *tonality* independent of *tone height* (which is *pitch* in Rich's study) and brightness, and to let subjects make their respective judgments. The limens given for several subjects, among them the music psychologist, H.P. Weld, differ considerably. Taking Weld's data for limens of *tonality* relative to reference tones at frequencies of 275, 550 and 1100 Hz, respectively, they were 1.44, 2.75, 3.85 Hz and are larger than the limens for *pitch* (tone height) and brightness of the same subject (0.36, 0.41, 0.67 Hz and 0.42, 0.33, 0.74 Hz, respectively). Evidently, the judgments of *tone height* are almost identical with those of brightness. Expressed in cents, the limen for *tonality* still would be just a few cents. In a set of experiments expanding those of Rich, *Straub* [31.65] did seek to determine the JND for *tone height* independently from *tone quality*, finding that the JND for *quality* was about three times the JND for *height*. For a range of frequencies (most reliably 256–480 Hz) the JND for *quality* was ≈ 25–30 cent; however, the design of these experiments in regard to *quality* came close to exploring the range of small pitch variants which, by observers, are assigned to the same scale step (the distributions of judgments Straub obtained for upper and lower limits of single scale steps around a center are quite similar to such from experiments on *categorical perception*, Sect. 31.7). *Hornbostel* [31.42], who labeled the specific quality of tones in a scale *Tonigkeit* (equivalent to *tonality* in *Rich* [31.64]; however, the term *tonality* in English as well as *Tonalität* in German include meanings beyond *tone quality*), explained the emergence of the quality phenomenon thus: If we hear two pure tones in succession that differ slightly in frequency, they appear as equal in regard to *Tonigkeit*. If the frequency of the second tone is changed further, in small increments, there is a certain point where the two tones no longer appear as equal in quality

yet as markedly different. *Hornbostel* [31.42, p. 712] thus described the transition from one *pitch category* to the next. He reported (in line with [31.59, 60]) that *Tonigkeit* was vanishing, even for musicians, in very low and very high registers as well as with tones of very short duration.

Bachem [31.48] labeled the qualitative component of pitch *tone chroma*, thereby making reference to *Brentano* [31.49] who had addressed the structure of tonal organization in hearing by drawing parallels to vision and colors respectively. Taking up some current ideas concerning perception of colors and brightness, *Brentano* [31.49] argued that, within each octave, a series of *saturated elements* returns while the difference from one octave to the next is one of, expressed in visual terms, the ratio of *dark* to *bright* (both are conceived as being combined in all tones audible for humans). In effect, the *dark* component is strong for low register (bass range) and the *bright* for high (treble range). According to Brentano, this unsaturated, continuously variable element of dark and bright (relative darkness and brightness) fuses or intermingles with those *saturated elements* in every octave; going up a scale, the saturated elements retain their specific quality while they can be distinguished from one octave to the next with a decrease of the *dark* and an increase of the *bright* ingredient. In a nutshell, what Brentano proposed was the two-componential theory of pitch (expanded by *Révész* [31.37] who acknowledged the contribution made by Brentano) that comprises the steadily rising or falling *tone height* (confounded with the sensation of tonal brightness) and that series of *tone qualities* forming *saturated elements* comparable to, as Brentano believed, basic colors. The question, then, is how close parallels between vision and hearing could be drawn. As we all know, two colors can fuse or blend to become not just inseparable, but to result in a third color. Two tones forming a harmonic interval may *fuse* (Sect. 31.6.4), but do not change jointly so that the originals disappear and a new tone is created instead. Also, the phenomenon of octave equivalence seems to be restricted to audition, and has not been reported for other modalities. Assuming there is a recurrent cycle of saturated tonal elements that can be identified in every octave, one would have to ask what the nature of saturation is, in particular if these elements are perceived in isolation (as in experiments on so-called *absolute* pitch, AP; see *Miyazaki* [31.66] and Sect. 31.7). There seems to be a salience in the perception of basic chromatic colors (red, green, yellow, blue, orange, purple, brown, pink [31.67]) that relates to the structure of photoreceptors and physiological processes pertaining to the spectral analysis of light sources (for basic mechanisms of vision, see chapters on sensation and perception in [31.68, 69]). In hearing, possible cues for determination of a specific *tone chroma* within the range of an octave would be frequency and period of pure tones as well as the relative brightness conveyed with an *absolute* frequency; for a series of relatively homogeneous complex sounds (i. e., those which have the same spectral pattern and envelope) dispersed over the range of an octave, the spectral centroid (Sect. 30.2) changes accordingly.

The parallels Brentano drew from vision to hearing may seem obvious in regard to brightness, which in fact is an intermodal quality [31.70]. Concerning those saturated elements in terms of a *chroma* series of tones, things are more complex. Historically, Greek music theory already had the term *chroai* ($\chi\rho\omega\alpha\iota$ = colorings), however, this refers to small tuning differences within the stable frame of tetrachords [31.71, pp. 33 f.] and, thus, not to saturated but to *fluid* elements that could be recognized as deviating in pitch from the positions marked by a diatonic or chromatic scale (there are similar phenomena to this day in Near Eastern and Indian music traditions). Also, in modern music theory *chromatic* tones in a scale are often regarded as mere variants or *alterations* of the stable diatonic scale steps [31.55]; the tones of a seven-note diatonic scale would thus count as *saturated elements* of a stable structure that, moreover, can be derived by a progression in pure fifths [31.72]. Of course, one can extend this progression to 12 or even more tones (as in medieval and modern treatises on music theory from Near Eastern traditions [31.73] and Sect. 31.8) which, however, result in a chain of fifths (and not necessarily in a cycle that repeats in each octave). The relatedness of tones by fifths like f–c–g–d–a–e–b is experienced by subjects in listening to music and making music in many music cultures; it is a phenomenon based on acoustic facts and supported by auditory processing characteristics (Sects. 31.4–31.8). In this respect, one might associate the *tonal quality* of particular scale steps and tones with their position and function within a structure defined by basic intervals, most of all, the pure fifth (and its complementary interval, the pure fourth) as the most fundamental consonant interval besides the octave [31.72].

Observations on octave equivalence and tonal quality based on interval relations reflect basic musical experience such as melodies retaining their contour when transposed [31.74, Chap. 5]. *Révész* [31.37, 56] argued that, in addition to melodic constancy, a melody rendered first on one pitch of the scale and then transposed by an octave appears as a *repetition*. There is evidence that some primates, besides humans, are able to recognize simple melodies transposed by an octave as identical [31.75]. Different from the *mel scale*,

a scale based on tone qualities can be conceived as similar to *a solfeggio reference structure, the whole of which is freely transposable (below* 5000 Hz*) in a log frequency medium* [31.76, p. 158]. The reference structure is stored in LTM, however, there are some indications also for a cortical basis of tone quality perception including cyclicality of the *chroma* series as represented within or near the primary auditory cortex (A1) regions [31.77]; see Sect. 31.4.

Typically, tone quality and tone height as well as tonal brightness are combined in perception of musical tones (e.g., tones played on a trumpet or piano). *Révész* [31.37] reported a few *pathological cases* where quality and height had been perceived disjointedly. He [31.56, p. 82 ff.] also suggested that the 12 tone qualities per octave could be created, in a pure form, by playing all the Cs in the audible range (in principle, this would be C_1–C_9) simultaneously, and with equal intensity, then all the C#s, all the Ds, and so on. This, he proposed, would also demonstrate the cyclic nature of those 12 *qualities* (quasi-independent of *height*), at least in ET12. Years later, *Roger Shepard* [31.78, 79] experimented with sound sequences generated on computers where *chroma* was changing seemingly independent from *tone height*, thereby producing a construct known as *the endlessly rising scale* (that has been viewed to constitute an auditory parallel to the illusionary staircases of Maurits Escher). Extending the concept in certain ways, the composer *Jean-Claude Risset* [31.80] produced continuous shifts of both *chroma* and *height* in opposite direction (such sounds might allegorize atomic bombs falling towards their target). Without going much into details of *Shepherd*'s and *Risset*'s constructs [31.78–82], the decisive factor for a *chroma scale* to appear rising *endlessly* is keeping tone height and brightness (as expressed by the spectral centroid, see Sect. 30.2) on a constant level while the 12 *Shepherd tones* consisting of octave-spaced components are repeated over and over again in a chromatic ET12 scale. This is achieved simply by using a bell-shaped (Gaussian) spectral envelope on a log frequency scale; the spectral components – a number of sinusoidals spaced in octaves – are then moved stepwise (from one *chroma* to the next) or slided continuously upwards or downwards under the envelope. The distribution of spectral energy thereby does not change significantly with respect to the centroid [31.81]. To produce the effect, in principle any symmetric envelope with a peak at the centroid will do (a Gaussian envelope works smoothly). In some of Risset's sounds, the *endlessly rising scale* is turned into a quasicontinuous glide [31.83] and in addition the envelope itself is shifted up or down the log frequency scale so that the centroid frequency changes. By running the *endless* glide in one direction (say, upwards) and slowly shifting the centroid of the envelope to the other, a peculiar sound process can be experienced that may be viewed as *illusionary* in that *chroma*, *tone height* and brightness, which normally vary jointly in a rising or falling scale, have been manipulated separately, to some degree.

Finally, an issue known as the *stretched octave* should be briefly discussed. From spectral measurements of thick piano strings (bass strings consisting of a carbon steel core wound with copper wire) it was observed that the frequencies of partials do not exactly match harmonic ratios but are slightly inharmonic due to the stiffness of such strings. The deviation Δf from harmonic ratios ($f_n = nf_1$) increases with harmonic number; the effect is significant yet not dramatic since partial amplitudes in general decrease with harmonic number, meaning higher partials have less weight in the harmonic complex. For example, in a grand piano G_1 string we measured the frequency for $f_{10} = 10.047f_1$, $f_{20} = 20.23f_1$, $f_{30} = 30.76f_1$ ($f_1 =$ 47.425 Hz [31.84]). Piano tuners compensate for the inharmonicity of partials by stretching octaves slightly (as well as by balancing each key within an octave with respect to pitch and timbre). A similar process is observed in the high treble range where the strings are very short.

From observations such as piano tuning, at times a general tendency for stretched octaves in intonation practice of musicians as well as a preference for stretched octaves on the side of listeners has been concluded. Some of the data published from experiments indicate some enlargement of *subjective octaves* (the ratio of fundamental frequencies is somewhat greater than 2 : 1); for example, *Hesse* [31.85] found that musically trained listeners preferred slightly enlarged octaves for successively presented complex tones, with an average (median) size of 1200 + 7 cents. However, in some measurements also octaves with a slightly compressed frequency ratio were found ($f_p/f_q < 2:1$ [31.86, 87] and [31.88, Fig. 1]). One study conducted on intonation practice of eight professional violinists playing the C-major scale over three octaves (C_4–C_7) upwards and downwards showed practically perfect octaves (in upwards motion, the octaves were slightly too large, downwards, a little too small [31.89]). In another study [31.90–92], octaves (tones A_4–A_5) recorded from violinists where correct at 2 : 1 when they used the open A-string while it was slightly too large when they played tones (B_4–B_5) with finger stops, indicating that the sound of the open A_4 was still audible when the violinists played the A_5 and matched the harmonics of the higher tone to those of the lower. Different from these studies, which offered a basic musical setting, most of the earlier lab experiments are difficult

to assess in regard to reliability and validity because the stimuli were presented monaurally per earphones (a condition unsuited for precise pitch judgments) and the sample size often was small with only a few subjects taking part. In experiments carried out simply to check the alleged general tendency for enlargement of *subjective octaves*, this author has used a demonstration provided by *Houtsma* et al. [31.83] (demonstration 15: octave matching) in which (spoken commentary on CD) *a* 500 Hz *tone alternates with a stepwise increasing comparison tone near* 1000 Hz. *Which step seems to represent a correct octave?* The steps are in 5 Hz from 985 to 1035 Hz. Though steps of 5 Hz near 1000 Hz seem a bit coarse in regard to JND and DL data (rather indicating steps of 2 Hz as appropriate), the experimental design seems sufficient for the purpose of controlling the assumption that *stretched octaves* are what subjects prefer. The pairs of tones with which *octaves* of $500 : \{985 \ldots 1035\,\text{Hz}\}$ are realized were presented to samples of subjects (students with either a *major* or a *minor* in systematic musicology) in binaural–diotic condition with audio studio equipment in a room prepared for sound recordings at a convenient SPL (≈ 65 dB). Statistics for four samples (summing to $n = 115$ subjects [31.93, pp. 482–484]) yield a median of 1000 Hz (frequency ratio 2 : 1, 1200 cent) and an aM of 999.043 Hz with SD = 4.4 Hz. The data do not support the hypothesis that subjects *in general* would prefer an enlarged or stretched octave. This issue perhaps needs further investigation in which musically relevant stimuli and conditions should be provided.

31.2 Sketch of the Auditory Pathway (AuP)

From a comparative perspective, auditory processing in mammals has common anatomical, physiological and functional bases [31.94–98]. One has to bear in mind that most of the findings reported on the structure and function of the cochlea and of the AuP up to the cortex were obtained from animal experiments (where animals usually figure as *the chinchilla model*, *the guinea pig model*, etc.). Since the anatomy and physiology as well as specific functions of the auditory system have been reviewed in great detail in a number of volumes of the Springer Handbook of Auditory Research (of which 50 volumes were edited and published from 1992 to 2014) as well as in other publications [31.98–101], a brief summary of facts and hypotheses relevant for sensation and perception of sounds will suffice at this place (see also the review in [31.102]). The auditory system comprises the outer and the middle ear, the cochlea (with the organ of Corti including inner hair cells (IHC) and outer hair cells (OHC) resting on the BM), the spiral ganglion leading to the AN (branch of the VIIIth cranial nerve), and the consecutive relays (nuclei) of the ascending AuP from the cochlear nucleus (CN: nucleus cochlearis ventralis (VCN) and nucleus cochlearis dorsalis (DCN)) to the superior olivary complex (SOC), the N. Lemniscus lateralis (NLL), the inferior colliculus (IC), the medial geniculate body (corpus geniculatum mediale) (CGM), and then to the auditory cortex (AI, AII and adjacent belt regions). A sketch of the ascending AuP can be drawn involving only the main relays and connections (Fig. 31.2).

The afferent AuP is complemented by efferent pathways such as the olivocochlear bundle (OCB [31.98, Chap. 8]), which controls OHC motility and is critical for pitch perception (see below). It should be clear that the AuP has a highly complex system structure incorporating ipsilateral and contralateral communication channels, sequential and parallel processing chains, as well as feedback regulation circuits. In addition, connections of the auditory cortices to other cortical areas, notably in the frontal lobe, must be considered. Apparently, in primates there are dual streams of processing leading from caudal and rostral auditory cortex to prefrontal areas where one circuit may be specialized in object analysis (the *what* channel) and the other in spatial analysis (the *where* channel needed for sound localization; [31.103, 104]). The degree of complexity of the main relays of the AuP such as the IC and the CGM is astounding (for a detailed description see [31.98, 105, 106]).

In addition to Fig. 31.2, a flow chart of the auditory system indicating main stations and functions in regard to processing the sound input can be outlined (Fig.31.3).

Functions as defined in this chart relate to the diagram sketched in Fig. 30.1 above where, after mechanical (middle ear) and then hydrodynamic excitation (cochlea, BM) a transduction stage (IHC, with involvement of OHC) is followed by feature extraction along the AuP, probably up to the level of the IC where, from the evidence available, integration of features seems to begin, which is continued at the level of the CGM. The CGM closely intertwines with the cortex (there are many afferent and efferent projections); because of the high degree of thalamocortical connections [31.107], CGM and AI are often viewed as one large functional module.

The term *auditory object* that appears in the scheme on the cortical level (AI) even in a neurocognitive per-

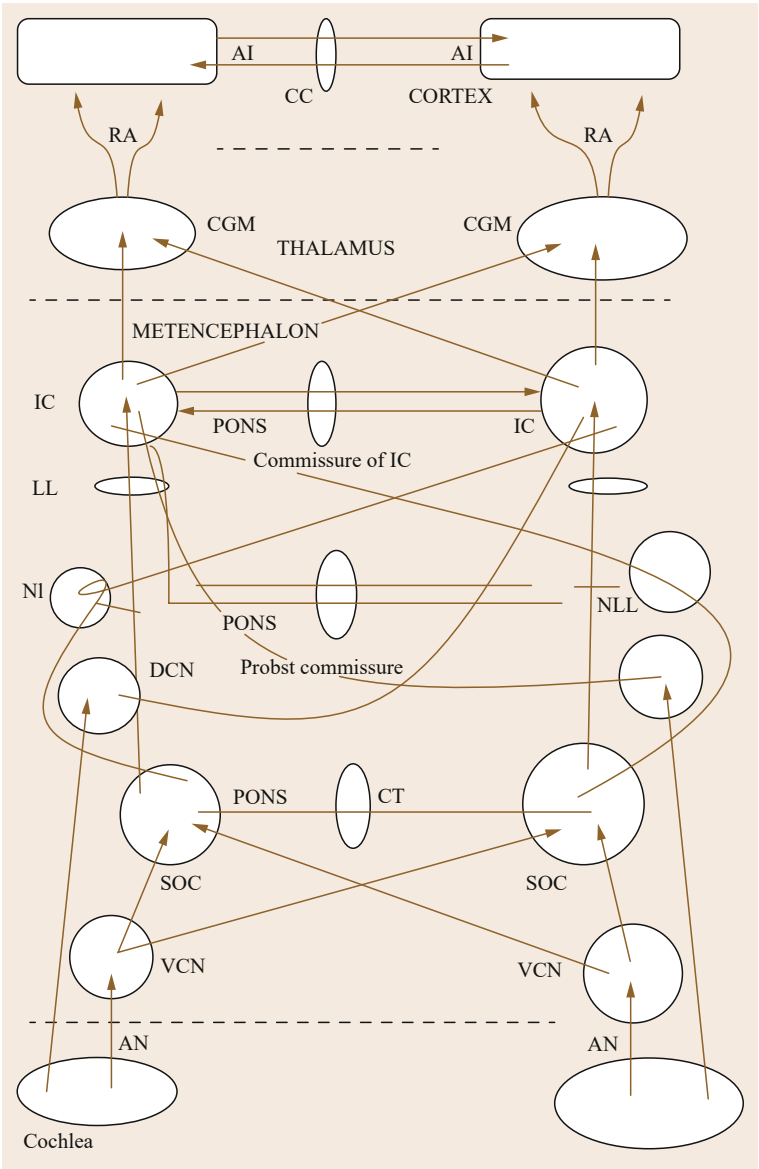

Fig. 31.2 AuP: main stations and connections. Abbreviations: AN = nervus acusticus, VCN = nucleus cochlearis ventralis, DCN = nucleus cochlearis dorsalis, CT = corpus trapezoideum, SOC = nucleus olivia metenceph., NLL = nuclei lemniscus lateralis, LL = laterial lemniscus, IC = colliculus inferior, CGM = corpus geniculatum mediale, RA = radiatio acustica, AI = cortex auditivus (primus), CC = corpus callosum, Nl = nucleus lateralis (superior olivary complex)

spective can have several meanings [31.108]. While sensing an *object* may apply, first of all, to the visual or haptic modality because of the visible or tangible shape of material objects, the term covers auditory phenomena as well. For instance, sensing a harmonic complex tone such as produced from a stringed instrument results from binding components together that may have been extracted from complex sounds in the inner ear and along stations of the ascending AuP. Binding in this case can be based on spectral and temporal cues (harmonicity of partials, common period, concurrent onsets, common envelope) and results in a coherent object that can be perceived as a distinct element (against a background of noise, or in a stream of other such tones). In a more general approach, a fundamental condition for binding features into objects as well as several objects into higher formations (such as several complex harmonic tones into a chord) can be traced to oscillations in the brain (such as the well-known brain waves δ, θ, α, β, γ), which serve to *screen* brain states and to *update* or *refresh* the system in duty cycles. In addition, there seem to be specific oscillations in neural structures of the AuP that might play a role in detecting periodicities in auditory signals relevant for the sensation of pitch and modulation processes. As has been elaborated in detail recently [31.109], various oscilla-

Sound Source(s) in the Environment
↓
Pinna collection of sound energy
↓
Meatus transport of sound energy
↓ impedance matching, linear filter: resonance
Tympanum, ossicles 'conditioning of sound energy'
↓ impedance and gain adaptation
Cochlea: BM frequency dispersion, spectrum analysis
↓ tonotopic frequency representation
Cochlea: IHC mechanoelectrical transduction, low pass filter, halfwave rectifier
↓ coding of signals into neural impulse patterns
Ganglion spirale (AN) spike trains distributed over ca. 30.000 fibers per ear
↓ → connects also to contralateral SOC
CN tonotopic organization, feature detection
↓ → connects to contralateral nucleus
SOC efferent reflex, control of OHC, feature detection
↓ → connects also to NLL and contralateral IC; connects to formatio reticularis
LL/NLL
↓
IC feature detection, spatial hearing, motor responses
↓ → connects to contralateral IC (also connects directly to AI)
CGM feature detection, pattern recognition, integration (1)
↓ → connects to amygdala, limbic system
AI integration (2), formation of 'auditory objects'
→ connects to contralateral AI and to various brain areas (in particular, PFC)

tions (which, however, relate to a basic time constant of 0.4 ms that can be attributed to an average synaptic delay) combined into a model of auditory neural processing could account not only for binding of features into objects but also for a correlational analysis suited to detect pitch and sensory consonance.

31.3 Excitation of the Auditory System: From the Tympanum to the BM, the IHC and OHC

Since sound signals including various types of music arrive at the ear of mammals as small disturbances of the normal atmospheric pressure (Sect. 30.3), information relevant to the auditory system is contained in the changes of pressure as a function of time and place. Leaving aside the outer ear channel (which provides a linear filter with a resonance peak around 3.3 kHz; [31.11, pp. 229–230]), the eardrum is the place where sound waves arrive. The tympanum (eardrum) is a membrane of ≈ 0.1 mm thickness and ≈ 8.5 mm diameter covering an area of about 60 mm^2. Elongation of the tympanum for very low tones of 20 Hz just audible is about 0.1 mm, and for tones of 3 kHz the elongation necessary to evoke a faint sensation has been given as 10 picometers (10×10^{-12} m; [31.110, p. 97]), which is less than the diameter of air molecules set to motion.

The main function of the middle ear is to adapt waves from the low impedance of air to the high impedance of cochlear fluid. This is achieved by significantly increasing the pressure in the middle-ear transfer chain. Since the area of the tympanum in humans is about 60 mm^2, and the area of the stapes

footplate working on the oval window (OW, the entrance for sound waves to the cochlea) is $\approx 3-3.2\,\mathrm{mm}^2$, the ratio is about 18 : 1, and the ratio of the two ossicles (malleus, incus) acting as levers is (depending on how the effective length is defined) about 1.5 : 1 up to 2 : 1. The product thus would be in the range from 27–36. Also, the tympanum as a concave membrane increases the pressure delivered to the ossicles and the OW by a factor of two. The transformer ratio in total thus is in the range of $\approx 70:1$ to $80:1$ ([31.111, p. 467] has 80.5 : 1, [31.98, p. 18] has 82.5 : 1, and [31.101, p. 94] has 69.2 : 1, corresponding to 36.8 dB). The middle-ear transfer function and the complex input impedance of the cochlea have been calculated from observations on human temporal bones extracted shortly after death from cadavers [31.112] where the middle-ear sound pressure gain (GME) was 23.5 dB at 1.2 kHz with a slope of $\approx 6\,\mathrm{dB/octave}$ from 0.1 to 1.2 kHz, and about $-6\,\mathrm{dB/octave}$ above 1.2 kHz. The transfer function for ear canal sound pressure to stapes footplate velocity (SVTF) had a maximum at 1 kHz where $0.33\,(\mathrm{mm\,s^{-1}})/\mathrm{Pa}$ is observed. Mean complex impedance Z_c was almost flat between 0.1 and 5 kHz at 21.1 acoustic GΩ MKS. Above 5 kHz, Z_c had a maximum at 6.7 kHz with 49.9 GΩ. Phase of Z_c in the range from ≈ 0.5 to 5 kHz was close to 0°, decreasing to negative values below 0.5 and above 5 kHz. Without the impedance matching in the middle ear, up to 98% of the sound energy would be reflected at the OW because of the high impedance of the cochlea. Stapes movement seems to increase in a linear fashion even for high SPL up to 130 dB [31.98, p. 22], indicating (almost) linear system behavior over a wide dynamic range. However, the lever action of the ossicles has also been regarded as a possible source of some harmonic distortion at higher sound levels, and in particular of difference tones [31.11, p. 231]. Combination tones (sum and difference tones) usually are attributed to cochlear nonlinearities [31.113–115] and [31.98, pp. 147 f.] and below.

The footplate of the stapes working on the OW leads to compression of the fluid in the cochlear duct and to a traveling wave in the scala vestibuli. Patterns of motion in the cochlea and the phenomenon known now as the *traveling wave* were first described by *Georg von Békésy*, in several articles mainly from the 1940s (collected in [31.29, Chaps. 11,12]; for recent research on cochlea functions up to 2000 see [31.115]). Since waves usually travel through a medium at a certain phase speed (dependent on the compressibility and the density of material; in fluids,

$$c = \sqrt{\frac{K}{\rho}}\,,$$

where K is the compression module, and ρ is the density at rest of the medium), there must be something special to this traveling wave, which is to be distinguished from the normal sound wave propagating in a fluid like water. As in fact the viscosity and the density of the cochlear fluids (endolymph, perilymph) are practically identical to water [31.116, 35-3], the phase speed of a sound pressure wave in the cochlea would be expected to be close to 1550 m/s, meaning the distance from the OW to the apex of the human cochlea would be crossed in about 2 µs. Though such a fast wave exists in the cochlea (reflected at the apex/helicotrema to become a standing wave), the *traveling wave* is much slower at about 100 m/s [31.117] and is dispersive in frequency as are bending waves propagating in solids (for a discussion of such analogies, and for fundamental mechanics of the cochlea, see [31.113, 114, 118, 119]). The main reason for the dispersion that has been observed throughout the cochlea is a coupled interaction between fluids in the scalae of the cochlea (for details of cochlea anatomy and physiology see [31.98, 101]) that undergo compression while the BM as a structure is subjected to displacement [31.120]. Dispersion can be attributed in particular to variable longitudinal stiffness of the BM, which decreases from the base to the apex (for a BM length of 35 mm, which is the average from human male and female BM measures) by a ratio of $\approx 100:1$ [31.29]. For the gerbil, a stiffness gradient of 4.43 dB/mm has been reported [31.121]. Since the stiffness decreases along the BM, the compliance increases correspondingly. Dispersion on the BM involves phase delay relative to stapes motion. A number of measurements performed with different methods suggest that the phase delay from the base to the place of a characteristic frequency (CF) in the cochlea is about 1 ms for 10 kHz, 1.5 ms for 5 kHz, ≈ 4 ms for 1 kHz, and close to 6 ms for 0.5 kHz [31.122]. The travel time, however, depends to some extent on SPL; the delay values cited here probably apply for SPL in the range of 50–60 dB. BM displacement depends on species, frequency and SPL. For the chinchilla, displacement at several CF was about 1 nm for a 30 ms tone burst at 30 dB SPL [31.123]. For humans it is of the order of $\approx 3-3.5$ nm at 20 dB SPL, which means ≈ 40 dB cochlear amplifier gain due to OHC activity. From animal experiments (guinea pig) it was estimated that, at a very low SPL of 15 dB, for a CF of 15 kHz the section of the BM that undergoes displacement was just 0.15 mm wide, meaning 14 IHCs and 53 OHCs would be activated [31.124]. In fact, at low excitation levels, the frequency response at the CF equals that of a sharply tuned bandpass, a feature observed also for AN fiber tuning curves.

In some of the early research (reviewed in [31.16, 26]) the BM had been regarded as a chain of mechanical resonators. However, observations on material properties of the BM (which seem to indicate more of a *basilar plate* than a basilar membrane, [31.125, pp. 207 f.]) as well as of phase relations between stapes footplate motion and BM displacement and BM velocity [31.113, 115, 119, 126, 127] are not in line with a simple resonator model. When the traveling wave arrives at the place where its amplitude reaches maximum (indicating maximum pressure and BM displacement respectively), group velocity decreases and the envelope of the traveling wave, viewed instantaneously, attains a characteristic shape as the slope is steep on the side towards the apex, and relatively shallow on the basal side. For a wave from a sine tone of a chosen frequency, the amplitude reaches maximum at a certain place on the BM where the energy contained in the wave dissipates; the wave decays rapidly thereafter. Since the excitation pattern locates a certain frequency at a specific *spot* relative to BM length, such a correlation is termed *tonotopic* or *cochleotopic*. It has been the basis of cochlear maps that have been established for several species [31.128, 129]. Part of the human frequency-place coordinates for the first 20 mm distance from apex is shown in Fig. 31.4 with octaves marked at A_3, A_4, A_5, A_6 {220, 440, 880, 1760 Hz}. To calculate the coordinates, Greenwood's formula $f = A(10^{ax} - k)$ with $A = 165.4$, $a = 0.06$ and $k = 0.87$ has been used.

In a similar vein, distance from apex (expressed as a proportion where 0 = apex and 1 = base near OW/stapes footplate) can be related to log frequency [31.130, p. 222]; the resulting graph (Fig. 31.5) expresses a Fechnerian scaling (Fig. 30.3).

The BM (or, alternatively, the cochlear partition (CP) as the structure between the scala vestibuli and the scala tympani comprising the BM with the organ of Corti, and the scala media up to Reissner's membrane) seems to work, when viewed for single pure tones of various frequencies, as a mechanical low-pass filter with the cutoff frequency decreasing with distance from stapes and OW to the apex/helicotrema. However, for mixtures of complex sounds BM filtering can be understood perhaps more adequately with a model combining a bank of asymmetrical band-pass filters wired in parallel. This is what most models of the auditory periphery based on signal processing realize (for an overview see [31.131]). BM operation, in a mechanical and hydrodynamic approach (as pioneered by von Békésy), can be regarded as *passive* filtering insofar as it was found still operating in the cochleae of human cadavers (where physiological processes bound to metabolism and oxygen supply have more or less ceased). There is evidence, however, that the filter function deteriorates rather soon postmortem so that the quality factor (Q) of tuning/filtering, which relates bandwidth to center or to resonance frequency, is not as good as in vivo condition. Also, there is evidence that the cochlea – a tiny, delicate and highly sensitive organ [31.98, 101] – is extremely vulnerable in a living organism; observations made on (usually anesthetized) animals even under subtle surgical treatment might, therefore, not represent the *true* performance of which cochlear filtering is capable. Moreover, in a living organism, cochlear filtering apparently is supported by OHC motility in what seems to be a feedback loop circuit [31.132] often addressed as the *cochlear amplifier* (current discussion on this issue is summed up in [31.133]). The main function of the OHC (of which humans have about 12 000) thereby seems to amplify the traveling wave in the cochlea, a process particularly useful in regard to low sound levels near threshold. The cochlear amplifier apparently is the main source of cochlear level-dependent nonlinearity that sets in at low SPL (about 30 dB) and shows increasing compression for high SPL (up to ≈ 0.2 dB/dB).

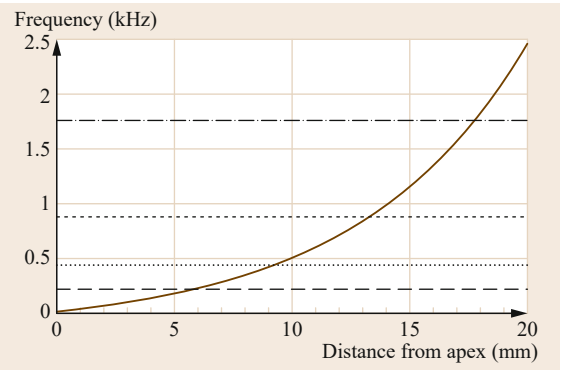

Fig. 31.4 Human BM coordinates: relation of frequency (Hz) to distance (0–20 mm) from apex; four octave markers at 220, 440, 880, 1760 Hz

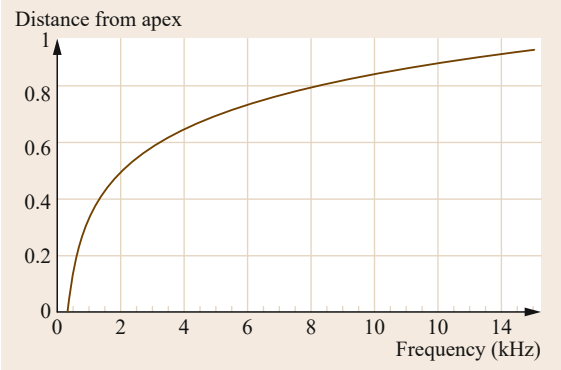

Fig. 31.5 Human BM coordinates: distance from apex (0 = apex, 1 = base)/frequency

Empirical data demonstrate also that *OHC integrity is crucial for sharp tuning of cochlear nerve fibers emanating from the IHC* [31.134, p. 297], confirming the role of the BM-IHC-OHC feedback loop. Results from nonlinear biophysical modeling suggest that the main effect of OHC activity could be undamping of a small area of the BM corresponding to the peak of the traveling wave [31.135]. With a linear (passive) biophysical model of the cochlea (built on cochlear dimensions and fluid dynamics by *Mammano* and *Nobili* [31.136]), the product of time and frequency resolution

$$\Delta t \Delta f \geq \frac{1}{2}$$

known as the *uncertainty principle* (the original formulation by Heisenberg relates to place and momentum in quantum mechanics while a version by Gabor refers also to signal analysis and hearing; [31.137]) was found, for the frequency range above 200 Hz up to 4 kHz, to be close to 0.55, that is, near the theoretical minimum [31.138]. With an active nonlinear biophysical model [31.135], performance still improved, indicating that the BM area elongated by a sine tone under OHC control must be extremely small. Such a mechanism, in which high frequency selectivity seems to be achieved through *lateral* suppression of frequencies in the vicinity of a strong stimulus frequency [31.139], is essential in generating precise information in regard to frequency already in the peripheral sensory organ and transduction process. There are many observations supporting a *cochleotopic* organization of frequency analysis and encoding [31.134]. Also, there are experimental findings according to which correct tonotopic representation of spectral components is essential for pitch perception of complex sounds [31.140]. However, a *peak shift* in excitation dependent on SPL measured in the organ of Corti of animals has been reported [31.141] that might possibly interfere with place theories of frequency coding in the cochlea. According to these observations, increasing the SPL of a stimulating sine tone shifts the peak of excitation on the IHC level to lower (!) frequencies but apparently does *not* affect the apical cutoff on the BM corresponding to a certain frequency. The observation in fact is that [31.126] (in chinchilla), for a given site on the BM corresponding to a CF, the peak responses vary with stimulus level as to frequency. For a CF of 10 kHz, the peak response was obtained for a 10 kHz tone and a level ≤ 50 dB; when the level grew to 60 or 70 dB, the largest response was obtained with an 8 kHz tone. At 80 and 90 dB stimulus level, the largest response resulted from a 7 kHz tone; the shift in maximum sensitivity hence amounts to ≈ 617 cent. The effect, however, cannot be taken as producing a pitch shift in sensation of anything of this size for, in this case, we would experience a significant pitch shift with every change in SPL, and in particular with each crescendo in a concert. As is known from behavioral experiments with humans, influence of SPL on sensation of pitch is slight for pure tones, and even less for complex tones [31.12, p. 114]. However, subjects can experience a pitch shift for sine tones with high SPL applied for a certain time due to fatigue of the BM section that is excited the most (also a temporary or permanent loss in sensitivity may be suffered; Chap. 33).

The transduction process from mechanical excitation to neural spike patterns measured in AN fibers is effected by means of the IHC, of which humans have about 3500 per cochlea. Each hair cell carries about 100 stereocilia [31.142] capable of quite rapid motion, and thus of generating a large number of sensor (or *receptor*) potentials per second. However, IHC intracellular voltage changes in relation to stimulus frequencies decline markedly above 1 kHz (as observed in the guinea pig [31.98, 143]) reflecting cellular membrane low-pass characteristics as well as refractory periods. The distribution of IHC along the BM is somewhat uneven (the number of IHC per mm BM decreases towards the apex, indicating a lesser degree of innervation that could explain reduced frequency sensitivity for $f < 100$ Hz). The AN in humans comprises about 30 000 fibers per cochlea whereby each IHC is connected to several afferent AN neurons. Transduction in IHC from hydromechanical forces into sensor potentials involves mechanical, chemical and electrical processes (reviewed in detail in [31.98, 144]).

31.4 Place Coding and Temporal Coding of Sound Features

On the basis of physiological and psychophysical data, it has been suggested that, in the AN, both time and place information are used for coding pitch [31.36]. In particular, the place information has been assigned to *frequency* and *tone height* (Sect. 31.1.2) while time information, connected with *period*, should account for *low pitch* (including the *missing fundamental*) and *tone chroma*; in effect, pitch processing in this way would occupy two channels [31.145]. In this section, evidence for both principles is reviewed beginning with place.

In the light of the BM-IHC-OHC feedback loop, one can conceive of modules each of which comprises

a very small section of the BM along with the corresponding IHC, OHC as well as the afferent and efferent innervation. In regard to stimulus transfer, each module is selective in that it operates at a characteristic frequency (CF), and also shows maximal output at a so-called best frequency (BF). The basis for sharp tuning apparently lies in BM vibration patterns, which show bandpass characteristics at each CF where signals produce small displacement and velocity at a low threshold [31.126, 127]. In this respect, CF means that a response measurable as output occurs at a low input level; the threshold indicates maximum sensitivity of a module for a certain frequency (or a narrow range of frequencies). The BF is the frequency that produces maximum output of a module, measured as the firing rate of neurons/fibers (above spontaneous discharge rates, and up to saturation) for any given input level. Both CF and BF response are observed at various stations of the afferent AuP up to the cortical level [31.146, 147], indicating a place principle of transduction and neural encoding as well as a transfer function comparable to a bandpass filter. The frequency-threshold curve (FTC [31.143]) of fibers, which represents the neural firing rate for a given input (frequency, level) can be viewed as the inverse of a bandpass with the CF at the minimum. Typically, the FTC for fibers is asymmetric, with a steep rise towards the high frequency side and a soft ascending slope for frequencies below the CF and BF respectively. The relative sharpness of the FTC depends on frequency and level, and is different for units along the AuP. For comparison, FTC are often taken as $Q_{10\,dB}$ (which is the quality or Q-factor of the filter at 10 dB above threshold; $Q_{10\,dB}$ = CF/bandwidth at CF).

The AN of mammals, comprising thousands of fibers, can be viewed as a two-dimensional array, *with the first dimension corresponding to CF (or alternatively, to cochlear place), and the second one to sensitivity or threshold* [31.36, p. 161]. Measurements showed that spectral components of synthesized steady-state vowels can be represented by average discharge rates in a population of fibers with different CF in the AN of the cat [31.148]. However, the spectral envelope of the stimulus fits to discharge rates plotted against the CFs (kHz) only for low SPL. Rate-place representations of stimulus features in the AN [31.149] undergo significant change with level apparently depending on the spontaneous rate (SR) and the threshold of fibers as well as their overall dynamic range and the level where saturation in discharge rate is reached. Since each of the AN fibers seems to have a certain CF and BF that account for a bandpass-like transfer function, a precise evaluation of spectral and dynamic rate-place capabilities of the AN would need synchronous recording of the complete set of fibers engaged in transmitting a broadband signal (such as complex sounds incorporated in speech or music), and possibly signal reconstruction from the neural pattern distributed over many fibers. However, rate-place models on the level of the AN are sufficient for providing neural cues relevant for pitch and timbre perception if such models include *a realistic cochlear frequency map, cochlear filters, suppression, rate-level functions, and threshold distribution* [31.36, p. 204].

As an alternative to rate-place representations, temporal analysis of neural spike patterns in AN fibers and CN units has become a standard method in regard to finding periodicities suited to provide the basis for sensations of various pitch phenomena including pitch of pure and of harmonic complex tones, pitch of harmonic sounds with the fundamental frequency missing, pitches evoked from harmonic and inharmonic AM and frequency modulation (FM) sounds, etc. (for an overview see [31.150]). The beginnings of temporal analysis date back to the 1930s and 1940s when the relation of stimulus frequency to action potentials came into view, which led to hypotheses of neural firing patterns such as the *volley principle* [31.151, 152]. More recent experiments showed that, in the CN, neurons sensitive to onsets fired at highly regular intervals precisely synchronized to the period of a speech signal [31.153], indicating that the periodicity inherent in the stimulus is preserved in neural spike patterns recorded in the AN and the CN.

With the analysis of almost periodic functions set forth by *Wiener* [31.154] and *Khintchine* [31.155], it was possible to study some of the more irregular sound phenomena as well as the periodicities hidden in brain waves. *Licklider* [31.156, 157] expanded the approach to audition by proposing a model of *duplex* pitch perception in which, after initial cochlear filtering of a broadband signal $f(t)$ into a running spectrum, $F(t, x)$, conceived as similar to a spectrogram, a running autocorrelation analysis is performed in each channel on the rectified and smoothed filter output to yield a neural representation in a two-dimensional plane (comprising the length of the BM as x and the lag τ needed for autocorrelation analysis (AC)), which may be fed to higher stations of the AuP. A problem that becomes evident with binaural and dichotic listening is integration and differential processing of temporal information provided from both ears. One model that became quite influential is known as *coincidence detection* applied to neural spike trains [31.158]. The formal operation needed for comparison of input from two channels in regard to estimating the degree of coherence as well as phase effects is cross-correlation function (CCF) [31.159, Chap. 14]. *Licklider* [31.160] formulated a *triplex* theory of pitch perception, tak-

ing into account dichotic phenomena such as the so-called Huggins' pitch (based on interaural phase transition [31.161]) and spatial sound localization where, in addition to autocorrelation function (ACF), CCF is needed to compute binaural interaction with signals fed into both ears. The *triplex* model would represent the three levels of analysis (cochlear place coding of frequencies, temporal coding of periodicities, and information from binaural processing) in a neural architecture of three dimensions.

The *duplex* model developed by Licklider served as the blueprint for a range of computational models to follow [31.131, 162–166]; one part of the neural autocorrelator that became an issue later of course was the delay line needed in particular for low-frequency components of a broadband signal. Given that the lower limit of musical pitch is close to 30 Hz [31.167, 168], the period thus is 33.33 ms, and the delay line necessary to provide the lag of the signal should be of the same order. Though speed of transmission and processing of neural spike trains decreases from AN along the AuP up to cortical AI and belt regions, peaks of the seven prominent brainstem auditory evoked potential (AEP) responses (which are not dependent on the subject's arousal or vigilance) occur within 1–9 ms after stimulus onset [31.169], indicating there is but little *delay* in stations below the thalamus and the cortex. In order to avoid a delay line not supported by anatomical and physiological data, alternative models have been proposed that can still perform the correlational analysis in the time domain [31.109].

Autocorrelation analysis (which draws on the concept of self-similarity with respect to the time dimension) has been applied to neural spike data in regard to various pitch phenomena. Such studies covered, for example, response patterns recorded from the AN and ventral CN for signals comprising either the fourth and fifth harmonic (of a fundamental frequency f_1 that itself is not present) or their odd variants ($4.5f_1$, $5.5f_1$). Autocorrelation analysis of period histograms found peaks representing the period of the input waveform for the harmonic signal and the actual period of the inharmonic signal [31.170]. Extended experiments on AN fibers of the cat resulted in neural spike patterns for a range of stimuli (pure tone, single-formant vowel, click trains, harmonic complexes, AM tone, AM noise) suited to evoke various types of pitch [31.44, 45]. Spike trains, which provide efficient temporal coding [31.171] for natural and artificial sounds can be analyzed according to the time interval between successive spikes (first-order interspike intervals) as well as in regard to successive and nonsuccessive spikes (*all-order* interspike intervals). Analysis of all-order interspike interval histograms (ISIH) is formally equivalent to an autocorrelation analysis. Such histograms were summed up for a population of fibers, and the pitch for each stimulus was estimated from pooled autocorrelation histograms. In addition, the salience of pitch was computed. As can be expected, periodicity inherent in periodic stimuli turns up in the analyses, and is a robust feature not affected by level in a range from 40–80 dB [31.44]. With the analysis based on ISIH, the pitch salience of harmonic complexes was found to be higher than that of a pure tone. This seems plausible because a harmonic complex comprising a series of partials including f_1 offers more clues for pitch extraction than does a pure tone. In particular, temporal analysis of spike patterns accounts for the pitch associated with harmonic complexes lacking f_1 (the *missing fundamental*). In regard to the acoustic input, the period of a harmonic complex does not change when f_1 is missing or even if several low partials are removed (Fig. 31.6a,b).

The harmonic complex shown in Fig. 31.6a comprises eight partials ($f_1 = 100$ Hz) of equal amplitude, superposed as sine tones locked in phase. In Fig. 31.6b, $f_1 = 100$ Hz and $f_2 = 200$ Hz have been removed. As a result, the waveform changes and the amplitude peak at the onset of each period is smaller due to reduced spectral energy; removing f_1 and also f_2 (as in Fig. 31.6b) from a harmonic complex affects the timbre as well as the loudness level perceived, and to some extent also pitch salience, which is weaker for a sound based on the vibration pattern shown in Fig. 31.6b than for a sound that contains a series of harmonic partials including f_1. However, the period in Fig. 31.6b remains at $T = 10$ ms corresponding to the repetition frequency f_0 of the complex waveshape (in a harmonic complex comprising a sufficient number of partials, f_0 equals f_1). Period length (or duration) for a given harmonic complex remains identical as long as several consecutive harmonics are left in the signal, and even with a number of nonconsecutive partials the same period length occurs. Consider, for example, a signal formed by linear superposition of harmonics no. 7, 9 and 11 of $f_1 = 100$ Hz. The resulting waveform is perfectly symmetric and periodic with a period of $T = 10$ ms as shown in Fig. 31.7.

However, one factor affecting pitch salience of a sound composed in this way is that higher harmonics may not be resolved as spectral components by cochlear filtering [31.15, 31] and another factor probably suited to weaken salience and to introduce some ambiguity is the structure of the waveshape, which, different from the selections shown in Fig. 31.6a,b, contains more than one peak per period. Assuming that autocorrelation analysis is apt (at least as a model [31.163–165]), a sound created like Fig. 31.7, when subjected to the *enhanced AC* algorithm [31.172], not only yields the

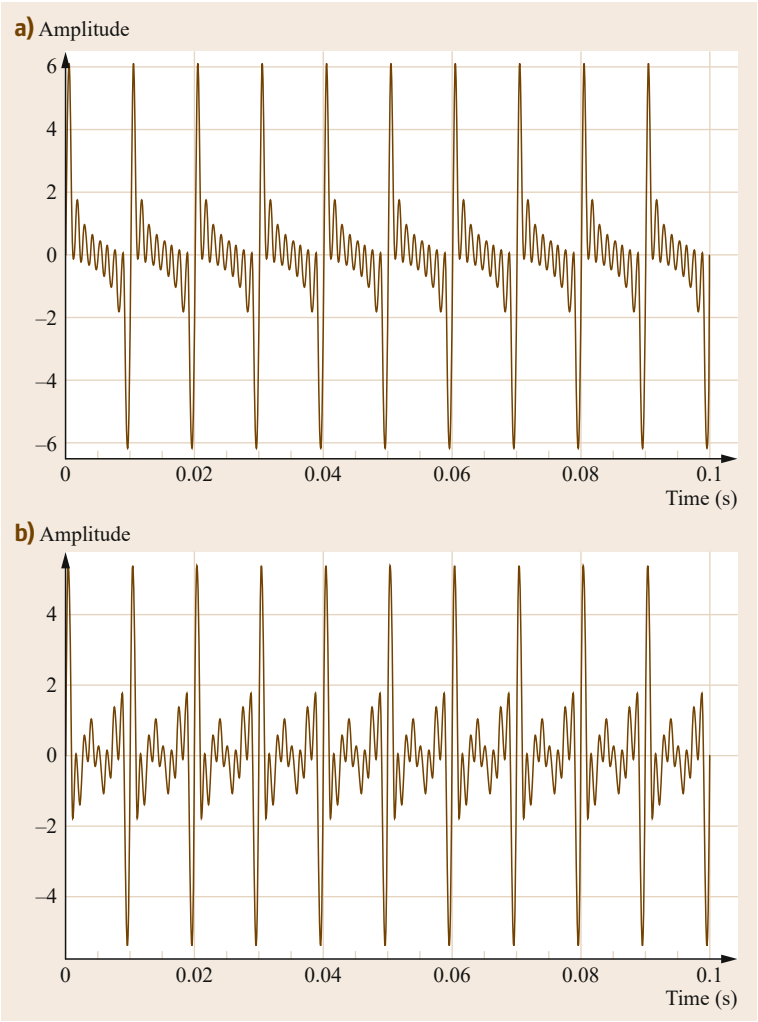

Fig. 31.6 **(a)** Harmonic complex, eight partials, $f_1 = 100$ Hz; **(b)** harmonic complex, partials 3–8 (300–800 Hz)

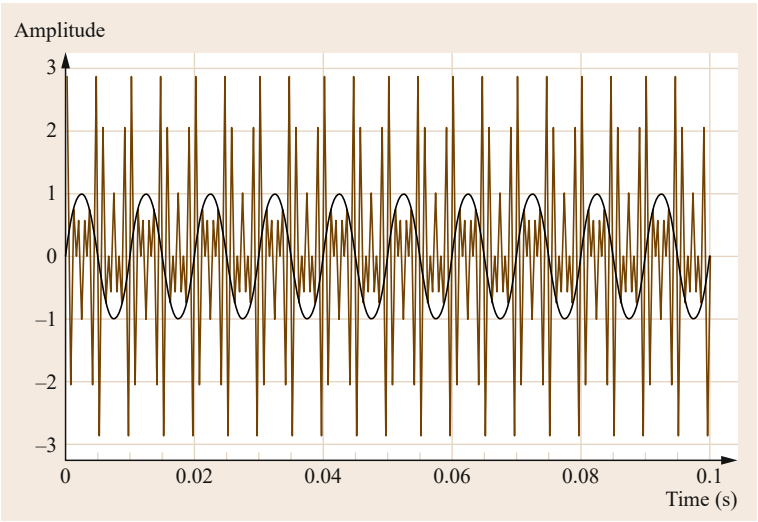

Fig. 31.7 Waveshape from superposition of harmonics 7, 9 and 11 {700, 900, 1100 Hz} of $f_1 = 100$ Hz. The *missing fundamental* f_1 (equal to the repetition frequency f_0 of the complex) is plotted separately (*in black*)

period at $T = 10$ ms but also strong periodicities at 4.5 and 15.5 ms, which means the ACF draws on several peaks contained in the waveshape (and its periodic repetitions) to calculate periods between these peaks. An observation worth reporting, in this circumstance, was that for a stimulus consisting of a pulse train with alternating intervals of 4.7 and 5.3 ms, respectively, recordings of spikes from fibers of the cat's AN subjected to ISIH analysis and autocorrelation histograms revealed periodicities at multiples of 5 ms [31.173], that is, the average of the two alternating intervals ($T \approx 5$ ms) as well as the period resulting from their combination ($T = 10$ ms).

It is of interest to note that spike trains recorded from AN fibers can transmit information representing the periodicity of a harmonic complex (with or without f_1 present [31.44, 45, 174]), thereby providing a strong neural basis for pitch sensation and perception. Neural encoding of periodicities in AN fibers includes musical intervals formed of two complex tones. ISIH analysis performed for several such intervals (minor second 16/15, perfect fourth 4/3, tritone 45/32, perfect fifth 3/2) demonstrates that the periodicities inherent in the acoustic stimulus signal are also found in the neural response where the ISIH peak structure closely mirrors the AC structure of the acoustic input [31.46]. Hence, the temporal input information seems to be fully preserved at the AN level.

The spectral fine structure of complex sounds can also be reconstructed from a Fourier transform of spike trains in the AN collected as period histograms or as interspike interval histograms [31.175], which demonstrates that the cochlear output contains spectral information encoded in temporal sequences. As with rate-place recordings from a rather small number of AN fibers, the Fourier transform of ISIH yields spectra which, for low stimulus SPL, resemble the input spectrum filtered by the CF/BF characteristics of fibers fairly well [31.174].

From a range of investigations of AN fibers as well as of neurons of the CN and of higher stations of the AuP up to the IC there is coherent evidence for both *place* and *time* representations of input signals [31.36, 150, 176]. Since rate-place mechanisms are markedly level-dependent, while purely temporal models fail to account for the greater salience of resolved against unresolved harmonics, a mixed *spatiotemporal* approach has been proposed [31.177]. In regard to place, tonotopic or cochleotopic organization is a feature found in nuclei of the ascending AuP and also in the auditory cortex (A1; [31.146, 147]). Topography of CF gradients and other features differ, however, from one station to the next. In the central nucleus of the IC (ICC), the cochlear frequency map is represented by an array of parallel frequency-band laminae where each lamina corresponds to about 1/3 octave, the width of a CB [31.178]. Also, the functional organization of the ICC (as observed in the cat) seems to indicate there are constant frequency ratios established between corresponding locations on neighboring laminae.

Periodicity encoded in spike trains has been detected in the AN, the CN and still in the ICC [31.106, pp. 270–280]. In the ICC a range of neurons responding strongly to particular modulation frequencies has been found. Such neurons can be characterized by their modulation transfer function, which refers to the discharge rate or the synchronization of units to the envelope of a sound as well as by their best modulation frequency (BMF). It has been suggested, from some observations, that in the auditory midbrain a periodotopic organization exists in ICC laminae where the periodotopic axis seems to extend in a nearly orthogonal pattern to the tonotopic axis [31.179–181]. Though this model as yet may be hypothetical, there is plenty of evidence that periodic stimulus patterns such as the repetition of the envelope of harmonic complexes or regular AM imposed on sounds are encoded in the neural response at the level of the AN, the CN and higher stations up to the IC [31.44, 45, 150, 153, 182–185]. Recordings from single units in the cat's IC show that the beat frequency of 26 Hz corresponding to two pure tones forming a minor second (466, 440 Hz in equal temperament, i. e., ≈ 100 cent) was matched in the discharge rate (relative to the onset of each beat cycle; [31.46]).

A temporal approach also seems apt in regard to binaural (spatial) hearing and dichotic phenomena such as the pitch of the *missing fundamental* created from two successive harmonic partials fed into the left and right ear respectively [31.186]; see Sect. 31.6.3. A temporal model working on ACF and CCF at least explains the perceptual outcome in a straightforward way. As an alternative, two independent sets of neurally encoded place informations from the left and right BM combined into a *central spectrum* have been discussed where harmonic partials are regarded as being matched against harmonic templates from which, in a final step, the fundamental f_0 is derived [31.187–189]. In addition, a mixed model combining place cues and periodicity to derive the *central spectrum* from an additional filtering stage of neural spike trains has been proposed [31.190]. One will have to distinguish the heuristic value of models demonstrating, in a plausible way based on system design and testing, how the pitch extraction process might operate, from the anatomical and neurophysiological evidence needed to validate models.

Moreover, it is obvious from a host of psychophysical experiments that envelope periodicity in many conditions is sufficient to evoke a salient pitch per-

cept. Consequently, neural periodicity analysis must be carried out in stations along the AuP. Factors rather indicating lower stations, up to and including the ICC, are the degenerative nature of phase locking in afferent AuP stations beyond the IC, and increasingly reduced neural firing rates observed in thalamic and cortical processing. In AN fibers, phase locking to pure tones may be as high as 4–5 kHz while the upper limit of neural phase locking to envelope periodicity based on AM is about 2.2 kHz [31.185]. Along the AuP, the upper limit of phase locking decreases significantly, absolute values depending on species investigated as well as on conditions (anesthetized or awake, etc.); a sizable decline is observed between the ICC and the thalamus (CGM), and more so between the CGM and the auditory cortices. In only a small fraction of CGM units, phase locking up to 1–2 kHz was measured while many units synchronized to lower frequencies (125–250 Hz [31.191, pp. 332–334]). In cortical units, phase locking to pure tones may occur up to several 100 Hz while locking to envelopes rarely seems to exceed 100 Hz [31.192]. This, however, is still enough to encode relatively slow AM such as the beat frequencies occurring between two simple or complex tones. Hence, there is evidence for a neural representation of roughness and sensory dissonance based on phase-locked activity at the level of the A1 [31.193]. Further, experiments on perception of the *missing fundamental* showed that patients who had suffered lesions of the right temporal lobe (including Heschl's gyri) performed significantly less consistently than controls [31.194], indicating that detection of envelope periodicity is effected in neural circuits embedded in the right temporal lobe. However, since phase locking declines and processing speed slows down towards cortical areas while the number of neurons involved increases greatly, neural processing of fine-grained temporal information seems less probable (though perhaps possible, depending on the type of code and the distribution of neurons involved [31.150, 195]). As an alternative, transformation of temporal coding into rate-place codes in stations of the AuP has been considered. One problem with rate functions is that, while firing rate usually is found to grow with sound level (subjected to compression increasing with SPL) at lower stations of the AuP, there is evidence of nonmonotonic rate functions from the ICC, the CGM, and the A1 largely due to inhibition [31.146].

The primary auditory cortex (A1) in humans *is found typically in the medial portion of the first anterior transverse temporal gyrus, also known as Heschl's gyrus* [31.196, p. 263]. Detailed anatomical and functional descriptions distinguish between primary auditory cortex, anterior auditory field (AAF), and posterior auditory field (PAF). Topography is also discussed with respect to core, belt, and parabelt regions of cortical areas [31.197]. From electrophysiological as well as imaging studies a tonotopic organization of A1 has been proposed [31.146, 147, 198]. A topography has also been suggested for stimulus intensity (with respect to the cat A1 [31.199]). One frequency gradient for low to high CFs has been identified to run from posterior to anterior A1. Two mirror-imaged tonotopic regions were found with magnetoencephalography (MEG) in the auditory cortex [31.200]. In addition, from MEG of six subjects, it has been inferred that the quasi-orthogonal arrangement of frequency (CF) and periodicity (BMF) suggested earlier for the ICC [31.180] applies also to orthogonal maps in the human auditory cortex [31.178]. Further, neurons in the auditory cortex of the marmoset monkey were reported to respond to pure tones and complex tones with missing fundamentals that have the same f_0 [31.201], that is, where the single frequency f_n (Hz) of the pure tone equals the repetition frequency (f_0) of the complex that has no spectral energy at f_1. Consequently, the same neurons must be capable of detecting either a frequency for which a spectral cue exists or derive the same frequency from a temporal cue (envelope periodicity), thus providing a neural basis for perceptual pitch constancy, i. e., the experience according to which sounds with different spectral and/or temporal structure can evoke *the same pitch* (or nearly so). Since earlier investigations [31.202] had failed to find neural substrates for pitch processing of harmonic complexes with a *missing fundamental* in the auditory cortex of rhesus monkeys, this particular report was met with some skepticism [31.195]. However, there might be neurons in stations of the AuP up to the auditory cortices responding to the same periodicity transmitted either from pure tones or from envelopes of harmonic complex tones lacking f_1.

Applying four functional criteria, namely pitch selectivity, pitch constancy, covariation of response magnitude with pitch salience, and elimination of peripheral phenomena, a study [31.203] combining functional magnetic resonance imaging (fMRI) methodology and psychophysical experiment ($n = 16$ subjects) was undertaken to locate, if possible, a cortical *pitch center*. Five different stimuli (a pure tone plus Gaussian noise masker, a harmonic complex, resolved partials of the same complex band-pass filtered to remove several low partials, again together with Gaussian noise masker, etc.) were presented all of which should evoke *the same pitch* equivalent to that of a pure tone at 200 Hz. Findings included *the fact that pitch-related activation rarely occurred at exactly the same point in the auditory cortex across the different listeners* while *spatial consistency was much more striking within listeners*. Locating the *pitch center*, for seven subjects *it fell in*

different portions of the planum temporale (PT), in one listener it fell in planum polare (PP) and in two listeners it was elsewhere [31.203, pp. 87 f.]. Also, the response magnitude in the pitch center for the different stimuli was unrelated to the pitch salience found in psychophysical experiment. There have been numbers of MEG and fMRI studies directed to finding *the* pitch center (for primates and humans [31.204]), but although they localize distinctive cortical areas active in pitch processing, neither technique converges on microanatomical mapping and assignment nor on the number (one, two) of tonotopic frequency gradients. More recently, again two tonotopic gradients were reported on the basis of fMRI data [31.205] to be located in bilateral cortex on Heschl's gyrus, one on its caudal and one on its rostral bank. From experiments using an adaptation electroencephalogram (EEG) (AEP) design, a circular cortical pitch map has been suggested to account for the circularity of *tone chroma* within the octave [31.77]; Sect. 31.1.2.

Recent discussions of the role of A1 and adjacent cortical areas reflect changes in perspective. Traditionally, the AuP including A1 has been viewed as a basically hierarchical system where certain tasks are performed on each level in regard to feature extraction (see Fig. 31.2 and the flow chart following the graph), with further processing of neural code for pitch and perhaps also timbre and loudness at A1 as well as in adjacent nonprimary areas. Such a view was obtained from, for the most part, electrophysiological recordings where neural response patterns reflecting the acoustical input were traced along the AuP as well as in A1 and other cortical areas. Results did account for a range of stimuli such as pure and complex tones, periodic click trains, AM and FM of pure tones, noise bands, etc. suited to evoke sensations of pitch. In A1 and adjacent areas gradients for frequency and intensity were found. Also, maps with more than one dimension have been proposed with respect to spectral and temporal representations of pitch (for an overview see [31.147, 192, 206]). In order to pinpoint processing of certain features, much of this research employed sound stimuli comprising a small number of dimensions, and single stimuli rather than combinations thereof (for reasons of experimental control and also to minimize context sensitivity). Meanwhile, the use of more complex, real-life stimuli such as animal vocalizations (in animal experiments [31.207]) or speech and musical sound is more widespread. Such studies revealed there is a belt of areas surrounding A1 involved in a more distributed processing reflecting stimulus complexity [31.208, 209]; distributed processing thus seems to distinguish complex from elementary stimuli. Also, animal experiments indicate there are neurons sensitive to particular feature combinations indicative of pitch, timbre, and localization [31.210]. In regard to integration of several features (e.g., tone height, intensity, spectral harmonicity, modulation, roughness), which have been analyzed along stations of the AuP, it has been suggested that a *central* task of the auditory cortices (implied are also belt regions around A1) could be forming auditory objects identifiable in a mixture of sounds [31.211, 212]. From high sensitivity of cortical neurons for certain spectral and/or temporal features on the one hand, and the need to integrate features into objects on the other, a determination for neural coding comprising three types of representation has been proposed [31.213]. These are:

1. Isomorphic representations where firing patterns *faithfully* reflect stimulus features and magnitudes
2. Nonisomorphic transformation of acoustical features into neural code
3. Internal representations of objects derived from a transformation of acoustical features into perceptual dimensions.

Since many real-world sound stimuli are fairly complex in regard to temporal and spectral structure, involvement of cortical areas beyond the acoustical cortices can be expected in order to analyze the *meaning* of distinct objects, and also for binding a sequence of objects into a formation (Sect. 30.1.2). From earlier experiments employing positron emission tomography (PET) it has been suggested that, for perceptual analysis of rather simple melodic phrases, networks of the right prefrontal and right frontal cortex are involved besides areas of the right superior temporal cortex [31.214]; comparison of pitches (in regard to intervals) seems to be carried out in the intraparietal sulcus (IPS [31.196]). Extending the dual-stream model of object (*what*?) and spatial (*where*?) processing, a differentiation between right and left hemispheres has been suggested according to which spectral processing would be predominantly done in the right hemisphere while temporal analysis would be achieved in the left [31.215] to account for often rapidly changing sound structures such as transients. However, given the very fast recognition of musical pitches and timbres in actual listening, the outcome of spectral and of temporal analysis then would have to be integrated instantly for object identification. Such operations, though *automated* in actual perception, draw on and reinforce memory. With respect to pitch perception, a representation of the relevant sound features in short-term memory (STM) seems necessary to allow for more detailed analysis. There are various hypotheses concerning the structure of the working memory as well as involvement of PFC substrates in actually integrating information (there is growing evidence for domain-specific working mem-

ories available for certain tasks [31.216, 217]). As has been observed in many experiments, the STM buffer for pitches and pitch sequences is considerably wider than that for visual stimuli. Musically trained subjects with relative pitch typically have a memory trace suited to reproduce pitches of single tones and undisturbed pitch sequences with only small errors within 1−2 min [31.218]; in general, the error (expressed as SD of pitch deviations) increases markedly with time indicating working memory for auditory input seems to function like a *leaky integrator*. However, in particular musically trained subjects seem to be able to draw on LTM resources and thereby can identify intervals and chords as well as tone sequences ordered along a scale or presented within a melodic Gestalt with higher precision, and also after a greater lapse of time (as was found already by [31.219]; see [31.74, pp. 130 ff.]).

Underpinning cortical plasticity, it has been shown that musical training and learning influences cortical processing of music in perception and performance [31.220, 221]; see also Part C of this book. There are some indications from evoked brainstem responses that musical training has even an effect on phase locking to periodic stimuli and hence on subcortical pitch processing [31.222]. Further, brainstem frequency-following responses (FFR) recorded from musicians and nonmusicians show that musicians synchronize faster to chord arpeggios and respond stronger to notes changed in tuning (as the third in either an A-major or an a-minor chord) than nonmusicians [31.223]. In addition, brainstem responses recorded in nonmusicians were more salient to consonant than to dissonant intervals formed of two complex tones [31.224] suggesting that neural processing makes use of the enhanced periodicity and harmonicity of intervals such as the perfect fifth 3/2 or the perfect fourth 4/3 (as compared against the minor second 16/15 or the major seventh 15/8). Findings established on the AN level of the cat [31.225] thus are corroborated by human brainstem FFR data.

31.5 Auditory Models and Pitch Extraction

On the basis of many empirical findings, obtained from both investigations of the AuP as well as psychophysical experiments, a number of auditory models have been issued since the 1980s (for an overview see [31.9, 131, 226]). Such models typically comprise a number of modules to emulate functions of the outer and middle ear, the BM (or the CP), the IHC and the AN; some include relays of the AuP (CN, IC). Models can be distinguished by either adopting a spectral or a temporal paradigm though they share some features with respect to peripheral processing. Typically, a linear filter is implemented for the transfer function of the ear channel and a bank of slightly overlapping bandpass filters for cochlear tonotopic frequency selectivity. The performance of cochlear models (including Gabor filtering and gammatone filter) has been reviewed recently [31.227]. The spectral approach to pitch extraction models [31.11, 228] operates on a pattern of resolved spectral components (ideally, but not necessarily, partials of a harmonic complex) derived from filtering the input signal. The filter in this case models the cochlear transfer function (CTF) and is similar to the gammatone filter that has been widely used in auditory signal processing [31.229]. The number of filter channels, their center frequencies and their bandwidth can be chosen so as to either match one of the established psychophysical scalings for frequency with respect to CBs or JNDs (Bark scale, ERB scale, SPINC scale; see Sect. 31.6.2), or can be derived directly from the CTF filter characteristics. In Terhardt's model, cochlear filtering results in a number of components that represent candidates for spectral pitches that might be audible as such (since many natural sounds contain spectral components spaced widely enough and strong enough in amplitude to evoke individual pitch percepts). After evaluation of possible masking effects and a weighting of such components that are retained, virtual pitches are extracted by means of a subharmonic matching process. Subharmonic matching means the search for a common denominator fitting a *root* to harmonic or quasiharmonic series (see below). Finally, a pitch-salience pattern is calculated from spectral and virtual pitches. The advantage of Terhardt's model is that it acknowledges the fact that musical sounds (for example, such recorded from swinging or carillon bells) may comprise several clearly audible pitches, which can either correspond to *resolved* harmonic partials or inharmonic spectral components or can result from the interaction of such components giving rise to one or even several virtual pitches [31.228, 230]. In addition to his model of spectral and virtual pitch extraction, *Terhardt* [31.11, 231] has proposed a special kind of Fourier transform called Fourier time transformation (FTT) suited to match spectral and temporal characteristics of peripheral auditory filtering. In certain respects [31.137], FTT analysis can be compared to wavelet analysis (or, in a more general view, to Gabor's concept of *logons* representing analyzable units in time-

frequency planes). Offering constant Q filtering rather than the constant bandwidth of conventional Fourier transform algorithms, FTT offers a better resolution for low frequency spectral components than short-term Fourier transform (STFT) (and a less precise spectral analysis for high frequency bands where harmonic complexes are not *resolved* into individual partials).

Several computational spectral models were designed following concepts of *harmonic templates* or *harmonic sieves* that had been proposed earlier in psychoacoustics on the basis of hearing experiments. Such template models hypothesize that a *central pitch* for complex sounds is established from peripherally resolved harmonics [31.186–188, 232] and that statistics are performed on resolved harmonics for a decision process leading to pitch estimates [31.187, 189]. Statistics based on calculating means and variances for frequency distributions and estimates based on criteria such as maximum likelihood will be needed in the case of hearing several harmonic complexes with overlapping partials as well as in regard to detuned partials or inharmonic complexes where components must be fitted to a template and more than one pitch estimate (expressed as a fundamental period or as f_0 of a complex) per sound may occur. A computational implementation of the *harmonic sieve* concept is the spatial pitch network model (or SPINET [31.233]).

Temporal models of peripheral and central pitch processing usually include a cochlear filter stage. Transduction of filter output into neural spike trains is effected by means of halfwave rectifiers (since IHC fire when stereocilia are deflected in one direction) as well as by implementing gain adaption to simulate nonlinear hair cell compressive behavior. Spike trains in simulated single AN fibers are subjected to AC analysis for channel periodicities, and a sum AC (or correlogram) analysis typically is performed to determine common periodicities across channels, which are fed into a final pitch detection or pitch estimation stage [31.162–164]. The neural activity pattern within and across channels may be represented as auditory images [31.229] that closely reflect the periodic structure of harmonic input signals (such as vowels in speech or sounds from organ flue and reed pipes). Strobed temporal integration may be substituted for AC to account for temporal asymmetry in perception as can result from sounds that are either *damped* or *ramped* with respect to the temporal envelope [31.234, 235]. Also, nonlinear filter types have been substituted for linear gammatone filters to match models even closer to observed BM or CP behavior [31.236]. Computational AN models [31.237] likewise incorporate nonlinearities to account for realistic tuning curves as well as for level-dependent compression and suppression effects.

The basic architecture of early temporal models followed *Licklider*'s [31.157] *duplex* design based on peripheral filtering and subsequent AC analysis. AC analysis can handle a broad range of stimuli and is suited to explain many pitch phenomena [31.163, 164]. It needs, however, a long delay line to deal with low frequencies (see above) for which physiological evidence is lacking. For this reason, alternative systems have been designed where the overall periodicity is determined by means of coincidence detection. The mechanism of coincidence detection has played a role in auditory theory for a long time [31.158] with respect to spatial hearing and sound localization. A model for detection of harmonic intervals in the mammalian CGM based on coincidence of clock cell discharges and spike trains from pure tones forming small integer ratios has been hypothesized [31.238]. To perform periodicity analysis in a physiological plausible model, large assemblies of CN chopper units (for anatomical and physiological background [31.98]) and IC coincidence detectors have been implemented [31.239]. This model extracts periodicity pitch from signals composed of both *resolved* and *unresolved* harmonics and also from a type of inharmonic signal where all harmonic frequencies are shifted by an equal amount, Δf [31.16]. Since the pitch based on the periodicity of a signal can shift if one or several partials are detuned by a certain amount from harmonic ratios, period estimation becomes more demanding than in conventional AC (for a possible solution see [31.240]).

There have been more attempts at building realistic auditory modules including AN, CN (in particular its ventral part, VCN, a main AuP relay), SOC and IC [31.241]. Also, the signal processing approach has been expanded to include a presumptive cortical stage simulating analysis of complex sounds in AI spectrotemporal response fields [31.242]. To this end, peripheral (constant-Q) filtering and nonlinear transduction to neural signal representation is followed by a bank of (linear) modulation filters that yield information about both the temporal and the spectral modulation of the input.

Among the goals for physiologically plausible modeling is to explain, besides pitch perception, some rather uncommon auditory phenomena such as comodulation masking release (CMR; masking is *reduced* by adding *flanker* signals to a probe and a masker, all of which are amplitude-modulated at the same rate; for details see [31.243]). In a model of auditory brainstem processing, CMR has been tentatively explained as *wideband inhibition of narrowband and delayed inhibition* effected by CN circuits [31.244, p. 389]. CMR indicates interaction of spectral components which, adopting the correspondence of CBs to auditory filters (AFs), are

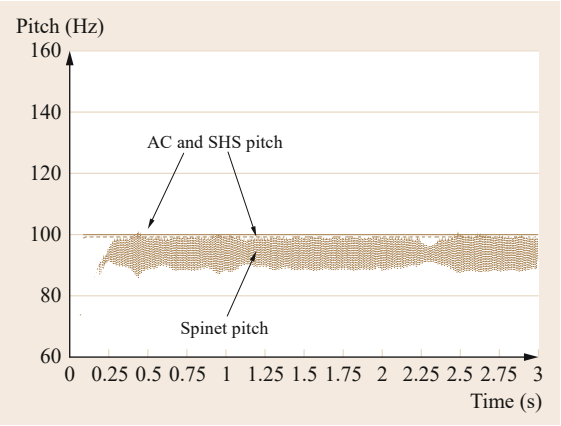

Fig. 31.8 Pitch estimates for a harmonic complex (ten partials, 100−1000 Hz); AC and SHS are at 100 Hz, SPINET offers a *pitch zone* at an average of 94 Hz

falling into separate CBs; CMR seems thereby to be contradicting traditional CB concepts (Sect. 31.6.2).

In order to compare the performance of some of the models mentioned above, a harmonic complex comprising ten partials (100−1000 Hz) in sine phase and a harmonic complex with partials of numbers 4−13 (400−1300 Hz) in sine phase were analyzed by two AC-based algorithms [31.172, 245], one model designed for subharmonic pitch summation (SHS [31.246]; the approach is similar to Terhardt's concept), and one model using the *harmonic template* (SPINET as implemented in the Praat environment; [31.247]). For the harmonic complex, the two AC algorithms and SHS turn out 100 Hz (which is both f_1 and f_0 of this complex) as *fundamental* pitch; the advanced AC algorithm [31.172] in addition offers subharmonics (33, 20 Hz, etc.) as possible pitch candidates while the SPINET model yields a *pitch zone* with a minimum near 86 Hz, maximum close to 101 Hz, and a mean at 94.08 Hz (SD = 3.79 Hz) (Fig. 31.8).

For the harmonic complex comprising partials of numbers 4−13, both AC algorithms again indicate 100 Hz as *fundamental* (in this case, with f_1–f_3 missing, 100 Hz = f_0). SHS fails at finding a single pitch estimate for this sound (yet calculates several f_0 frequencies), and SPINET delivers some spurious output. Similar results are obtained when the two complex sounds (partials 1−10, partials 4−13) consist of alternate sine and cosine partials. The AC algorithms are robust under this condition (owing to the strength of the mathematical principle). Peripheral preprocessors (filter banks as BM/CP models), pitch estimation algorithms and ear models incorporating IHC and AN modules are really put to test when fed with complex sounds of varying spectral inharmonicity such as sounds from swinging and carillon bells or sounds recorded from Javanese and Balinese *gamelan* instruments [31.93, 248–250]. Since increasing spectral inharmonicity implies a decline in periodicity, subharmonic matching and even AC algorithms become less effective, and fail to obtain a single pitch estimate for many complex sounds. To be sure, such outcome reflects perceptual ambiguity as experienced even by musically trained listeners exposed to inharmonic sounds. Music performed on carillons can be regarded a paradigm for composite sounds that are quite intricate to analyze with respect to pitches, in particular when several minor-third bells are played simultaneously [31.251]. One has to remember that *Schouten* [31.24, 32, 33] discussed the concept of the *residue* by pointing to the first ten spectral components of a typical minor-third carillon bell (see Sect. 30.2, Table 30.5, and Fig. 30.16. For details see [31.251, 252]) to argue that the *strike note*, as a virtual pitch, could arise from the interaction of three nearly harmonic components (so that the strike note would equal the bell's prime in pitch but not in timbre). Pitch ambiguity, as is often experienced in bell sounds, can even occur when listening to harmonic complexes such as chords and sonorities where several spectral pitch cues exist and virtual pitches may also arise from an overlay of partials. In principle, almost all complex sounds can give rise to more than one pitch sensation [31.11, Chap. 11]. Also, there are interdependencies between *pitch* and *timbre* (Sect. 32.2); for example, the pitch of a harmonic complex may change by one octave depending on spectral energy distribution [31.253].

31.6 Psychophysics

In this section, a range of phenomena relevant for sensation and perception of pitch will be presented in an overview covering, in particular, JND and DL for *pitch*, critical bands, roughness and dissonance, the *residue* and the missing fundamental, combination tones, fusion and consonance.

31.6.1 JND and DL for Pitch

The JND usually is defined as the smallest increase in stimulus intensity or magnitude detectable by subjects within a sensory modality. Investigations for JNDs relate to a certain experimental technique

in psychophysics (outlined already by [31.254]; see Sect. 30.1.4 above) as well as to a statistical measure in that a JND is established on the basis of responses or observations obtained from subjects indicating a small difference between the magnitudes of two stimuli has been noticed in at least 50% of all trials. The DL often is regarded as the absolute threshold for the discrimination of two stimuli under certain conditions, or as the change in a stimulus that *the average observer* [31.156, p. 998] is capable of detecting. Either referring to an absolute threshold or to an *average* that holds for a population, a DL is a generalized magnitude derived from several or even many JND experiments. The very small JND found in many experiments for pure tone frequency discrimination indicates high sensitivity of hearing for small stimulus changes. On the basis of experiments where frequency-modulated pure tones served as stimuli, the number of JNDs for pure tones in the range of normal hearing has been estimated to comprise 640 steps distributed over 24 frequency groups [31.255], see Sect. 30.1.4, *Loudness Scaling and Scaling of Pitch: Two Illustrative Examples*. The size of the DL ($f/\Delta f$) depends on the reference frequency as well as on conditions (SPL, earphones or free field, monaural or binaural hearing) under which the sounds are perceived; in the range from ≈ 200 Hz to 1 kHz, JND for pitch of pure tones presented at 40 dB SPL in humans was about 1 Hz [31.256]. Both cochlear *place* and neural *time* patterns can convey pitch information in this frequency range. In experiments with a large sample ($n \approx 400$) of subjects, many of which had either professional musical training or were active as amateur musicians, for complex synthetic and natural sounds with f_1 in the range of 250–300 Hz about 90% of the sample recognized frequency shifts of 7 cent [31.257] and still 55% of only 4 cent (4 cent = 1/25 of the size of a half tone (HT) in equal temperament, ET). For the DL of 2 cent (the absolute threshold for pitch deviations that can be detected by humans), the figure was 20% since in particular violinists and sound recording supervisors (German: Tonmeister) were able to deal with such subtle shifts. JNDs for pure tones have also been obtained for nonhuman primates [31.258] where a range of 1 Hz to more than 10 Hz at 1 kHz was found in several studies. It was shown for some species that they can discriminate complex harmonic tones as well [31.13].

31.6.2 Critical Bands (CB), Roughness and Sensation of Dissonance

The concept of CB was formally introduced by *Fletcher* [31.259, 260] who explored the relation of noise masker and pure tone intensities in regard to cochlear excitation patterns and loudness perception. For a pure tone of frequency f_k to be perceived, its intensity must at least equal the average intensity of a noise band of a certain bandwidth. *Fletcher* [31.259, p. 55, Fig. 17], offered a graph where the bandwidth of the noise masker is related to the pure tone frequency; according to Fletcher, the bandwidth of the CB (in Hz)

> *is numerically equal to the ratio of the intensity of the tone masked to the intensity per cycle of the noise producing masking and always corresponds to* 1/2 mm *of length on the BM.*

This ratio has been termed the *critical ratio* (CR). A formal definition [31.261, p. 174] of the CR (in dB) is $\mathrm{CR} = \mathrm{thr} - L_{\mathrm{ps}}$, where thr is the threshold (in dB) of the pure tone, and L_{ps} is the spectrum level of the noise band. The CR as expressed by *Fletcher* [31.259] differs from the bandwidth of the CB found later on in experiments on loudness summation [31.262]; it seems that, at many frequencies, the CR is about 0.4 the value of the CB [31.261, 263]. Characteristic of a CB as described by Fletcher was that, for a given tone of frequency f and intensity I, increasing the bandwidth of the masker beyond a certain value does not change the masking effect. *Fletcher* [31.260] regarded the masker of a certain bandwidth relative to the frequency of the pure tone as activating a constant portion of length of the BM (plus neurons attached; his concept included dividing the BM into 100 *patches of nerve endings*; see Sect. 33.2). In this respect, the CB is the basic unit of the cochlear map that thereby can be described as a chain of filters wired in parallel. Performance features of the auditory filter (AF) have been studied in many experiments where it was found that the bandwidth and the shape of the AF depend, to some degree, on frequency position along the BM as well as on stimulus level (for overviews see [31.263, 264] and [31.159, Chap. 10]). While the AF at low levels is almost symmetric, the low frequency slope of the filter becomes less steep with increasing level. In regard to frequency discrimination and pitch perception, the AF having a bandwidth corresponding to one CB will cover a number of frequency components presented simultaneously falling into this band; hence, such components cannot be *resolved* and perceived as individual constituents. In regard to sensation of loudness, the AF can be viewed as a *bin* that collects the energy or power falling into each AF [31.262, 265]. Both the pitch and the loudness aspect have been discussed with the CB as the basic unit relevant to auditory perception [31.7, 266]. In addition, *Fletcher* [31.259] had speculated that his CB corresponds to 1/2 mm of BM. A similar idea was expressed by *Zwicker* et al. [31.262] who had found CB

bandwidth to be *almost invariant* with level, and had expressed CB bandwidth in mel (Sect. 30.1.4, *Loudness Scaling* ...). From CB data available then as well as from studies *von Békésy* [31.29] had undertaken to establish a cochlear frequency map for several species, *Greenwood* [31.128, p. 1350] derived a formula for calculating cochlear coordinates (Sect. 30.1.4, *Loudness Scaling* ...). From his calculations (and assuming nonoverlapping CBs) he concluded *that one critical band is equal to approx.* 1 mm (of BM), and that about 35 CBs would account for the human range of hearing (20 Hz to 20 kHz). A scale comprising 24 CBs was issued by *Zwicker* [31.255], [31.12, Chap. 6] where for each band the center and the lower and upper limit frequency is given. The CBs are taken as a unit of a critical band rate (z) that spans a frequency range from 100–15 500 Hz; the CB units are termed *Bark* (to honor the contributions of Heinrich Barkhausen (Sect. 30.1.4, *Loudness Scaling* ...) to psychoacoustics). More recently, a refined CB scale was proposed by *Moore* and *Glasberg* [31.267] based on units calculated as *equivalent rectangular bandwidth* (ERB [31.263, 264]). The concept was developed to approximate AF characteristics more closely, and to account for known phenomena such as level dependence of AF bandwidth. The ERB scale is similar in shape to the Bark scale for frequencies above 500 Hz, yet different below where the Bark scale assumed a constant bandwidth of 100 Hz per CB while the ERB decreases in bandwidth toward low frequencies. Also, the ERB scale comprises nearly 40 CBs as compared to the 24 Bark CBs and hence offers a finer grid that is closer to actual frequency selectivity observed in humans. BM sections corresponding to each of the ERBs would be ≈ 0.86 mm wide. As shown in Fig. 31.9 for a range of 50–500 Hz, ERB grows linearly with center frequency.

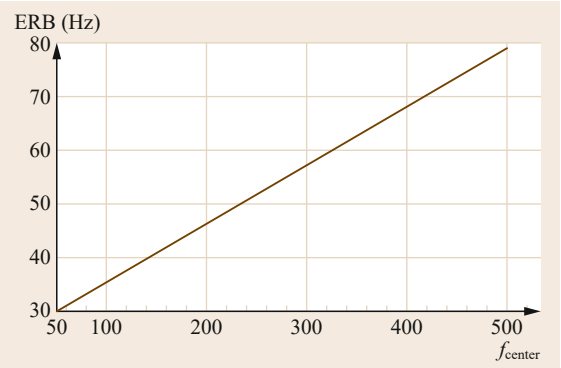

Fig. 31.9 ERB (Hz) as a function of center frequency (f_{center}, 50–500 Hz)

The Bark scale at low frequencies ($f < 500$ Hz) does not conform to listening experience in regard to musical intervals and to the CBs obtained in experiments on roughness sensation. This is quite evident for Bark band 1 (0–100 Hz), which is not well defined (it probably should have used the lower limen for pitch perception at 20 Hz as a reference point) while the next three Bark CBs numerically have the size of an octave, a fifth and a fourth respectively, if expressed in cents, that is, in a perceptually meaningful unit [31.268]. An interval of two sine tones 100 : 150 Hz presented at 50 dB SPL on suitable loudspeakers by most subjects will be heard as a fifth (of 702 cent) formed of two tones that can be identified as such (that is, these two tones are *resolved* and do not fall into one CB). At 200 Hz, two tones forming a minor third (200 : 240 Hz = 316 cent) can be as clearly identified as the interval itself (otherwise, music as we know it would not be possible). Thus, the respective Bark band, assumed to range from 200–300 Hz [31.12, p. 159], is much too wide. The ERB, because of the decrease of bandwidth below 500 Hz, is more appropriate, but still seems a bit wide at very low frequencies, $f < 100$ Hz [31.168]. In experiments on psychophysical tuning curves (PTC) for low frequencies, the *bottom* AF *appears to be located between* 40 *and* 50 Hz [31.269, p. 3179]. In fact, scores obtained for subjects (with some musical training) from interval recognition tasks improved to some degree if the fundamental of the lowest tone was at or above 50 Hz [31.168].

The CB concept is of particular relevance for the sensation of roughness and beats, which in turn are closely involved in sensory dissonance. In his theory of sensory consonance and dissonance, *Helmholtz* [31.28] described sound phenomena where, in pairs of complex tones, fundamental frequencies and higher partials either coincide or deviate from each other so as to cause *disturbances* in sensation. Such disturbances according to Helmholtz are scalable phenomena (on a sensory scale ranging from pleasant to unpleasant) since small deviations from just frequency ratios (e.g., the fifth and fourth in ET) will be tolerated, and a soft modulation may even be sensed as pleasant while there are sonorities that are intermittent in their temporal envelope, to result in a sensation of strong beats. Helmholtz judged such intermittent *creaky* sounds as unpleasant because the neural excitation pattern would reflect the intermittent sound structure (there is empirical evidence for this hypothesis now available [31.225]). He found that sensations of beats and roughness in regard to musical intervals played simultaneously were dependent on two factors, namely (1) the size of the interval and (2) the octave position where the interval is put to sound. For

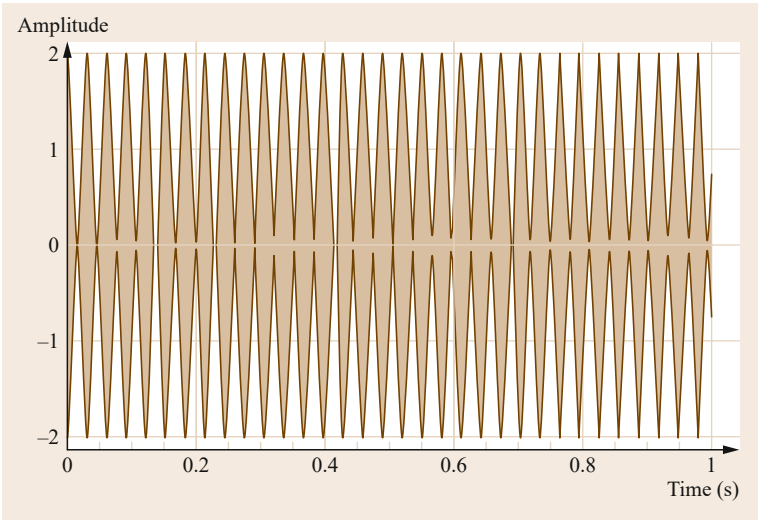

Fig. 31.10 Helmholtz minor second B_4–C_5, 1″ of sound

two pure tones played in the middle range of musical tones, he argued roughness reaches maximum at beat frequencies of 30–40 Hz. As an example, he pointed to the minor second (h′–c″ in Helmholtz's designation, which is B_4–C_5 in USA standard) where the frequency difference amounts to almost 33 Hz (relative to A_4 = 435 Hz). From Helmholtz's description it is clear that by *beats* (German: *Stöße*) he meant the number of intermittent peaks per second (Fig. 31.10).

For most listeners, the beat frequency may be too high to be counted. Also, the two frequency components that form the interval are too close to be discriminable as constituents of the interval, i. e., a minor second. Helmholtz discovered that by keeping one tone constant in frequency and shifting the other slowly from unison upwards or downwards, maximum roughness occurs at the minor second (frequency ratio 16/15, $\approx$ 112 cent) while it is less at the major second (9/8, $\approx$ 204 cent), and about to disappear when reaching the minor third (6/5, $\approx$ 316 cent). He calculated a roughness profile for simultaneous intervals within two octaves (c′–c‴ = C_4–C_6) based on coincidences and interferences between partials of violin tones. While studying consonance and dissonance, Helmholtz had discovered what later became known as the CB, that is, the phenomenon where two pure tones played simultaneously at a narrow interval interfere so as to produce beats and audible roughness while they cannot be identified as single constituents in the sound.

For two sine tones of unity amplitude, one fixed (say, at 200 Hz) and one variable in frequency, their relation changes from unison to slow modulation, then to increasing roughness, which is followed by an *interference zone* where strong beats occur. With the distance (in cents) of the two tones further increasing, roughness in proportion decreases. Finally, two discrete tones become audible at an interval that, in the range from about 300 to 2000 Hz, is larger than a major second and smaller than a minor third (Fig. 31.11). The distance (in cents) where the fixed and the variable tone become audible as two distinct parts of the stimulus can be regarded as the bandwidth of the CB.

The term *interference zone* here is chosen to avoid the term *fusion*, which is often used to denote the phenomenon that two tones cannot be distinguished if too close in frequency. Since the term fusion plays a central role in the theory of consonance (see below) and as two tones beating strongly in fact are sensed as markedly dissonant, terminology should reflect their interference. As was observed already by Helmholtz, the absolute size of the interval where pairs of tones leave the interference zone and become audible as two distinct tones depends to some degree on the frequency range. At low frequencies ($f < 200$ Hz), the bandwidth of the CB seems enlarged as compared to the middle range (where the CB is about 250 cent). For example, taking the minor third A_1–C_2 as played on a grand piano, the fundamental frequencies of the interval in ET are at 55 and 65.4 Hz (= 300 cent) respectively. According to the ERB function, they cannot be sufficiently separated. Assuming AFs to overlap in reality, one would observe some spectral leakage from one CB filter into the next. In fact, listening to such intervals, one can sense roughness due to spectral interference of the two complex tones.

Mayer [31.270] has been regarded as having discovered, almost by chance, the CB [31.128]. In fact he deals with small changes in the size of consonant intervals detectable by trained listeners. For example, the interval 256 : 315 Hz (produced from two tuning

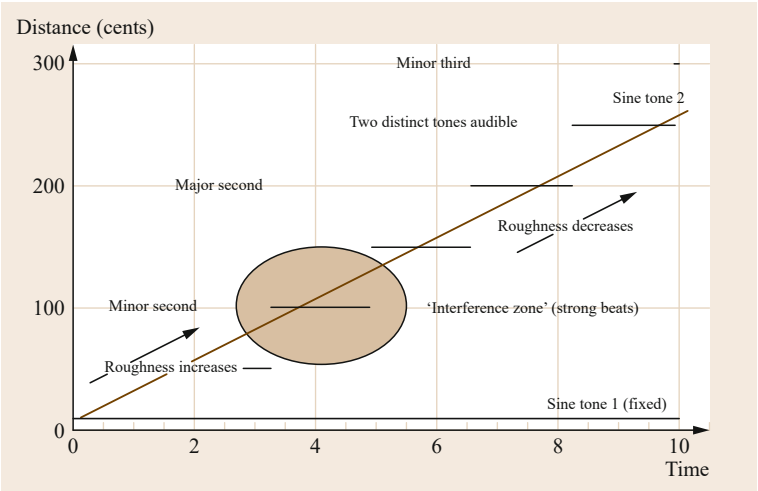

Fig. 31.11 Roughness, beats, CB bandwidth as observed at ≈ 200–500 Hz

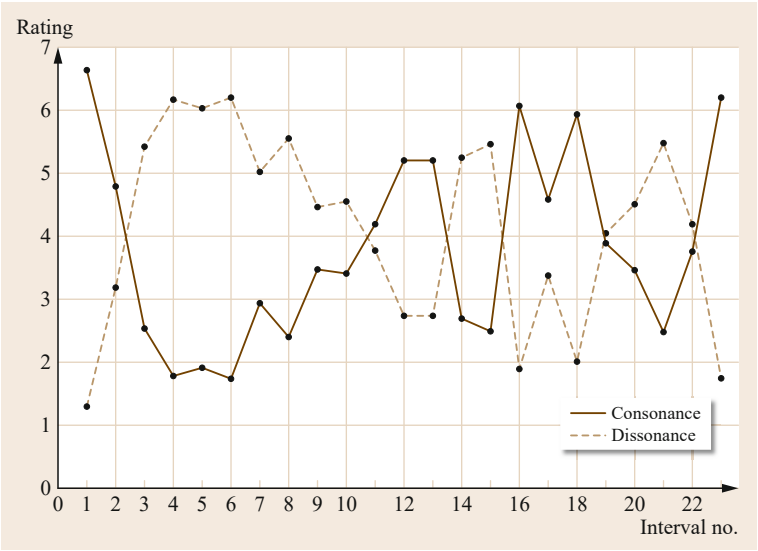

Fig. 31.12 Consonance (*solid line*) and dissonance (*dashed line*) profiles for 23 intervals from unison (no. 1) to octave (no. 23). No. 13 is the pure fourth, no. 16 is the pure fifth, no. 18 is the just major sixth (after [31.268])

forks), representing the tones UT_3–MI_3 was judged as *consonant* by Mayer's observers (among them musical experts). The ratio 256 : 314 Hz appeared as *just consonant* while 256 : 313.5 Hz was said to be *slightly rough* and 256 : 313 Hz *decidedly rough*. To be sure, all four intervals constitute a *neutral third* (about halfway between major and minor third; an interval found in European folk and non-Western music) and have a size of 359, 353.5, 351, and 348 cent respectively. Applying ERB measures, none of these neutral thirds falls within a single CB.

Auditory phenomena related to CBs as concept have far-reaching implications for human psychophysics and also for audio technology [31.159, 271]. Taking the original report *Helmholtz* [31.28] gave on sensations of roughness and dissonance, both are closely related in the experience of musical intervals within one octave (or even within a double octave). Putting a range of 23 intervals within one octave to test, *Schneider* et al. [31.268] obtained judgments from musically trained observers ($n = 51$) on a seven-point scale for *consonance* and *dissonance* of each pair of complex tones. The data were transformed into two complementary profiles for consonance and dissonance (Fig. 31.12). Similar to Helmholtz's observation, dissonance was highest at and around the minor second, at the tritone ($45/32 = 590$ cent) and at the major seventh ($15/8 = 1088$ cent) while consonance was highest at the unison, the pure fifth ($3/2$) and the pure major sixth ($5/3 = 884$ cent).

One should bear in mind that Helmholtz based his observations and conclusions on spectral features and

place analysis rather than on *period* and temporal analysis. While much of the earlier discussions of roughness and dissonance were concerned with spectral structures in regard to *disturbances* or *friction* between narrowly spaced partials on the BM level, there was a shift towards temporal features later on [31.272, 273]. Among the reasons is that, taking the model of the BM as a chain of parallel bandpass filters [31.259], one can argue several narrowly spaced spectral components can be expected to result in one AM signal at the output of each AF. Another aspect is that temporal models usually are phase sensitive. Moreover, signals that give rise to a sensation of roughness can be synthesized in a straightforward manner according to the basic formula

$$y(t) = (A + a \sin [2\pi f_M t]) \sin [2\pi f_T t] ,$$

where A is the mean of the amplitude and a/A is the modulation factor. Applying trigonometric rules, this formula becomes

$$\begin{aligned} y(t) = {} & A \sin [2\pi f_T t] \\ & + \frac{a}{2} \cos [2\pi \, (f_T - f_M) \, t] \\ & - \frac{a}{2} \cos [2\pi \, (f_T + f_M) \, t] . \end{aligned}$$

Hence, the AM signal consists of the carrier at frequency f_T and two sidebands at frequencies $(f_T - f_M)$ and $(f_T + f_M)$. Various AM signals can be generated by manipulating f_T and f_M as well as their amplitudes. As a reference for AM-induced roughness, a signal with $f_T = 1000\,\text{Hz}$ and a modulation frequency $f_M = 70\,\text{Hz}$ played back to observers at 70 dB SPL has been defined as *1 asper* (in Latin *asper* = rough). Taking modulation depth and SPL of (artificial) signals as parameters relevant for roughness sensation into account, it has been suggested that, on the asper scale, about 20 roughness steps could be distinguished [31.12, Chap. 11].

The spectral and the temporal approach to roughness sensation might be regarded as equivalent since both superposition of sinusoidals and AM should result in identical stimulus spectra and temporal envelopes. However, in regard to sensation, to make a sine tone carrier sinusoidally amplitude-modulated at a rate of 40 Hz and two sinusoidal components beating at 40 Hz appear equal in roughness, the modulation factor in the AM signal needs to be set to 0.6 or 0.7, for a wide range of AM carrier frequencies and mean frequencies of the tone pair respectively [31.274, p. 207]. The reason is the temporal envelopes of the two signals are not identical. In music, one typically has to deal with complex spectra where roughness primarily arises from interferences between neighboring spectral components due to dissonant sonorities and/or sounds from idiophones that are clearly inharmonic. A good case to illustrate the problem of roughness from concurrent dissonant sonorities is singing styles of the Balkans where two voices are often singing at an interval smaller than a whole tone, and sometimes two voices go in parallel at a frequency distance of only $\approx 50{-}80$ cent [31.268, 275]. A musical tradition where inharmonicity from idiophones comes into play is carillon music of the Low Countries where frequently pieces written in a major tonality are played on a carillon comprising minor-third bells. Concords (two or even three bells sounding at once) thereby result in marked roughness, besides ambiguity of pitches (the two effects combine perceptually [31.249, 251, 252]). In musical sound analysis, it is essential to take spectral structure into account for modeling roughness [31.276]. In our own experiments, when a range of synthesized stimuli was fed into either computer models based in the time domain or into a (preliminary) model based in the frequency domain making use of an algorithm proposed by *Sethares* [31.277, 278] that in turn takes into account roughness profiles from *Plomp* and *Levelt* [31.279], it was found that the frequency-based model was much more in agreement with behavioral data obtained for the same stimuli [31.268]. Since AF characteristics, in the first *place*, determine to which degree spectral components can be either *resolved* or interfere with each other [31.7, 263, 264], spectral characteristics of signals have to be considered as much as temporal parameters in evaluating roughness phenomena [31.11, Chap. 10.2].

31.6.3 *Residue, Virtual Pitch,* Combination Tones

As has been exposed in Sect. 31.1.1, *Seebeck* [31.22] discussed the phenomenon of the *missing fundamental* (MF), at least as a hypothesis. It was known among organ builders and organists for a long time that two pipes of 16′ and $10\frac{2}{3}'$ length respectively, when sounded together would produce a pitch one octave below the 16′ pipe. Since 16 and $10\frac{2}{3}$ form the ratio 3 : 2 (regarding pipe length) and 2 : 3 in regard to fundamental frequencies (a fifth), the pitch resulting from the combination is the *root* of the series: (1) : 2 : 3. Of the three pitch components, two are real and one is *virtual*. The phenomenon known as *acoustic bass* has been explained either as a difference tone (f_2–f_1 [31.52, p. 59 f.]) or as a *virtual pitch* ([31.11] demonstration 27 on CD accompanying the book). In fact, two organ pipes tuned to A_1 ($f_1 \approx 54.8\,\text{Hz}$) and E_2 ($f_1 \approx 82.3\,\text{Hz}$) respectively, when sounded together generate a pitch that, in an AC-based analysis, is an A_0 at 27.4 Hz (Fig. 31.13). To be

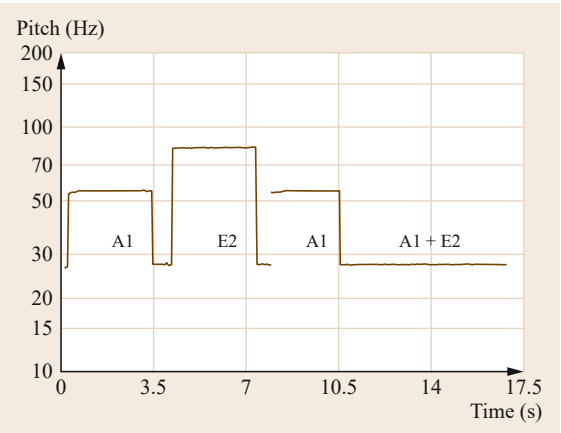

Fig. 31.13 Acoustic bass on pipe organ: A_0 generated from $A_1 + E_2$ played together

sure, such a low pitch, to be produced by one pipe alone, would require a 32′ pipe tuned to A_0.

Further evidence that f_1 of a harmonic complex may not be the sole cue for pitch sensations was found when electric filtering of musical tones demonstrated that, in bowed strings, the fundamental is relatively weak in the spectrum of the lowest tone [31.280]. Notwithstanding this weak f_1 component, the pitch of the bowed violin g-string is registered, by listeners, as G_3. *Schouten* [31.24, 32, 33] developed the concept of the MF to account for a range of sounds and perceptual pitch effects such as the *strike note* of bells. Schouten provided further evidence for a dual mechanism of pitch perception, one making use of f_1 while the *residue* evokes the same *low* pitch at f_0 as conveyed by f_1. *Schouten* [31.24, p. 360] described the residue *as one component with a pitch determined by the periodicity of the collective waveform*, namely, that of higher partials of a harmonic spectrum from which f_1 and possibly several low partials have been removed. According to Schouten's mechanical resonator model (as an analogue for BM filters [31.32, Fig. 9]), groups of successive harmonics will result in excitation patterns that, though different in shape, all represent the same fundamental period (in Schouten's experiments, the period was $T = 5$ ms of a pulse train evoking a pitch of $1/T = 200$ Hz). Experiments later demonstrated that, to evoke residue pitches, a rather small number of lower partials gain *dominance* against a large number of higher partials (if such are present [31.16, 281]). For example, to generate a *residue pitch* at $f_0 =$ 200 Hz, partials from 600 to 1400 Hz (partial nos. 3, 4, 5, 6, 7) appear *dominant* against all higher partials. To be sure, most of these partials can be resolved individually at the BM/CP filter level, which indicates there is *place* information available (Sect. 31.3) besides common periodicity. However, a residue pitch at $f_0 = 200$ Hz might as well be generated from harmonic partials of numbers 15–20 (at 3000–4000 Hz) even though such a sound cannot be resolved into its spectral constituents at given AF/CB characteristics. Moreover, since this sound (partials 15–20 of equal amplitude) carries all the energy in a rather high frequency range, the timbre now is quite *sharp* (Chap. 32) and the pitch is less salient than that of f_0 evoked from low partials. However, even with harmonic complexes consisting of high partials it is still possible to play simple melodic patterns that can be identified, above chance level, by listeners [31.3, 282, 283]. In regard to different distributions of low partials that are resolvable individually by cochlear filtering versus groups of higher partials not resolvable into constituents, there have been considerations whether both phenomena might be operating on the same neural mechanism [31.283].

It is astounding that pairs of successive partials presented at a suitable level and even fed into opposite ears are sufficient to evoke a pitch sensation corresponding to f_0 [31.186]. Also, one can identify melodies played with harmonic complexes in which, for each tone, a different set of partials is used. Since these partials do not include f_1, the melody one perceives consists of a sequence of *residue pitches* [31.11, 83]. Two possible explanations for dichotic residue pitch (one of a pair of successive partials fed into each ear) have been discussed: (1) pitch is derived from the temporal information, which, in the case of two (peripherally resolved) partials presented in dichotic listening, would need a *central* periodicity extraction circuit that combines the periodicities from two ears (probably on the level of the IC; see Fig. 31.2); (2) pitch is derived from a *central spectrum* combining the BM/AN place information into a cochleotopic map (probably on the cortical level) from where a final pitch percept emerges in a harmonic template matching process. In both cases, pitch is derived from a *central* mechanism capable of inferring the *missing fundamental* frequency f_0 from those harmonic components that are present either as *place* or as *time* information. The precision and reliability of the pitch estimate of course are dependent on the temporal and spectral structure of the sounds used as stimuli. *Schouten* [31.24, 32, 33] considered the *strike note* of bells as a possible case of residue pitch. The *strike note* is a virtual pitch brought about by the combined effect of several spectral components that come close to harmonic frequency ratios. Since bell spectra are often quite complex with respect to the number and spacing of components, more than one strike note might become audible as a residue pitch (for empirical data [31.284]) or, in Terhardt's model, as *virtual* pitches [31.228, 230]. Also, a strike note can

be perceived in addition to a low spectral pitch. Quite often, the strike note differs slightly in pitch from the prime, the second strong partial in a typical minor-third bell [31.284, 285]. Another spectral pitch usually well audible is the minor third which, as a strong component in most bells [31.252], *stands out* against the quasiharmonic series formed by those components that give rise to the strike note. As a result of several spectral pitch cues perceived separately from the strike note as a virtual pitch, subjects find that most bell sounds are ambiguous as to pitch when heard individually. However, in a sequence of such sounds, musically trained subjects can judge the interval between a pair of bells, for instance, by singing or humming the interval they believe to be represented by the *main* pitch in each bell [31.251, 286]. One may view pitches that the auditory system provides in particular from complex inharmonic sounds as *emergent* in the sense that such percepts are the outcome of a probabilistic estimate aiming for a *best fit* of actual spectral content against a template (as reflected in auditory models involving statistics [31.187, 189, 228, 230]). There are sounds produced from musical instruments such as Javanese and Balinese gong chimes (e.g., *bonang*, *trompong*) that, due to spectral inharmonicity and spectral density, are quite ambiguous with respect to the number and quality of pitches they tend to evoke [31.93, 248, 287]. However, even for such sounds, pitch perception rarely leads to completely unexpected or novel results but is still causally related to the input. It is rather that, in a sample of subjects listening to such sounds, individuals may pick up different cues (more or less prominent spectral components or combinations of such components) on which they base their pitch estimate.

As mentioned above, the *acoustic bass* known from pipe organs has been explained as a difference tone f_2–f_1. The phenomenon of two physically real tones resulting in the sensation of at least one more tone was described, around 1750, by Georg Andreas Sorge (a German organist, music theorist, and composer), by Jean-Baptiste Romieu (a French lawyer and scientist), by Jean Adam Serre (a painter from Génève who also published on music theory), and by Guiseppe Tartini, the well-known Italian composer and music theorist. An inspection of the relevant text paragraphs (which are assembled by Rubeli as part of a commentary in his translation of *Tartini*'s treatise [31.288, pp. 58 ff.]) shows Romieu and Serre refer to a *low third tone* (troisième son grave) that is the fundamental of two other tones forming an interval of a fifth, a fourth, etc. This *third tone* could be a virtual pitch of the residue type as well as a difference tone. *Tartini* [31.288, pp. 70 ff.] also has this *third tone* (terzo suono); after presenting his examples for two-tone intervals leading to sensation of a third tone that is a difference tone, Tartini claims that *all intervals of the harmonic series 1, 1/2, 1/3, 1/4, etc. produce the same 'third tone', namely the tone at 1/2*. Though one would expect the third tone at 1 and not at $1/2$ (the series $1, 1/2, 1/3, \ldots$ refers to intervals expressed as string lengths), what is implied is that the additional pitch evoked by intervals each consisting of two consecutive harmonics is the same and is, as Tartini emphasizes, *the physical fundamental of the harmonic system*. In this respect, it would be a virtual fundamental pitch f_0 resulting from two primaries f_m, f_n at harmonic ratios rather than a difference tone. Though both the periodicity pitch f_0 corresponding to the missing fundamental and the difference tone $f_d = f_2$–f_1 are virtual in the sense that the sound signal outside the ear does not contain energy at f_0 or f_d, they have different origins. While f_0 is a product of *central* processing ([31.186]; Sect. 31.4), difference tones, of which $D_1 = f_2$–f_1 and $D_2 = 2f_1$–f_2 are most relevant, are generated in the cochlear BM-IHC-OHC circuit due to nonlinear input–output functions of OHC; combination tones (sum and difference tones) produce traveling waves in the cochlea that have a maximum at a CF corresponding to the sum or difference of the primaries [31.98, pp. 147–150]. Hence, the quadratic difference tone D_1 and the cubic difference tone D_2 are distortion products (quadratic and cubic refer to terms in the nonlinear transfer function [31.31, 289] and [31.159, Chap. 22]). Typically, the quadratic difference tone D_1 becomes audible at medium and higher sound levels (> 50 dB). In contrast, difference tones of the type $f_1 - k(f_2 - f_1)$, $k = 1, 2, 3, \ldots$ (for $k = 1, D_2 = 2f_1 - f_2$ results) become audible already at low sound levels, but only within a limited frequency region below f_1 [31.290]. Moreover, audibility and prominence of D_2 appears markedly dependent on level and on the frequency ratio f_2/f_1 while D_1 is hardly affected by level above threshold as well as the f_2/f_1 ratio (test sounds are included in *Houtsma* et al. [31.83], demonstration 34). Combination tones that are sums of primaries are difficult to hear. If the primaries are harmonic complex tones, sums can be easily masked by partials of the primaries.

Combination tones (sum and difference tones) and the role they may have in regard to pitch and consonance were an issue in many publications of the 19th and early 20th century (for a historical review see [31.291]). Exploring perception of combination tones, *Stumpf* [31.292] concluded that, for pairs of (almost) pure tones one of which is fixed in frequency while the other goes slowly up over the range of two octaves, only a few combinations are of relevance, namely f_2–f_1 (D_1), $f_2 + f_1$, $2f_1$–f_2 (D_2), $2f_2$–f_1 and, already to a lesser degree, $3f_1$-$2f_2$ and $3f_2$–$2f_1$. He condensed his observations into a scheme [31.292, p. 135, Fig. 13];

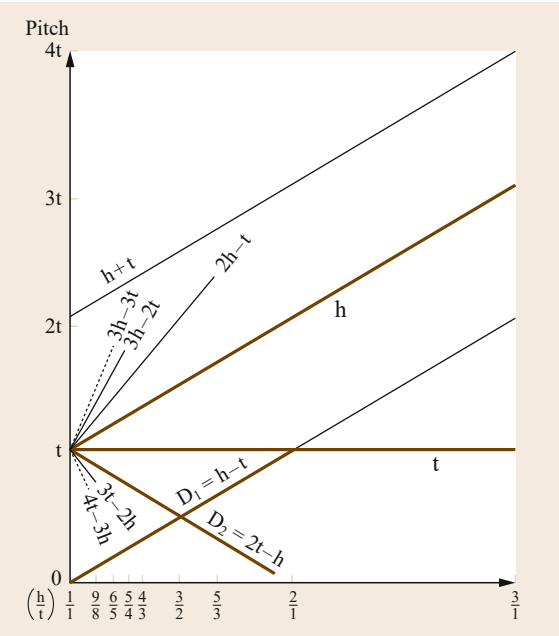

Fig. 31.14 Combination tones as explored by *Stumpf* [31.292]. Inside the coordinate system, h and t refer to high and low tone (of a pair of pure tones). On the ordinate, 0, t, 2t, 3t, 4t indicate the frequency relative to the low tone, t (constant in frequency). The abscissa gives the ratio of the two tones in musical intervals (from the unison 1/1 to the octave 2/1 and the 12th 3/1) ◀

that shows that the main effects of combination tones occur within the first octave, and rarely beyond the range of a twelfth (Fig. 31.14).

A scheme similar to Stumpf's can be found in more recent publications on psychophysics [31.293]. Hearing D_2 and possibly also D_1 is a condition that Tartini and other violinists, playing their instruments quite close to their ears, could have realized. Though combination tones are known to result from cochlear nonlinearities [31.98, 289], [31.31, Chap. 2], musicians and even Helmholtz have pondered the possibility of combination tones arising also from the acoustics of certain instruments. There are some indications that, when a harmonic interval such as a fifth or fourth is played as a double stop on a cello, relatively weak components can be detected in the spectrum corresponding to a frequency that is the difference of the two fundamentals; if these components ($f_2 - f_1$ and its multiples) are amplified and added to the original cello sound, they can provide a *third voice* to a two-part cello piece performed on stage (for details [31.294]).

31.6.4 Fusion, *Verschmelzung*, Consonance

One of the fundamental experiences of musical sound is that of several pure and/or complex tones presented simultaneously. A multiplicity of sounds emanating from one source or from several sources in regard to vibrational patterns and resulting sound structure either blend well or rather dissociate; the degree to which sounds *fit together* depends primarily on acoustic parameters such as frequency ratios and phase relationships [31.93, 159]. In regard to listeners, mixtures of sounds can give rise to sensations of roughness or beats on the one hand, which have been identified as characteristic of dissonance (Sect. 31.6.2); on the other, sounds blending well lead to a stable temporal (periodicity) and spectral (harmonicity) patterns in the auditory system, which are fundamental for a perceptual quality known as *consonance*. According to a definition given by Boethius (around the year 500) in his *De institutione musica* (Lib. I, 8, ed. Friedlein), consonance is the mixture of a high and a low tone that arrive at the ears pleasantly and uniformly. This experience was known already to Greek theorists (for source material see [31.295, 296]) experimenting with concords on string instruments. Ptolemaios, writing in the second century, grouped tones into three classes labeled homophonic, symphonic, and emmelic. Homophonic, he says (harm. Lib. I, 4, 7, ed. Düring [31.297]), are the octave and the double octave since two tones at these intervals give the impression of one tone, which implies hearing the intervals as simultaneities. Symphonic are the fifth and fourth as well as their extensions into higher octaves. Emmelic are those tones which, presented side by side (perhaps in succession, as melodic steps) are found pleasing to the ear (pairs that don't are considered ekmelic). Several Greek theorists use the term *krasis* (κρασις [31.295]) which can be translated as mixture, to denote the specific quality of consonance.

Stumpf, in his theory of consonance, adopted from Greek music theorists the aspect that two tones presented simultaneously at distinct intervals can blend to the extent that listeners take them for one. However, Stumpf's theory of *Verschmelzung* includes a range of additional considerations in regard to possible causes and psychological effects of consonance. Translating the German term *Verschmelzung* as used by *Stumpf* [31.40, 298, 299] into *fusion* tends to narrow the concept, which was intended to implement a psychological theory of consonance expanding the psychoacoustic approach taken by Helmholtz. According to *Helmholtz* [31.28, Sect. 10], a sensation of consonance results from such intervals of complex harmonic tones that have partials in common. For intervals in just intonation (JI), partial frequencies coincide due to small integer frequency ratios as are realized, in a perfect

match, for the octave (2 : 1), double octave (4 : 1), and the twelfth (3 : 1) as well as nearly so for the fifth (3 : 2). For Helmholtz, consonance requires hearing two concurrent harmonic complexes free from beats. Since the relative amount of beats and, correspondingly, sensation of roughness increases with harmonic ratio (being somewhat greater in 6 : 5 than in 5 : 4, and markedly so in 9 : 8 as compared to 5 : 4) as well as with tuning away from just intervals (as in ET), scaling of intervals on a dimension consonance–dissonance can be executed, by listeners, based on their sensation of beats and roughness either being absent or present to varying degrees. *Helmholtz* [31.28, p. 291] gave the following order due to coincidences of partials:

1. Octave 1 : 2
2. Twelfth 1 : 3
3. Fifth 2 : 3
4. Fourth 3 : 4
5. Major Sixth 3 : 5
6. Major Third 4 : 5
7. Minor Third 5 : 6.

According to Helmholtz's classification, octave, twelfth and double octave constitute *absolute consonances*, fifth and fourth are *perfect consonances* (as in Greek and medieval music theory), major sixth and major third are *medium consonances*, and minor third and minor sixth (5 : 8) are regarded *imperfect consonances*. Helmholtz acknowledged that the natural minor seventh 4 : 7 also bears to a consonant sensation, often more so than the minor sixth.

Stumpf [31.40, 298, 299] challenged the explanation of consonance offered by Helmholtz as being both incomplete and not free from errors. First, he argued that consonance or dissonance is experienced also for pairs of pure tones (as well as for certain chords made up of pure tones) where coinciding or beating partials do not come into play. Hence, the criterion of coinciding or beating higher partials does not hold for such cases, and cannot be the decisive basis for either consonance or dissonance perception. Second, Stumpf insisted that consonance and dissonance are also registered if two tones forming an interval are presented dichotically (one tone to each ear) so that there is no interaction of partials on the BM level, leaving consonance and dissonance for a *central* analysis stage. Third, with the decisive processing moved away from the inner ear to the brain, Stumpf stated consonance and dissonance are psychological experiences that have a quality of their own. Even if sensation of consonance and dissonance relate to acoustic features (such as patterns of spectral partials), these are merely foundations for the perceptual experience that, in regard to consonance, is peculiar with respect to *Verschmelzung*, a concept that, most of all, refers to the relations several tones can have in acts of perceiving.

Stumpf saw sensation, perception, and cognition combined into a hierarchical processing that leads from sensory input to apperception, the latter focusing on relational structures between individual elements as well as complexes of elements [31.300]. In his *Tonpsychologie* [31.39, 40] as well as in other works, Stumpf elaborated on parameters and criteria governing perception, which almost always includes judgments with respect to the structural composition of sound and music stimuli. One particular judgment aims at the appearance of a multiplicity of elements in pairs of sounds forming musical intervals. If such pairs give rise to a percept that implies structural unity and coherence, the elements tend to be integrated in perception into a Gestalt-like configuration. The corresponding experience is what *Stumpf* [31.40, pp. 65 ff., 128 ff.], [31.298] labeled *Verschmelzung* (for a detailed account of the concept see [31.301]). Though Verschmelzung is a scalable perceptual quality [31.40, 298, 302], it is not simply that of *fusion* since the elements making up an interval or chord remain to be noticed individually, in analytic listening, and they may be perceived as interpenetrating each other (*Stumpf* [31.303, p. 261] himself regarded *Verschmelzung* as *Durchdringung* = interpenetration of several constituents). Correspondingly, the *whole* resulting from a combination of (two or more) pure or complex tones is not unstructured as a sum yet is perceived as a coherent configuration of elements (such as in a geometrical figure or in a crystal lattice). Stumpf considered such structures that can be apprehended by musically skilled listeners as a *unity of relations* (German: *Verhältnisganzes*). Hence, even though *Verschmelzung* is experienced instantly and immediately (in holistic listening), subjects become fully aware of the elements blending into *Verschmelzung* through analytical listening and cognitive assessment (apperception, apprehension) of what has been perceived. To experience consonance of pairs of tones, chords, or more complex sonorities, subjects may be switching back and forth between analytic and holistic modes of listening. Holistic listening thereby should provide a salient percept of parts matching perfectly while the analytic mode leads to recognition of the individual parts and their relational structure within a coherent configuration. *Stumpf* [31.299, p. 394] offered a striking example of an *ideal concord* (*Zusammenklang*) consisting of five perfect major triads (4 : 5 : 6) played simultaneously at root frequencies of 100, 200, 400, 800 and 1600 Hz respectively. If synthesized from 15 pure tones, the waveshape plotted in Fig. 31.15 results.

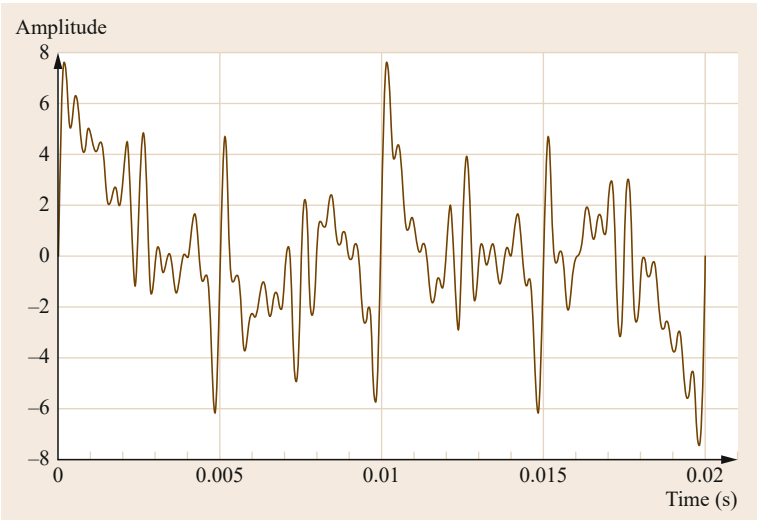

Fig. 31.15 Stumpf's *ideal concord* (5×3 harmonic components = five just triads)

As an inspection of the waveshape reveals, the main period is at 10 ms, and a second period at 5 ms. In an ACF analysis, in addition to these two candidates for periodicity pitches (reinforcing spectral pitches), a number of subharmonics below 100 Hz are detected. Listening to Stumpf's concord, one can try to identify its constituents as well as attend to the mixture or *fusion* of the 15 components which, to be sure, are not partials within a single harmonic series. For maximum fusion of partials, one can generate symmetric pulse-type sounds [31.301] that comprise very many harmonics covering the frequency range from 100–200 Hz up to 22–25 kHz. Such sounds lead to a maximum sensation of consonance since dozens of harmonics *fuse* or blend into another (in holistic listening). It is of musical interest that, in Baroque organs in particular of northern Germany, organ builders created various reed stops where the reed mechanism produces pulse sequences that excite up to, and even above, a hundred harmonics per tone played (the absolute number depending on the type of reed generator, the geometry of the resonator, and on register [31.304]). Reed stops as well as mixture stops in which also very many harmonics are audible for each tone played (in northern Germany, a stop known as *Terzzimbel* offering pure major thirds besides fifths and octaves was much in use) convey the experience of *Verschmelzung* to everyone listening.

As these examples demonstrate, consonance, experienced as *Verschmelzung*, does have an objective basis in the sound structure as well as in auditory processing. Sounds containing many harmonic components can be combined into chords, which in JI yield structures that again account for maximum periodicity and harmonicity in the signal as well as in peripheral auditory analysis [31.250, 301, 305, 306]; for audio demonstrations see [31.307]. In this regard, perceiving consonance is a natural phenomenon [31.26] and not something learned in the course of life (as has been suggested from a behaviorist perspective). Considering objective bases of consonance, various theories of consonance focusing on different aspects can be integrated into one. The criterion emphasized by *Helmholtz* [31.28], namely coincidence of harmonic partials and presence or absence of beats, is certainly of relevance since subjects according to some studies [31.308] prefer just intervals and, as explored in other investigations [31.309, 310], tend to accept tempered intervals within a range where the beating is not annoying. Taking into account that, in music, complex harmonic tones are predominant, it can be said that consonance of two or several such tones is maximum if these are strictly periodic in their waveshape, implying perfect harmonic spectra. If several such tones with their f_1 at small integer ratios and spectral envelopes composed like $A_n = 1/n$ (n = harmonic number) are combined phase-locked (onsets are identical) into a major chord, one will observe coincidence of partials, the criterion emphasized by *Helmholtz* [31.28] as well as by *Stumpf* [31.299]. Underpinning the same criterion, *Husmann* [31.311] reported that perception of consonance remains when pairs of harmonic complex tones are presented dichotically, presuming a *central spectrum* representation to process coinciding partials. When two or more harmonic complexes (with partials phase-locked) tuned to JI are presented diotically, strictly periodic excitation patterns are likely to occur on the level of the BM/CP and the AN. It is hardly surprising to find periodic input yields periodic excitation and neural responses [31.225, 312]. The criterion of converging pulse patterns to account for consonance had been introduced as a hypothesis in 19th century works

on music theory and psychology [31.313, 314]. In addition, harmonic complexes presented at intervals with small integer frequency ratios would be the condition suited for combination tones to occur even if these might be of minor importance. Moreover, chord structures in JI are suited to generate virtual pitches, one of which is clearly marked as the *root* of the chord (in the sense of Rameau's *basse fondamentale* [31.305]). In sum, there are several concurrent factors relevant for sensation and perception of consonance suited to demonstrate that consonance basically is a natural phenomenon. It relates closely to periodicity and harmonicity, two elementary principles found governing structures and processes in almost all areas of nature [31.315]. In regard to signal and systems theory as well as acoustics, these principles are at the core of the Wiener–Khintchine theorem (Sect. 30.2), which in turn can be used to model pitch perception as well as sensation of consonance. As a matter of fact, three harmonic complexes (each comprising the first seven harmonics) combined so as to realize a major chord 4 : 5 : 6 in JI are enough to give rise to maximum *fusion* and the most salient pitch configuration possible [31.250]; for similar considerations see [31.316]. To be sure, the principle of harmonicity as expressed by small integer ratios that govern spectral partial structures as well as formation of chords has nothing to do with *number mysticism* (the well-known phrase put forward by behaviorists to denounce *natural causes* relevant for music perception). The two principles fundamental to science, namely counting and measuring [31.317], can help to understand also sound and music (for applications see [31.159, 318, 319]). Stating a nativist theory of consonance does not imply that *harmony* in music can be, or should be, completely naturalized (rather, it needs to be given natural foundations). However, taking the interdependence of acoustics, psychoacoustics and musical structures into account, it makes sense to realize chords in music in appropriate tuning and spectral structure so that, for instance, chords intended to be perceived as consonant can be transformed into musical sound with maximum spectral harmonicity while minimizing roughness and beats ([31.318] with audio examples on CD). Conversely, dissonant sonorities thus can be realized with appropriate fine tuning of pitches and spectra. In this respect, a close correspondence between musical structure, actual sound profile and perceptual qualities will be established.

31.7 Categorical Pitch Perception, Relative and Absolute Pitch

In the course of Chap. 30, the difference between discriminable and identifiable stimuli (or stimulus features) has been stressed (Sect. 30.1.4). It is a distinction that was of prime importance in debates concerning *continuous* versus *categorical* perception that became an issue, most of all, in linguistics and phonetics where it was discussed in regard to phoneme boundaries (for background information [31.320] and [31.111, Chap. 9]). In a strong formulation, it has been stated that (emphasis theirs):

> *categorical perception refers to a mode by which stimuli are responded to, and can only be responded to, in absolute terms. Successive stimuli drawn from a physical continuum are not perceived as forming a continuum, but as members of discrete categories. They are identified absolutely, that is, independently of the context in which they occur.* [31.321, p. 234]

These authors further argued that subjects can discriminate between pairs of stimuli drawn from different categories *but not between stimuli drawn from the same category*.

The doctrine of categorical perception has spun debates in many areas of research (for an overview see [31.320] and a range of articles in [31.322]) including music psychology where it was discussed in conjunction with other concepts relating to tone systems, scales, and in particular intonation. An analysis of relevant publications reveals there are some obvious misconceptions in regard to theoretical and factual issues, which need some clarification. This concerns, first of all, the terms *category* and *categorization*.

The term *category* is often used synonymously with *class*, meaning that a number of n objects are sorted into m *categories* or classes ($n \gg m$) according to certain features or properties. This, however is just a description of a process that can be quite mechanical (like sorting many things into a few drawers) while *category* has a more profound meaning in areas like epistemology and ontology as well as in mathematics and linguistics. In regard to subjects building up coherent experience, *categorization* and *classification* involve judgments [31.323] even though these can be executed in a more or less *automated* manner [31.324, Chap. 2]; also [31.325, pp. 46 ff.]. Such judgments may pertain to, for example, segmentation of quasicontinuous sound streams we perceive (as in speech or music) into *units* that have a syntactic function and/or semantic meaning [31.111]. Segmentation processes involve sensation

and perception as one hears a speech or musical sound that is then analyzed as an acoustical signal, mainly so in bottom-up processing; however, segmentation of sound streams is more than finding transitory and quasistationary sections since subjects make use of their previous experience and recall both meaningful *units* (elements that are of relevance with respect to phonology, prosody, grammar, syntax, semantics) as well as rules of how such units should be connected sequentially or (regarding music) simultaneously. Cognitive processing of both speech and music involves memory and is achieved, in the main, in a top-down approach. The sensory-driven part and the cognitive part are combined in a complex processing model described in detail as *auditory scene analysis* [31.326].

Categorical perception in this respect involves sensory-driven analysis of acoustical signals combined with judgments pertaining to identification of *units* as well as an assessment of how they relate to other elements that occur within a given structure and context. Such assessments can be facilitated by referring to prototypes [31.324, 327] or by activating certain schemata that may be innate or may have been acquired in processes of learning [31.328–330]. However, in a quasi real-time process such as listening to music the rate of information available to listeners per time unit can be very high, to the effect that perceptual and cognitive processing is very demanding even for subjects with musical training. It has been calculated that, for example in Ligeti's *Atmosphères*, perceiving all of the very short notes distributed over many instruments in the score would come close to a flow of information of 719 bit/s [31.331, p. 72], which is several times that of the capacity of the auditory channel (estimated to allow for processing of about 100 bit/s [31.332, p. 56 ff.]). Even though the concept employed by Ligeti, in *Atmosphères* as well as in other so-called micropolyphonic works was not to have listeners perceive all the individual voices individually or even the very many notes these comprise (but, rather, the resultant textures and sound fields [31.333]), perception under the constraint of real-time processing, to be achieved successfully, requires the *information load* not to exceed the channel capacity, and possibly to be reduced in suited ways. There are several concepts of how information processing in human subjects can be optimized, for example reduction of the perceptual dimensionality of stimuli, a filtering process directed at finding distinctive features in the sensory input, and selective attention and suppression of *irrelevant* information [31.111, 326, 334, 335], [31.69, Chap. 21]. Also *categorical perception*, meaning that a continuous dimension is segmented into a rather small set of discrete categories into which a broad range of stimuli might be sorted with respect to certain features, would be an effective means to reduce the perceptual load.

Both speech and music are communication modes operating in the time domain so that, to facilitate successful transmission of information, a limited set of categories both on the side of the *sender* as well as that of the *receiver* seems useful. In order to make acoustic communication like speech or similar utterances possible, meaningful units must be distinguishable and, at least in principle, identifiable. This is why phonemes are different in spectral content (and often also in modulation parameters [31.336]). Differentiating such units by their acoustic cues can be achieved not only by humans but also by other mammals [31.337]. However, boundaries between phonetic categories are to some extent flexible [31.338]. Categorization in speech apparently is very much sensitive to context and adaptive in nature (for an overview see [31.339]). A serious problem that has been tackled in computer models of speech processing is recognition of allophones, that is, of sounds that are used to express a certain phoneme in a certain language but which differ slightly in temporal and spectral fine structure when spoken by many individuals (men, women, children). Though allophones can be distinguished to some extent, they must be close enough not to introduce phonemic boundary effects and, thereby, differences in meaning. The concept of *allophone* has been taken as an analogy for intonation variants in music [31.340, 341] in regard to categorical perception, implying that the scale steps in music would be equivalent to phonemes in speech. Comparing speech to music perception, things are different in many respects notwithstanding some convergent features. In the following, some of the points raised in articles on *categorical perception* of pitch [31.340–347] will be discussed. For this reason, a few more considerations relating to sensation and its measurement (Sect. 30.1.4) need to be included.

Sensation and perception are often viewed as processing of input information whereby the input is distributed along one or several dimensions. By definition, dimensions require effective parameters to be variable continuously between a lower and an upper limit value. In regard to pitch, the single parameter taken into account in some concepts is frequency. Since frequency, as a physical quantity, can be varied continuously, stimulation of the hearing system can be assumed to be continuous (at least in principle). However, even if excitation on the BM/CP level would match this characteristic, sensation measured psychophysically as a reaction to the stimulus [31.348] is discrete because of JND and DL thresholds (Sect. 31.6.1). In this respect, the discrimination process leads to segmenting the stimulus continuum into small (yet not infinitesimally small)

steps. Stimuli that can be discriminated still may appear to be quite similar as are, for instance, two pure tones of 1000 and 1005 Hz in tone height if presented at the same SPL. *Stumpf* [31.39, 40] discussed *similarity* as a general psychological concept that subjects make use of when comparing tones as to their *height*, their perceived loudness, or when evaluating some other attribute. *Stumpf* [31.39, pp. 111 ff.] defined equality of phenomena as sensed by subjects as *extreme similarity*, whereby, for a number of complex objects to be compared, similarity can arise from (a) equal ratios among parts or elements, or from (b) equal or identical parts found in several objects. Similarities found on the level of (a) and of (b) can add up to the *similarity of the whole*. The point that is decisive here is that similarity is scalable and can be translated into geometrical distances; put the other way round, a comparison between two stimuli with respect to the sensations they bring about involves comparisons of qualities, intensities, or of temporal and spatial parameters so that similarities are conceived as distances (a high degree of similarity means a small distance [31.93, pp. 404 ff.]). Obviously, these considerations are very close to those found later in concepts of perceptual scaling of similarity, and of multidimensional scaling (MDS) in particular [31.349, Chap. 11] and [31.348, Chap. 6]. Judgments pertaining to similarity seem to be necessary for perceptual and cognitive generalizations ([31.350] and the discussion in [31.351]). Categorization based on sensory input and perceptual processing can be viewed as a necessary part of cognitive generalization and, thus, part of the ongoing process each individual undertakes to acquire coherent and systematic knowledge (for epistemological implications see [31.352–354]).

Because of cognitive generalization, subjects tend to group stimuli that are discriminable yet which appear to be similar in view of certain features or parameter settings, as belonging to the same *category*. In regard to sensing tone height and pitch perception, small changes in frequency as the (sole) physical stimulus parameter bring about sensations of tone height (as well as brightness) that are still quasicontinuous since the increments are usually close to the size of JND/DL. With such stimuli, subjects can make judgments as to the difference of two tones (e.g., the second is higher or lower than the first) without being able to estimate (let alone precisely judge) the size of the difference. Pairs of pure tones that are just discriminable in tone height and brightness will hardly be perceived as representatives of different categories but rather as variants of the same basic stimulus. Hence, differences subjects sense between two tones in *height* or in another attribute in general must exceed a certain margin large enough to be considered as introducing a new *category*, which may be taken as a difference in perceptual quality. In this respect, a growing difference in stimulus parameter values and, correspondingly, sensation can be accompanied by perceiving increasing phenomenal dissimilarity between pairs or series of stimuli. In the case where the degree of phenomenal dissimilarity perceived from comparison of pairs or series of stimuli exceeds a certain limit, a transition from one perceptual category into the next is likely to occur. Categorization, from a perceptual and cognitive perspective, aims at recognizing stimuli as *members* or as *representatives* of a certain category. For classifications in general it is assumed that the members of each class are equivalent in regard to certain features and properties notwithstanding slight differences they may have in actual parameter values. Concerning music perception, the categories relevant for pitch typically are manifest as steps on a scale (see below). In a strict view pursued in speech studies, *categorical perception* means identification of certain units (e.g., phonemes) by both recognition and labeling (imagined as mentally putting a *tag* on each item perceived).

The three levels referred to above can be related to each other thus:

1. Physical stimulus: Continuously variable (e.g., frequency in Hz)
2. Sensation: Quasicontinuous (small increments, measurable in JND/DL thresholds)
3. Perception: Discrete *categories* (each comprising a range of stimuli that differ by small increments in parameter values but are perceived as being more or less *similar* with respect to certain features or properties).

The problematic point now is that, according to the strong formulation of categorical perception [31.321, p. 234], subjects are said to be unable to discriminate between stimuli drawn from the same category. Taking, for example, the steps of a chromatic musical scale (in ET) as nonoverlapping *categories*, this would mean that, since fulfilling the classificatory criterion of *intraclass equivalence*, every tone played in a range of about ± 40 cent around the fundamental frequency of a certain scale tone (say, $A_4 = 440\,\text{Hz}$) would be a suitable representative of that scale step. In fact, such views have been issued in a number of publications, and have been mixed up, in some cases, with another concept leading to very broad interpretations of the musical scale step viewed as a *category*. The concept in question is the well-known *law of comparative judgment* proposed by *Thurstone* [31.355, 356] as an expansion of the theorems issued by Weber and by Fechner. This law states, in short, that an observer, judging the JND in intensity (or a qualitative difference) between two stimuli

in what Thurstone calls the discriminal process is not consistent on successive trials. Rather, the sensations of the observer and their judgments are viewed as intrinsically variable so as to make up a distribution of data with a mean and a standard deviation for each stimulus. Comparing two stimuli, S_1 and S_2, a number of times, the judgments one observer obtains based on his or her sensations can be considered as two random variables forming two dispersions [31.349, Chap. 8 and 9], [31.357, pp. 13 ff.], [31.358].

Aspects of categorical perception and of Thurstone's scaling model have been instrumental, often implicitly, in explaining variances observed in pitch perception and intonation. As to the former, it has been argued, for example, that pitch perception must be categorical because *pitch* would be unidimensional as a stimulus property (a function of frequency), and identification for unidimensional stimuli would be restricted to very few *categories* on a *stimulus continuum* (consisting of arbitrary frequencies). As a *proof* for such assertions, Miller's well-known *magical number* 7 ± 2 [31.359] has been quoted. As a matter of fact, such assertions are invalid on several counts. First, Miller's rule concerns unidimensional stimuli. Even if one would be willing to accept the rule, which Miller derived from a few experimental reports from the early 1950s, it could not easily be applied to pitch since pitch is neither unidimensional in regard to musically relevant stimuli nor takes perceptual attributes of pitch into account. Even with pure tones, there are several sensory attributes (tone height, brightness, also sharpness, vocality, density, volume) varying with frequency [31.40, 59, 299]. In fact, there are no unidimensional stimuli in musical contexts. As had been found in early experiments using tones varied on several dimensions (frequency, intensity, duration, etc.), the average information transmission was about six bits per stimulus [31.360], which yields $2^6 = 64$. Though the elementary stimuli and the conditions employed in these experiments fall short of musical material (like complex harmonic tones presented in a melodic phrase or chord), it is obvious that even for stimuli offering a *modicum* of variation on several dimensions the information is sufficient to identify more alternatives than implied by the 7 ± 2 rule (which itself calls for a more critical assessment [31.361]). Second, pitch outside such constructs as the *mel scale* (Sect. 30.1.4, *Loudness Scaling* ...) is not a continuous random variable. Even if two pure tones are presented so that one is fixed in frequency and the other continuously glides up or down, there are perceptual discontinuities marked by small integer frequency ratios, the most obvious of which is the octave (Sect. 31.1.2). Subjects with some musical training register not only octaves but also frequency ratios corresponding to other basic intervals (like the fifth, fourth, major third [31.40, 298, 362]. These intervals have a Gestalt-like quality and are identified perceptually if the frequency ratio is realized within certain limits. Third, in identifying such intervals, acoustic cues (consonance and *fusion* versus roughness and beating) come into play [31.308, 310]; though these cues are predominantly effective in tone pairs presented simultaneously, judgments on successive intervals can draw on perceptual information available in STM [31.218] when comparing tonal relations as well as on schemata or templates stored in LTM [31.328–330].

It should be clear, from what has been discussed so far, that perception of pitch in fact is categorical in that the most fundamental musical intervals function as categories; however, these must be viewed taking acoustical properties as well as perceptual categorization and cognitive structuring of tonal relations into account and not as mere *baskets* of classification. The concept of *pitch class*, well known from theoretical works on 12-tone and serial music, in this respect is problematic since it openly or implicitly equates musical pitches with the keys of a piano tuned to ET12 so that there are but 88 pitches falling into 12 classes, octave registers and enharmonic spellings being ignored. This, to be sure, is a rather crude simplification that does not reflect interval recognition capabilities and apprehension of chord progressions of subjects experienced in performing and listening to tonal music.

Assuming categorical perception of pitch would be restricted to sorting tones as one hears or produces in, for example, singing or playing a violin, into 12 *pitch classes*, one would in fact expect 12 *frequency baskets* of equal extent, namely 100 cent each, little (if any) overlap at the boundaries and a more or less flat (platykurtic) distribution of data within each ET12 *pitch class*. In a simple graph, the distribution of pitches produced and/or perceived, for three consecutive classes, would look like Fig. 31.16.

Dispersions in this model have the same shape (reflecting the 12-tone gospel that all chromatic tones are of *equal importance*), and there is an equal likelihood for pitches falling into the frequency range under the flat part of each class while there are also equal boundary transitions between adjacent classes (implying the psychometric function would be equal for all pitch classes and boundaries also).

However, data from both intonation analyses of tonal music and experiments on perception and production of musical intervals reveal that this model does not apply. First of all, the *pitch categories* that are actually used in sequential listening or melodic execution of intervals are not of equal size but vary with the structural weight of tones in a scale. In experiments, categori-

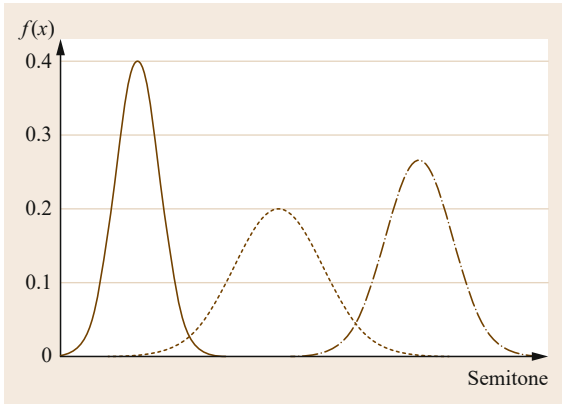

Fig. 31.17 Scale steps and *pitch categories* for three semitones viewed as PDF

cal identification of intervals yields curves of different width and smoothness, reflecting that some scale steps and melodic intervals are structurally more stable than others [31.340, p. 64, Fig. 4]. The same picture emerges in measurement of intonation where the range for structural important intervals such as the fourth, fifth, and octave in general is significantly smaller than for notes falling in between. For example, in a detailed study of professional violinists playing the Theme and Variation X from Paganini's Cappricio No. 24 in a-minor, *Janina Fyk* [31.92, Chap. 8, p. 185] found relatively small dispersions of about 25–30 cent for the perfect fifth, the minor sixth, major sixth and the octave for variation X (played at a slower tempo than the theme) while the dispersion for the major third and the perfect fourth were 39 and 40 cent, and the minor second and major second had 53 and 60 cent respectively. It is also of interest to note that, in various experiments, subjects distinguished between the augmented fourth and the diminished fifth [31.363, p. 133], [31.90, 91, 341]. The pitch difference between these intervals is ≈ 22 cent in both JI and Pythagorean systems (though in opposite direction!).

Taking differences of scale steps and intervals in regard to structural importance and actual dispersion data from perception and intonation measurements into account, an adequate model of *pitch categories* could be devised in terms of probability density functions (PDF) where stable categories (i. e., scale steps serving as perceptual and cognitive anchor points like prime, fourth, fifth) gain narrow (leptokurtic) dispersions, and those in between wider dispersions. In this way, Fig. 31.17 may be viewed as representing, for instance, the first three semitones of a scale (e.g., c–c#–d).

By the way, this model conforms to theory and practice of music in cultures where scales and modes are fundamental structures (as in Greek, Persian, Arab, Indian, and Turkish traditions). Typically, there are structurally important tones in scales framing intervals (octave, fourth, fifth) that can be filled with additional tones in a range of modal structures that in turn request certain intonation patterns (for theoretical background, examples, and empirical data from measurements see [31.52, 364–372]). The concept of *fixed* and *movable* tones in scales and modes is common to ancient Greek, Near Eastern, and Indian music traditions. One has to remember that stable tones corresponding to fundamental intervals within scales and modes of course have a melodic function but must be viewed also regarding types of drone accompaniment widely in use (the drone must not always be audible as sound but is implied in the performance of singers and solo melodic instruments as a referent). In *Western* theory and practice, tones besides melodic steps constitute harmonic relations even for tones played in succession; sensation and perception of consonance inevitably come into play since the STM *buffer* for pitches of tonal sequences is at least several seconds wide [31.218, 373].

Consonance is an important aspect that explains why different intonation patterns are not equivalent in realizing the same interval category. The quality of simultaneous intervals executed in music for musicians and listeners with musical training apparently depends on two factors, one being related to sensation of beating and roughness versus *fusion* and smoothness of partials in two or more complex tones, the other with an estimate of the size of the distance between tones [31.308–310]. The range within which intervals are judged as acceptable in most cases is ≈ 15–20 cent above and below the just ratio (like 3 : 2 or 5 : 4) while deviations greater than this range are perceived as mistuning [31.374, pp. 100 ff.]. We found in experiments where cadences were played in different tunings (Vallotti and Young, ET, JI, Meantone, Pythagorean) to

samples of students significant differences in ratings of intonation quality and of consonance [31.375, 376]. In particular, Vallotti and Young tuning received much higher ratings than tuning chords to the Pythagorean scale which, of course, was conceived for *melodic* execution as in the Dorian mode of ancient Greek music. Greek Dorian contains two whole tones $9/8 \approx 204$ cent and a *leimma* (Greek: *remainder*) of $256/243 \approx 90$ cent in each tetrachord; these are joined by another whole tone $9/8$ [31.52, pp. 183 ff.]. A melodic C-major scale derived from a chain of fifths [31.72], like $f-c-g-d-a-e-b \rightarrow c-d-e-f-g-a-b$, contains the same intervals as the Dorian mode and can, therefore, be played in a Pythagorean tuning (as in fact was observed by [31.89]; the violinists he investigated playing C-major scales came fairly close to Pythagorean tuning). However, for simultaneous intervals and chords, Pythagorean pitches are not recommendable since the major third of $81/64 \approx 408$ cent gives rise to beating while the major third in Vallotti and Young is close to 392 cent (about 6 cent wider than the just major third $5/4$) and quite *smooth* in regard to consonance. Since the difference between the major thirds in Vallotti and Young versus Pythagorean tuning is ≈ 15.5 cent, this gives a measure of the sensitivity subjects have for the consonance of major thirds in chords. For skilled performers, adjusting pitches within long held chords is common practice as has been demonstrated for barbershop [31.377] and madrigal ensembles [31.378], [31.305, pp. 66–67]; in an intonation test performed with two barbershop ensembles singing cadences, in the dominant seventh chord they produced almost the *natural seventh* $7/4$ (with, on average, 977 cent). In madrigal singing, one often finds frequency ratios in long held chords coming close to JI values [31.378]. Subtle adjustments and distinctions can be observed also in solo violin playing. Following observations according to which expert listeners were able to distinguish an augmented fourth and a diminished fifth with respect to correct intonation [31.341], *Fyk* [31.92, pp. 96 ff.] had two professional violinists play two four-tone melodic phrases, (1) $f_4-b_4-c_5-e_4$ and (2) $f\#_4-c_5-b_4-g_4$ with and without vibrato. The first melody can be conceived as a sequence IV–VII–VIII–III in C while the second is viewed as VII–IV–III–I in G. The intervals to be played then are (1) an augmented fourth and a minor second upwards, followed by a minor sixth downwards and (2) a diminished fifth upwards followed by a minor second and a major third downward. The intervals in cents averaged over many trials for both conditions show distinctive deviations from ET and also from JI and Pythagorean tuning as well as fair to close approximations to pitches (expressed as fundamental frequencies of complex harmonic tones as were recorded from the violins) defined by one or several of these tuning systems. It seems that violinists relate to several criteria guiding their intonation of intervals in melodic sequences, among them being tonal function of the tones within a scale and/or tonality, direction of interval (upward, downward), harmonic tension and leading note, expressive (vibrato) or straight intonation. Some of the pitches expressing basic intervals are more stable than others when measured over several trials; the range in such cases is small, and typically within $\approx$ 10–20 cent [31.92, pp. 110 ff.], [31.89]. Recent observations from professional violinists showed their pitch adjustment to tones modified in fundamental frequency is within a very small range ($2 < \mathrm{df} < 7$ cent), and includes adjustments performed even when the change of the stimulus frequency was below the perceptual threshold, suggesting an automated motor response probably independent from conscious perception [31.379].

The Russian musicologist *Nikolai A. Garbuzow* studied relative and absolute pitch and conducted many pitch and intonation measurements in the 1940s and 1950s (published in articles and monographs collected in [31.344]). From his observations and measurements, which covered not just pitch and intonation but also loudness, tempo, and rhythm, he came to propose that human hearing in general is of a *zonal nature* [31.344, 380]. In regard to intonation (in particular, of violinists) he found a considerable range of deviations from tuning systems (ET, JI, Pythagorean), however, many of the actual pitches played relate to the melodic and interval structure of the works he had selected as well as to phrasing and expression chosen by the musicians studied. Garbuzow also found that subjects were able to distinguish between several *shadings* or small steps within a *tonal zone*. In this regard, pitch is not so much a random variable (in the sense of a Thurstonian or similar scaling model) than it is a choice among reasonable alternatives. In a musical context, professional musicians *can* distinguish sharp from flat within pitch categories. Hence, a tonal zone should not be mistaken for a *pitch class* within which all selections would be *equally appropriate* for performers and listeners due to an assumption of intraclass equivalence of pitch realizations. Evidently, the difference between an augmented fourth and a diminished fifth matters to musically trained subjects [31.363, pp. 129 ff.] even though on a piano tuned to ET12 this would be the same *pitch class* (6HT). Optimal sizes and admissible ranges of intervals in intonation for musicians who control their performance by ear and are not specifically guided to realize intervals relative to a certain tone system and tuning depends, as empirical data indicate, much on musical context and expressive execution. In this respect, intonation is variable, yet not arbitrary, within

pitch categories. In terms of phonology, one might view different intonations within pitch categories as *allophones* [31.341] or, in regard to tonal languages, as *allotones*. However, the concept of categorical perception as developed in speech and language studies at least in the strong version [31.321] cannot be readily applied to music and, moreover, has been challenged by findings that showed discrimination as predicted by this theory might hold for stopped consonants but does not apply to vowels [31.381]. Sure enough, pitch as a perceptual quality and parameter of musical intonation relates to periodic sounds (such as vowels).

From empirical evidence available, it can be concluded that the *pitch categories* relevant in music reflect scale as well as melodic and harmonic interval structures. These categories and their interrelations are based on several factors, among them being:

a) Acoustic properties and neural processing characteristics as are evident for octaves and seem to be relevant also for some other intervals, in particular, the fifth and twelfth. There is striking evidence for the use of the pure fifth and pure fourth in many music cultures, and the pure fifth has been addressed as an interval of distinctive quality forming the most basic consonance next to the octave since antiquity (for a detailed discussion with reference to historical source material see [31.72]).
b) The experience of sensory consonance, on the one hand, and of dissonance as connected with beating and roughness, on the other, which are relevant not only in the perception of the octave, pure fifth and pure fourth but also other intervals (major and minor third, major and minor sixth, and to a lesser degree the tritone and the minor seventh).
c) The factor of proximity that is relevant for judging the distance between tones, in particular of tones representing adjacent scale steps [31.55]. Proximity of tones in a chromatic scale often has been viewed in regard to *similarity* (see above), however, there are two kinds of similarity effective in the perception of scales, one based on a convergence of components (as in the octave, twelfths, fifths; see above), the other addressing the nearness of components with respect to JNDs and distance estimates (this issue, the double nature of *similarity* in regard to tones and scales, and to pitch relations in general, has been discussed by *Stumpf* [31.39, 40, 59] and in many publications since). The factor of proximity becomes evident, in regard to the *nearness* and *adhesion* of tones, when one hears a scale in a system with more than 12 pitches per octave, for example the 31-tone system calculated by Christiaan Huygens in the 17th century and realized, on various keyboard instruments, by the Dutch physicist *Adriaan D. Fokker* and some modern composers [31.382, 383].

Going from one step to the next (in this system, the difference in fundamental frequencies is $1200/31 = 38.71$ cent, a so-called diësis), the transition can be still perceived as a small step, and also various intervals remain discriminable and even identifiable both in succession and when played simultaneously. Discrimination can be achieved since the step size of nearly 40 cent is large enough to distinguish melodic steps and intervals by their size, and multiples of the basic step in fact are good to very good approximations to common musical intervals (e.g., two diëses give a chromatic semitone, three a diatonic semitone, five result in a whole tone (meantone of 193.55 cent), ten in a perfect major third, etc.). However, it would require much training to be able to identify all the intervals that can be produced in this system as such, in particular in a real-time listening and/or performing situation. Therefore, listeners not familiar with this system may take some of the 31 pitches as detuned variants of the limited number of *pitch categories* they know from their musical practice (very often, this is playing a piano or other keyboard tuned to ET12). Obviously, the number of *pitch categories* available to listeners and performers as well as the conceptual framework of how they relate to each other depends on a process of learning and training notwithstanding the fact that at least some of these relations have a *natural* acoustic and perceptual basis. Perhaps the most decisive factor for identification of tones and intervals is previous storage of categories along with their distinctive features in LTM, and fast access to this stored information in a listening situation or when performing music.

The ability to identify tones according to established *pitch categories* in a fast and seemingly effortless operation has often been addressed in reports on so-called absolute pitch (AP; for overviews concerning relevant phenomena and publications see [31.384–388]. AP capabilities, which include also identification of musical keys [31.385], are often divided into *active* and *passive* [31.389], the former pointing to a subject's ability to produce a tone at a certain pitch indicated by a tone name (for example, A_4 or F_5) by singing or whistling while the latter means a subject can assign a tone name to a given stimulus. For reasons of convenience and familiarity of subjects with piano tones, these were the stimuli used most frequently in AP experiments [31.384, 385, 390, 391]. In order to avoid complex sounds that would perhaps offer more than one cue for pitch identification, sine tone generators have been employed as well. In general, all frequencies

are measured relative to ET12 and a *concert pitch* of $A_4 = 440\,\text{Hz}$, and deviations from these values subjects realize in singing or in adjusting the frequency of a tone generator are given in cents. Quite often, deviations within a certain range (expressed in ± cents around one of the ET12 pitch frequencies) are considered insignificant since they do not violate the boundaries of that *pitch class* or *category* (see above for *intraclass equivalence*). Relevant boundaries may be taken at ±30 cent [31.344, 380] or even at ±40 cent, with only short *transit zones* between categories of 20 cent. Moreover, octave errors are not always considered as relevant (hitting the correct *pitch class* is regarded as showing *active* AP ability). A *passive* AP ability means a subject is able to identify a (pure or complex harmonic) tone that she or he hears by correctly labeling it (e.g., *this is* G_5). The tone name signifies its pitch relative to, typically, 12 categories that are representing a chromatic scale. Very often, the tones used in AP experiments were those from a piano tuned to ET12 so that enharmonic differences pertaining to flats and sharps are ignored both in the stimuli and in the *categorical* judgments prevalent in subjects with this type of AP. Since piano tones can be fairly well distinguished both in regard to register (octaves) and within octaves due to tone height, timbre and brightness as well as remembering different frequencies with which these tones are used in works of music and in musical practice, *categorical* pitch identification of piano tones for subjects having received years of piano training is not too difficult, and often results in scores above chance level. However, such findings may indicate *absolute piano*, as [31.384, p. 436 f.] and [31.391, p. 271] remarked in a review that is quite critical of AP concepts in general, rather than AP. In view of common practice, AP means subjects are able to either categorize tones they hear with respect to 12 *pitch classes* as well as several registers, or that they can produce a certain pitch, within the limits of a chromatic ET12 scale, according to a tone name that represents the *label* of a certain category. The adjective *absolute* in AP refers to a form of immediate categorical judgment that should be executed without (external and/or internal) reference and without making comparisons. However, though absolute judgments relate to objects in isolation (no context provided), this is a condition that might be unrealistic, in certain respects. As *Stumpf* [31.39, p. 139] has pointed out, judgments on pitch involving *absolute* identification of tones by labeling them (e.g., F_3 or $C\#_5$) can be done so that the actual stimulus is compared to a reference stored in memory; in principle, a few reference pitches or just one like the most familiar A_4 (plus the octaves one can imagine as further anchor points) should suffice. It has been argued that,

> *even in so-called* absolute *identification, the listener is trying to transform the task into one of* relative *pitch, seeking to anchor the presented tone to an available context.* [31.392, p. 192]

While in fact some basic relational frames stored in LTM might be governing much of AP judgments, any comparison of a stimulus with stored anchors or even an adjustment of a certain pitch a subject produces in *active* AP tasks to a tone name (*give me a* $F\#_4$) takes time. Therefore, reaction times have often been measured in AP experiments [31.393]; it can be hypothesized that, with a complete set of pitch categories stored as a template in LTM, reaction time for performing either *active* or *passive* AP tasks is very short while it increases when only a partial reference frame or even a single pitch reference is available for internal comparisons providing the basis for *absolute* pitch judgments as well as for production of certain pitches. Also, it can be hypothesized that the error score for subjects (see below) reflects accessibility of internally stored references as well as the precision with which such references can be recalled from memory. In this respect, AP tasks address cognitive abilities (as the term *absolute tone consciousness* used by *Abraham* [31.389] and other researchers on AP indicates), namely (a) the capacity to draw, in a fast and reliable way, on a set or template of *pitch categories* stored in LTM, and (b) a capacity of correctly labeling tones heard or imagined in correspondence to these categories. The term *category*, as explained above, in regard to pitch perception indicates a certain frequency range or bandwidth while, in a strict sense, one could also argue that perceiving *absolute* pitch should confine this range to that of a single JND. However, it has been observed in experiments comprising larger samples of subjects with apparent traits of AP [31.385, 390] that such subjects have access to rather broad pitch categories (usually spanning a semitone) but often do not perform so well in tasks requiring precise discrimination of pitch changes or tuning differences [31.394, 395]. In this respect, many (but not all [31.90, 91]) subjects with AP indeed seem to come close to *categorical perception* as predicted by its strong formulation [31.321].

There are several hypotheses regarding the genesis and/or acquisition of AP [31.388]. One takes AP as an innate and possibly hereditary property that is rare (at least among subjects of Caucasian origin), and is often affiliated with other traits indicative of superior *musicality* as well as with general intellectual alertness observed in a child such as reading music, memorizing complete musical works, playing one or even several musical instruments, and creativity in composing and

improvising music at an early age (for detailed reports on musical child prodigy, see [31.396, 397]). A reason to assume innateness of AP was that some subjects had or have AP abilities (both *active* and *passive*) at a very early age where training can hardly account for actual performance. Also, some subjects display astounding AP abilities in that their categorization of tones in regard to pitch is achieved in a very fast, precise (i. e., very low error scores [31.393]), and seemingly effortless way, whereby categorization may extend to various musical and even to environmental sounds (apparently, there are also other animals besides humans capable of *absolute* pitch identification). Such observations do not deny effects of learning and practice since early onset of musical training seems to be another decisive factor. However, training alone cannot explain actual musical performance of subjects exhibiting clear AP abilities at a very early age (often, between four and ten) who may be viewed as *AP possessors* or as belonging to the AP phenotype [31.398, 399] to be distinguished from subjects who have acquired AP abilities in years. Some data show an aggregation of AP possessors within certain families [31.390, 399, 400], a factor that has been interpreted as indicating a genetic predisposition for the development of AP.

A second hypothesis also assumes that there is some innate disposition for developing AP at an early age (the time window mentioned in many publications is from about three to six years of age); acquisition of AP abilities within this *sensitive phase* (or *critical period*) is viewed as depending on appropriate training aiming at identification of tones according to fixed pitches and pitch categories, a task that involves of course labeling or mapping tones heard. Even more demanding seems production of isolated tones on hearing or reading a tone name (e.g., B^{b}_{5}). Sometimes conventional music education, which has a focus on relative pitch and pitch relations rather than on memorizing fixed pitches, is regarded as a factor deteriorating the initial AP disposition. Though there is, in certain countries, a practice of using solfeggio with *fixed do*, that is, do is always representing the note C, children usually learn to sing or play simple tunes (from which they memorize melodic contours) as well as intervals and chords with their inversions that are fundamental in tonal music. The issue of acquiring a template of pitch relations effectively replacing an initial AP disposition seems controversial for several reasons. Viewed in evolutionary terms, there are some indications that, for instance, certain bird species are responding to both relative and absolute pitch cues concurrently [31.401]. Though there are some hints that young children may respond to absolute features of a melody such as the pitch of the first note or the pitch range, there are also indications that they respond to pitch relationships [31.402, pp. 159 f.]. This seems unsurprising given that basic harmonic intervals like the octave and the fifth have a natural acoustic and perceptual basis (Sects. 31.1–31.4) so that such intervals should be learned by children with ease. In fact, children take advantage of the pure fifth and the major triad when processing melodic interval structures [31.403]. The decisive factor for both the development of AP abilities [31.388] and of good relative pitch perception indeed seems to be an early onset of musical training and practice. To be sure, there are more perceptual and cognitive skills that benefit from early onset of training (like learning foreign languages) so that this condition is by no means exclusive to AP. It has been suggested, for language acquisition, that infants are able to *map* critical aspects of a language they hear into neural substrates so that being exposed to ambient language sounds could be sufficient to induce such mappings [31.404]. One might probably see a parallel for developing AP in children who are exposed to music and will encode the pitches and intervals they practice, often on a piano or other keyboard [31.66, 405]. The rivalry between AP and relative pitch (RP) might then be understood so that a mapping of absolute pitches in infancy could be an obstacle for the mapping of scales and intervals in terms of relative *fluid* pitch templates later.

Another fact that should be considered when assuming an original AP *disposition* would exist in many or all of us is the late introduction of *absolute* pitch in acoustics and musical performance practice. Though calculation of absolute frequencies and definition of reference pitches (by means of the length of organ flue pipes) became accessible, in round figures, in the 17th century [31.18], there was no precisely defined *concert pitch* before the end of the 19th century (for a historical review, see the collection of articles in [31.406] and [31.407]). By about 1885, several European countries agreed on $A_4 = 435\,\mathrm{Hz}$, and only in 1939 was an international norm (ISO 16) for $A_4 = 440\,\mathrm{Hz}$ settled. In retrospect, *absolute pitches* defined by frequencies (measured in cycles per second (cps) (Hz)) was neither available to, nor needed for, musical performance practice in Europe (and elsewhere) before the 19th century. Two factors that played a significant role in the process of standardization were the spread of ET12 as the predominantly used keyboard tuning (roughly, between 1780 and 1860), and the development of the modern piano (fortepiano) in about the same era. It is of interest to note that ET12, the modern piano, and AP concepts, which became of interest in music education and music psychology by the end of the 19th century [31.389], relate closely to each other. It is this conglomerate that led to many experiments and their interpretations in the realm of *absolute piano* [31.384, 391].

The third hypothesis plainly states, in a behaviorist stance, that AP is nothing but a learned ability, and that almost everybody can achieve AP with adequate training conducted over a period long enough to make 12 pitch categories accessible from LTM and, if needed, STM (including sensomotoric coordination in *active* AP tasks). A classical case study often cited to prove the hypothesis is that of *Paul Brady* [31.408] who managed, at the age of 32, to acquire AP abilities within three months, in a tough effort where he spent many hours on tone and pitch identification. Though his achievement seems remarkable, it can hardly be compared to the performance of AP phenotype subjects who can do with moderate effort in childhood what Brady could as an adult after heroic training.

In what seems a typical *nature–nurture* controversy, there is factual evidence for both sides; there are observations indicating some differences between AP *possessors* and *nonpossessors* in regard to cortical activation patterns and the role of working memory and associative memory [31.387, 388, 409] and there are data from surveys of AP possessors [31.399, 400] relevant for determining possible familial and/or ethnic aggregation of AP traits. On the one hand, there is evidence for a distinguishable AP phenotype; on the other, there are many reports on positive effects of musical training on pitch identification tasks in particular during the *critical period* [31.410]. Also, it seems evident that members of ethnic groups using tonal languages such as Mandarin Chinese can acquire AP more easily (since they have to learn and encode certain *pitch categories* fundamental to the use of their native tongue anyhow). However, in many respects, the differences between AP possessors and musically trained subjects with good or even excellent *relative pitch* (RP) seem gradual rather than *absolute*. In experiments where musically trained RP subjects are employed as a control group, their scores in pitch and key identification tasks often are not much different from those of AP subjects who, to be sure, also show typical errors and limitations in pitch identification and pitch production tasks. Those typical errors include [31.385, 390, 392, 411]:

1. Missing the correct identification of the pitch/tone name of a given stimulus (piano tone, sine tone, or other) by a semitone up or down, or even by a whole step up or down.
2. Mistaking the tone/pitch presented for a fifth or a fourth up or down the target.
3. Identifying the correct category, but not the correct octave.

In regard to limitations, there are several considerations:

1. Typical findings are that many AP subjects have low error scores only for a gamut of one octave or, at best, two octaves (performance of Caucasian subjects usually is most reliable in the range C_4–C_5, and often also good in the range C_3–C_4, but markedly deteriorates below C_3 and, increasingly with pitch and register, above C_5).
2. Error scores are low for the diatonic tones of a scale, and markedly so for a diatonic C scale (corresponding to the white keys on a piano) while error scores are clearly higher for chromatic tones marked by accidentals.
3. According to observations, performance is to some extent dependent on the timbre of the tones presented for pitch identification; error rates increase for many subjects when tones from instruments other than the piano (with which most of the AP *possessors* are familiar) are used.
4. A final source of errors that is of interest in regard to *categorical perception* is a change in the tuning in which tones or musical phrases are played. Using tones recorded from instruments, piano cadences and excerpts from musical works in major and minor presented in three tunings (tuned to $A_4 = 440\,\text{Hz}$ or detuned by either $+40$ or -40 cent), *Heyde* [31.385] found that the tuning of -40 cent was correctly identified in nearly 62% of the judgments when the musical excerpt was in a minor key while identification of a tuning $+40$ cent of tones and musical excerpts in major keys was much poorer (with an average score of only 28.2% correct).

A factor one might think of for explanation is that tuning of instruments and *concert pitch* in orchestras nowadays often is higher than $A_4 = 440\,\text{Hz}$, and rather close to 445 Hz; AP subjects might therefore be inclined to take the higher tuning for the *concert pitch* they experience with modern orchestras. However, raising the pitch by 40 cent means $A_4 = 450.28\,\text{Hz}$, a difference that should be recognizable. Apparently detuning to the flat side was more noticeable for AP subjects (the score for correct identification averaged over all conditions reached 48.8%). There are more reports documenting that AP subjects have difficulties in correctly identifying intervals in the case where the tuning is changed by 50 cent or a transposition of the tonal context is introduced, while subjects with RP seem to adapt to such conditions more easily [31.394, 395].

As the data from *Heyde* [31.385] show, identification of keys (with the standard tuning at $A_4 = 440\,\text{Hz}$) was better than that for tones (77.3% of all judgments in her sample of AP subjects ($n = 47$) as compared to 65.6%), and identification of keys that are frequently

used in music (such with no or few accidentals) was better than that for keys with rare occurrence. In regard to the error scores obtained in such experiments, missing the target by one semitone (up or down the chromatic scale) seems perhaps the most frequent error with AP subjects, followed by errors by a whole step and octave errors. In comparison, errors mistaking the target for its perfect fifth or fourth are much less frequent (in Heyde's data, about 2% on average for tones, and 4.2% for keys). Mistaking the target category by a perfect fourth or by a perfect fifth notwithstanding the perceptual difference in tone height indicates that a relational principle of tone qualities as are expressed in musical intervals, and in the circle of fifths as a perceptual and cognitive framework, plays a significant role also for AP possessors (as was elaborated by [31.390]). Octave errors may arise from perceptual factors such as misjudging the tone height of a stimulus due to spectral convergence and phenomenal similarity between two complex tones one octave apart (Sect. 31.1.2); this type of error does not affect correct identification of the pitch category.

It is not quite clear what the cues are for complex tones presented in isolation to let subjects accomplish the task of identifying the appropriate pitch category. As has been elaborated above (Sect. 31.1.2), the concept of tone qualities taken as saturated elements within each octave was viewed in parallel to vision of colors. *Bachem* [31.48] consequently spoke of *tone chroma* to denote this peculiar quality assigned to 12 *chromatic* tones for a range of several octaves. However, a tone quality usually is defined referentially, by the relations one tone has with others in regard to a scale or the intervals they form [31.52, 72]. Without such a context, it is still a matter of debate what constitutes a particular *tone quality* or *tone chroma*. Assertions that such tonal qualities would *exist*, at least for AP possessors, as much as chromatic colors may *exist* for subjects capable of unimpeded vision, are built upon an analogy that does not explain the specifics of encoding and retrieval relevant for AP abilities. It has been conceded for a long time even by proponents of a special kind of *tone chroma* perception experienced by AP possessors [31.412, pp. 32 ff.] that perceiving *absolute* pitches is neither completely independent of relational ties nor free from limitations imposed by register, timbre, and other factors. In sum, except for very few cases (of the *child prodigy phenotype* like that reported in [31.396]) there is hardly an *absolute AP* that would cover the musical gamut in total as well as hold for many different timbres. Rather, there are various types and grades of AP as empirical data (including responses to questionnaires, self-assessments, error scores from experiments, etc.) demonstrate. Further, there are many subjects who have good or excellent RP abilities and have also encoded a number of fixed pitches because they have a long experience in tuning their instruments (such as bowed or plucked strings). Usually, such subjects can both identify and sing or whistle the relevant pitches. Though they might not qualify as *AP possessors*, in a narrow sense, they have encoded a range of pitches as anchors in LTM that they can use also in judgments on pitches falling in between anchor points [31.392]. A general ability to memorize pitch levels may exist in connection with the memory for certain songs. Observations on a fairly large sample of European subjects [31.413] recently showed that a certain percentage could reproduce a song of their choice relative to the original within a limit of ± 2 semitones.

Given that AP abilities are often observed in subjects who learned to play the piano at an early age [31.66, 405] and taking the role of the piano in music education into account, it seems feasible that many of these AP *possessors* encode absolute frequencies and brightness values for a number of complex tones of a diatonic or even a chromatic scale they experience intensively during the *critical period*. Piano tones seem suited to this task since the brightness (measured by the spectral centroid of complex tones) changes markedly with pitch. For example, for a chromatic scale C_3–C_5 played with the sound of a sampled grand piano (MIDI velocity for all notes was set to 80), the spectral centroid rises from about 1.2 kHz to ≈ 3.2 kHz while f_1 of the sounds rises from 130.8 to 523.3 Hz. In effect, brightness can be used as an additional cue to pitch for each single scale tone even if brightness is not independent of pitch but, rather, one component of the pitch of a complex as well as of a pure tone.

At this point, it should be emphasized that fundamental components of pitch as a product of sensation and perception, namely brightness, tone height, and *tone quality*, should not be confused with *dimensions*. In regard to models and methods of multivariate statistics, dimensions require to be (a) continuous (representing variables that, in principle, can express arbitrary values within lower and upper boundaries) and (b) linearly independent (so as constituting an n-dimensional vector space, see [31.414] and textbooks on multivariate analysis). While the condition of quasicontinuous representation and measurability obtains (within JND/DL limits) for brightness and *tone height*, whose magnitude increases with frequency, *tone quality* resists quasicontinuous grading inasmuch as it is conceived in terms of discrete, nonoverlapping and fairly wide pitch categories (like the 12 chromatic semitones on a keyboard). In regard to scaling [31.415, 416], there would be thus interval scales for brightness and *height*, and

an ordinal scale of *qualities*, the latter with the special feature of *octave equivalence*. Among the many objections brought forward against the two-componential theory of pitch was that, for complex harmonic tones such as produced by strings, woodwinds and brass, the percept of musical pitch is unitary and coherent, and not an aggregate of components [31.54, 55]. Dissociation of components would, therefore, be possible in abstract analysis (as also [31.37, 56] admits) but highly irrelevant for music perception where listeners (and musicians alike) would conceive of the pitch of a certain tone as a single point in a two-dimensional pitch–time-space (ordinate: pitch, abscissa: time). The position of a tone in this space relevant for music performance and pitch perception would be marked by its fundamental frequency (as in conventional Western staff notation where the ordinate corresponds, roughly, to log frequency [31.417]). In fact, reading either a melographic or a sonagraphic (spectrogram) representation of musical phrases in a 2-D (two-dimensional) representation (ordinate: frequency (lin or log) or cents; abscissa: time) reveals the structure of pitches, scale steps and intervals quite clearly [31.93, 137, 306, 418–420].

31.8 Scales, Tone Systems, Aspects of Intonation

In an evolutionary perspective, pitch perception was established firmly with vertebrate animals [31.421]. Birds (aves) express themselves by producing elaborate sequences of sounds that rightly are described as *birdsong* [31.422]. Many mammals likewise produce sounds at different pitches, and with different timbre; such utterances often serve the purpose of communication in a group, or to attract a female. In certain respects, human vocalizations are similar to those of other mammals, and music as used among humans can be viewed as a means of communication, if not survival that had to be invented in the course of hominid evolution [31.423]. Scale types and melodic patterns have been a topic often addressed in publications on comparative musicology since they were regarded as indicative of stages of musical development [31.424–427]. Well into the 20th century (before the advent of modern media and communication technology), most of the non-Western music cultures as well as many folk music traditions in Europe offered a broad range of scales and modal structures as well as a variety of tunings for instruments. Early investigations of *primitive* music (a term not to be read as derogative but in the sense of medieval Latin *primitivus* = the first of its kind) recorded in the field showed that in some cultures music in fact was very elementary as melodic formulae oscillate between no more than two pitch levels about a whole tone apart (but not always stable and to be viewed as relative pitch levels). Such forms were recorded in New Guinea and other remote places (e.g., Andaman Islands). However, melodic patterns built on a bichord or trichord were observed also among Finno-Ugrian peoples [31.428]. A lullaby recorded in New Mexico from an old Zuñi grandmother, in 1950 [31.429, Expl. 2], basically is a recitation on one stable pitch (G_4) with, repeatedly, a drop to a fourth below (D_4) held as a second stable pitch. In other cultures, prototypes of scales with four or five pitches were in use (some still are). A host of pentatonic scales has been observed in Old and New World cultures.

While those elementary forms of melody oscillating between two or three relative pitch levels can be viewed as exploring tone height differences rather than using distinct scale steps, rudiments of a scale become apparent for melodic phrases where two whole steps are combined with a semitone in between or where a whole tone is combined with an interval of a minor third (the gamut in both cases is a fourth; for examples from Australian Aborigines see [31.430]). A fourth often serves as a frame interval and is filled with two pitches in between. One of the widespread scales found in traditional music styles was and still is anhemitonic pentatony such as comprising the notes C–D–E–G–A. It offers whole tone steps close enough to each other to be perceived as *neighbors* in a scale so as to allow continuation of a melodic phrase upward or downward and intervals wider than a whole step to realize more expressive melodic gestures (in particular if the scale is extended to the octave). Anhemitonic and hemitonic pentatonic scales usually consist of stable pitch structures; in certain regions, the use of neutral thirds (the size is between a major and minor third) or other inflections of pitches may occur. In some music cultures the series of harmonic partials as available on aerophones and chordophones serves as melodic material [31.431]. Overtone singing (as in Mongolian *Chöömij* [31.432]), excitation of harmonic eigenmodes on duct flutes such as the large Slovak *Fujara* [31.433] and the use of the musical bow as in southern Africa are but a few examples of music based on harmonic partials. Evidently, there are several principles of scale formation [31.93, pp. 313 ff.]; a number of music cultures apparently realize an *additive* concept in that a nucleus at the size of a whole tone occupies the center of melodic

movement from which a few pitches up and down may be reached [31.428]. Others seem to pursue a *divisive* approach in that frame intervals (octave, fifth, fourth) are divided into a number of steps. Further, employing a basically pentatonic scale in a multipart context can necessitate octave transpositions of scale tones as one finds in East and Central African music genres [31.434, Chap. III]. In addition, the use of pentatonic modes in parallel voices easily introduces the fourth as a simultaneous consonance, and men and women (or men and boys), when singing the same melodic contour, often proceed in parallel octaves or fifths (as observed in non-Western and in Western musical practice [31.424, pp. 42 ff.]). Discovery of the octave, the perfect fifth and apparently also the perfect fourth as fundamental consonant intervals could be achieved in musical practice, and perhaps without much conceptualization. Moreover the octave, because of its natural foundations (Sects. 31.1.2 and 31.4), governs pitch perception in a way that seems difficult if not impossible to ignore in musical practice. Also the perfect fifth and the perfect fourth, for their distinct interval character and consonance (this applies especially for the perfect fifth used as a simultaneity) could serve as fundamentals in many musical structures; in fact, given their use in various musical cultures and genres they can be regarded musical *near-universals*. Further, the *sweetness* of major thirds and other consonant intervals apparently was discovered in indigenous music cultures of Polynesia and parts of Africa before the advent of Europeans who couldn't believe their ears when hearing multipart music that sounded quite similar to their *major tonality*, and musicologists and ethnographers were likewise surprised to hear melodic patterns based on harmonics (usually, from the second up to the 11th or 12th) in indigenous and folk music genres. Also, the tritone (suspect as *diabolus in musica* in medieval music theory) appears as melodic interval and even in simultaneities, in folk music contexts (e.g., vocal and instrumental music of Slovakia).

The variety of scales and modes (as to this concept [31.435]) utilized in vocal and instrumental music of many ethnic groups and cultures of course is the result of developments that are complicated as historical processes (and outside of the scope of the present study). In regard to the genesis of the tone systems that became basic to European art music, from about medieval times into the 20th century, one should, however, take notice of ancient Greek music theory (as well as its survival and partial reformulation in Persian, Arab, and Indian sources).

As has been emphasized in works on the history of mathematics, speculations on ratios of small integers can hardly be separated from empirical investigations in which string lengths corresponding to basic musical intervals were measured [31.436, Part. 2]. It was fairly easy to derive basic musical intervals from sections of a string on a kanon (the antique predecessor to the medieval monochord) as is evident from the *sectio canonis* of Euclides (third century B.C.E.; see [31.437, pp. 133 ff.] for the Greek text and a German translation; also [31.296, Chap. 14]). Euclides explains the relations of tones and intervals by line sections, which can be viewed as representing string sections. When he argues that consonant (in the Greek text: symphonous) tones give rise to but one sound in which they *fuse*, it is clear that he must have experienced by ear the intervals he elaborates on. Similarly, when Aristoxenos (fourth century B.C.E.), in his *Harmonics* [31.438, Chap. 7, pp. 158 ff.] explains the whole step as the difference between a (perfect) fifth and fourth, and the differences between concords and discords within the range of an octave, he refers to the actual experience of music, in particular to melody. Though mathematical speculation was a genuine part of Greek music theory (and vice versa [31.296, 436]) it must have included empirical observations early on. For example, basic intervals of the *Pythagorean* tone system can be derived by both a mathematical and a geometrical procedure (the latter applicable to line or string sections). In a context where the notion of *harmonia* is viewed as the principle uniting things that are unlike among each other, Philolaos (fifth century B.C.E. [31.439, p. 689], [31.438, pp. 37 f.]) determines the magnitude of *harmonia* (the octave) by the fourth and the fifth. The difference between the fifth $(2/3)$ and the fourth $(3/4)$ is a whole step $(8/9)$. He then states the tones between which intervals of a fourth or a fifth exist and concludes that the octave comprises five (whole) tones and two dieses. From the text, the tonal organization of the octave can be derived. A whole step can be subtracted two times from the fourth; one whole step subtracted from the fourth leaves the minor third $(27/32)$ while two whole tones subtracted from the fourth leave a *remainder* (the *leimma* $243/256$). The process of subtracting two whole steps from the fourth can be carried out also arithmetically; in a modern syntax this would read like

$$(4/3)/((9\times 9)/(8\times 8)) = 256/243\,.$$

In addition, the leimma can be found by a progression in fifths. One has to take notice that, in Greek music theory, scales are usually conceived in a downward direction. Five pure fifth downward from a given tone, the leimma is reached

$$f \leftarrow c \leftarrow g \leftarrow d \leftarrow a \leftarrow e\,.$$

Corrected for the octaves traveled, the ratio of the interval is calculated as

$$((2/3)^5) \times ((2/1)^3) = 256/243\,.$$

Without going into details pertaining to the construction and history of tone systems in antiquity and their survival in the Middle Ages in Europe and the Near East [31.52, 71, 73, 296, 438, 440, 441], the point of interest here is that the Greek *Dorian* scale, which is regarded as reflecting Pythagorean approaches to scale construction in progressions of fifths most clearly, has a parallel in the common European melodic major scale (Fig. 31.18)

Evidently, there are two identical tetrachords (Greek *tetrachord* means *four strings*) in both scales joined by a whole tone. The scale in question is suited for melodic lines, and intonation patterns of violinists come close to it [31.89]. However, the major third 81/64 (a *ditonus* since adding two whole tones 9/8) is too wide to *fuse* in a simultaneous interval, and this deficiency was already known in the Middle Ages when the use of major thirds in compositions of art music became an issue (early examples can be found, for example, in the so-called Robertsbridge Codex, dating circa 1350 [31.305]). Moreover, there was music composed (or adapted from folk music patterns already existing at the time) where parallel major and minor thirds are a constitutive feature like in the famous *Nobilis, humilis* from the Orkney Islands, a hymn from the 12th century written in praise of St. Magnus, Earl of Orkney [31.442]; parallels to *Nobilis, humilis* are found in Norwegian folk music.

The Greek theorist Archytas of Tarent (fourth–third century B.C.E.), according to Ptolemy (*Harmonikon*, p. 30 ed. Düring [31.297, p. 47]) elaborated on three different tetrachords, the diatonic, the chromatic, and the enharmonic. The intervals in these three tetrachords spanning a perfect fourth are

$$(9/8) \times (8/7) \times (28/27) = 4/3, \text{ which equals}$$
$$1512 - 1701 - 1944 - 2016$$
$$(32/27) \times (243/224) \times (28/27) = 4/3$$
$$1512 - 1792 - 1944 - 2016$$
$$(5/4) \times (36/35) \times (28/27) = 4/3$$
$$1512 - 1890 - 1944 - 2016\,.$$

It is easy to see that the three tetrachords have one interval in common (the diesis $28/27 = 2016/1944$) and that the whole numbers Ptolemy introduced for demonstration are just expansions of the fractions. The diatonic tetrachord offers a septimal whole tone 8/7 besides the common whole step 9/8, the chromatic

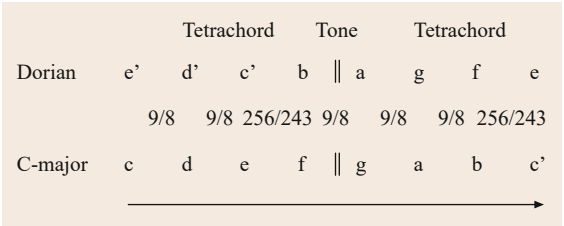

Fig. 31.18 Dorian scale and melodic major scale

tetrachord has a minor third 32/27, and the enharmonic a just major third 5/4. Though it seems that Archytas did try to describe tonal relations that were in use at his time [31.438, pp. 43 ff.], [31.443, pp. 413 f.], Ptolemy criticized some of the ratios as not fitting appropriate melodic intervals he was familiar with when played on a kanon. He, therefore, offered alternative solutions [31.297, p. 33 ff.], which include a tetrachord labeled

Diátonon sýntonon

$$(10/9) \times (9/8) \times (16/15) = 4/3,$$

in whole numbers

$$504 - 560 - 630 - 672\,.$$

This tetrachord comprises two different whole tones which, in combination, result in the just major third: $(10/9) \times (9/8) = 5/4$. The difference between the two whole tones is a *syntonic comma* (expressed in cents, $9/8 = 203.9$ and $10/9 = 182.4$ cent; the syntonic comma thus is 21.5 cent). The difference between a major third 5/4 and the perfect fourth 4/3 is the diatonic half tone of $16/15 = 111.7$ cent. Ptolemy claimed that all the intervals he calculated can be tested by attuning an eight-stringed kanon in a precise manner. The diatonon sýntonon had a prerunner ascribed to Didymos (first century), whose diatonon was of the form $(9/8) \times (10/9) \times (16/15)$; both became the blueprint for the modern harmonic scale, which can be written as noted in Fig. 31.19.

The ramifications of Greek and Hellenistic music theory were that several principles of scale construction were explored, some with a specific mathematical background such as defining intervals as superparticular ratios, $(m+1)/m$, a process that gives relevant musical

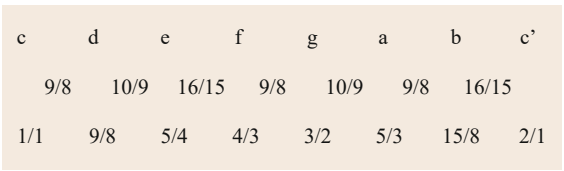

Fig. 31.19 Harmonic major scale

intervals in a straightforward way; for example,

Evaluate [Table [$(m+1)/m$, $\{m, 15\}$]]

turns out the list

$$\left\{2, \frac{3}{2}, \frac{4}{3}, \frac{5}{4}, \frac{6}{5}, \frac{7}{6}, \frac{8}{7}, \frac{9}{8}, \frac{10}{9}, \frac{11}{10}, \frac{12}{11}, \frac{13}{12}, \frac{14}{13}, \frac{15}{14}, \frac{16}{15}\right\}$$

Though such operations may seem removed from musical practice, this is not the case since intervals of the size 7/6 (the septimal minor third of 266.9 cent) had a musical function. In the Greek tone systems, the interval 7/6 is that between the tone called mese (the middle one) and the trite (a tone in the tetrachord above the mese [31.52, 71, 438]). Adding a diesis (paramese–trite) to a whole tone (mese–paramese) gives $(9/8) \times (28/27) = 7/6$. Such intervals were apparently part of musical practice at the time of Archytas [31.443, pp. 413 ff.] and are employed in genres of Near Eastern music to the present where also very small steps corresponding to the chromatic and, in particular, enharmonic genus as described by Archytas and other Greek theorists survived [31.370]. One can measure intervals such as 7/6 and even 36/35 in Turkish Ney music [31.418]. The whole tone 10/9 besides that of 9/8 can be found on fretted string instruments such as the Azerbaijan lute *tār* [31.93, p. 318, Tab. 18].

Perhaps the most basic operation relevant for the construction of tone systems and a variety of scales is a progression in fifths and fourths from whatever starting point is chosen. A sequence of five fifths (in downward direction) gives the leimma 256/243 (90.2 cent), a sequence of seven fifths upwards the so-called apotomē (2187/2048 = 113.7 cent, another semitone). Evidently, leimma and apotomē add up to the whole step

$$(256/243) \times (2187/2048) = 9/8\,.$$

Going eight fifths down from a given tone yields a complicated fraction, 8192/6561, which is, however, a close approximation to 5/4. The difference is less than 2 cent and thus below the threshold for pitch. For example, the tone F^b (eighth fifths down from C), when put into the same octave, is almost identical with the just major third above C (F^b = 384.4 cent, $\bar{E}$ = 386.3 cent). Thus, it is possible to derive an almost just major third by a progression in fifths, a process described by Şafī al-Dîn Urmavi, one of the leading scholars of Persian-Iraqi music theory, in the 13th century [31.73, Chap. 3]. He developed a scale comprising 17 tones per octave, which includes not only a number of almost just thirds but also the minor whole tone in addition to the major whole step and a septimal whole tone 7/8 (as expressed in string length; expressed in frequencies, it would be 8/7).

With the reception of Greek and Hellenic music theory in Europe, beginning in late Roman times and pursued up to the 15th century [31.440, 441], many of the intricacies of the Greek tone systems, their division into tetrachords and their internal organization according to the three genera (diatonic, chromatic, enharmonic) were still known as is evident from Boethius (around 500 AD) whose treatise *De institutione musica* became most influential for medieval theorists. Guido of Arezzo, in his *Micrologus* (circa 1026 AD) refers to dissonances arising from false intonation of singers as well as from sharpening or lowering the size of a certain interval too much [31.444, pp. 134–135]; several manuscript copies of the *Micrologus* include passages where Guido is criticizing singers to substitute a diesis for a semitone. It can be shown [31.440, p. 162 f.] that the diesis Guido had in mind is the diesis 28/27 of Archytas; added to the whole tone 9/8 it gives a septimal minor third: $(9/8) \times (28/27) = 7/6$. Echoes of antiquity were not just a matter of numerological speculation which, to be sure, must always be viewed in conjunction with geometrical diagrams and measurements on the monochord; mensuration of organ pipes played a role as well [31.441, 445]. Apparently, even musical practice at certain places included systematic microtonal inflections of pitches in basically diatonic melodic textures as can be traced in the Tonary of St. Bénigne de Dijon (Antiphonarium Codex Montpellier, late 10th century [31.446, p. 565 ff.]).

The fundamental problem experienced, in music theory and instrument building, in the course of the Middle Ages and ever since, is that of incommensurability: intervals and their multiples derived from different prime numbers do not converge. It was known to Greek theorists that a chain of 12 fifths was not equal to seven octaves: $(3/2)^{12} \neq (2/1)^7$. The 12 fifths overshoot the seven octaves like the ratio 531 441 : 524 288; the difference is small but significant and amounts to 23.46 cent (known as the *Pythagorean comma*). To make 12 fifths equal seven octaves (this is the range spanned by the progression in fifths), the interval of the fifth must shrink by a small amount to 2.996615/2 instead of 3/2. However, this is a modern calculation involving decimals while medieval music theory still was based on small integer ratios; besides the superparticular ratio $(m+1)/m$, there was the superpartiens ratio $(m+1+n)/m$ like the major sixth 5/3, and the multiplex ratio as in the octave 2/1; further, certain combinations of these proportions were allowed [31.440, p. 64 ff.]. In Pythagorean tuning, a perfect fifth of course comprises a perfect fourth and a whole tone. If the fifth is conceived to span from the diatonic note B

to the accidental F#, to be perfect, the fifth would need the following intervals (leimma, tonus, tonus, leimma, apotomē):

256/243 * 9/8 * 9/8 * 256/243 * 2187/2048 = 3/2

B c d e f f#

Tuning a chain of 12 fifths up and down from a center (g) would result in such a scheme

a^b e^b b^b f c g d a e b f# c# .

There are 11 perfect fifths and, to force the chain into a *circle*, one interval c# - a^b that falls short of a perfect fifth at 678.5 cent (sometimes labeled *wolf fifth* for its howling sound quality). Of the major thirds, eight are of the Pythagorean ratio 81/64 but four are almost just due to the schismatic equation known from Şafī al-Dîn Urmavi (see above). Pythagorean tuning can be assumed for the 14th century (as reflected in organ dispositions and surviving music of the time [31.447]). Tunings and temperaments became an issue when, around 1350–1400 AD, works appeared that made use of the major third as a simultaneity. A long controversy was started among theorists before, in the 16th century, both the major third (5/4) and the minor third (6/5) as well as their complementary intervals (the minor sixth 8/5 and the major sixth 5/3) were acknowledged as consonances, along with their extensions into the next octave (minor and major tenth, etc.). *Gioseffe Zarlino* [31.448, Lib. I, Cap. 36–40], [31.305, p. 72 f.] applied both the arithmetic and the harmonic mean to the division of intervals and demonstrated that the fifth contains the just major and the just minor third.

In regard to tuning, in collections of early organ music like the *Buxheimer Orgelbuch* (≈ 1460/70) there are pieces that still feature fifths and fourths as fundamental consonances; however, there are also pieces where in particular the long held final chord includes a major third (e.g., no. 216, where the final chord is $C_3 - G_4 - E_5$), indicating that the tuning of organs had changed, or was about to change at that time, from a basically Pythagorean pattern to one that could adequately account for major thirds. For example, *Ramos de Pareja* [31.449, Cap. 5] proposed a tuning that combines a number of perfect fifths and just major thirds. By about 1600, the major and minor third and their complementary intervals were widely in use. Works like the *Paduana lachrimae* (written by John Dowland and adapted to keyboard by Sweelinck and other composers of that era) are full of simultaneous thirds that bring the emotional message of the piece to the fore.

The just major third 5/4, which had been calculated in antiquity (see above), introduced another prime number into music and thus intervals incommensurable to their Pythagorean counterparts. It was not possible to tune a conventional keyboard so that it offered perfect fifths and just major thirds for all keys. Among the host of solutions that were tried, beginning in the 15th century, we find various temperaments (aiming at a compromise between tuning in fifths and tuning in major thirds) on the one hand, and expansion of the number of keys per octave on the other (for detailed accounts see [31.450–453]; for mathematical aspects see [31.53, 319, 454]). Quite often, both approaches were combined to result in keyboard instruments that had from 14–31 or even 53 keys per octave and offered either a regular temperament or a selection of pitches from just intonation. Around 1600–1700, the most common approach to tuning was that of so-called meantone temperament, which actually comprises a variety of tunings. Meantone temperament was invented to feature just major thirds, of which up to eight can be realized on a keyboard tuned to so-called quarter-comma meantone temperament (Fig. 31.20; the signs $0, -1, -2, +1$ denote comma differences of tones/pitches relative to tones in the 0-series of fifths).

The temperament that was advocated by *Michael Praetorius* [31.455], among others, is implemented by tuning four pairs of just major thirds ($b^b - d - f\#$, $f - a - c\#$, $c - e - g\#$, $e^b - g - b$), just thirds being written in the vertical and connected by the sign | in this scheme. With only 12 keys per octave available, the price to be paid for no less than eight just major thirds is a detuning of the remaining four major thirds (which are 428 cent wide). In addition, most of the fifths (written in horizontal direction and connected by ... in this scheme) are narrowed by 5.5 cent while its complementary interval, the fourth, is widened by the same margin in order to sum to the octave (696.5 + 503.5 = 1200 cent). Adding two such narrowed fifths and subtracting an octave, the

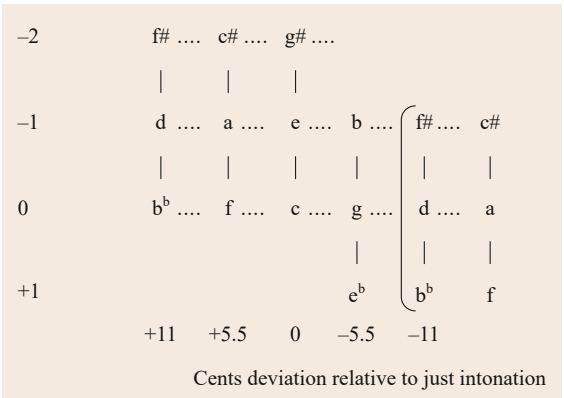

Fig. 31.20 Scheme of quarter-comma meantone temperament for 12 keys

Fig. 31.21 Quarter-comma meantone scale

meantone of 193 cent is found (which is 11 cent flat relative to the major second $9/8 \approx 204$ cent). A problematic interval in 1/4-comma meantone temperament is the fifth $g^{\#} - e^b$ which, at 738.5 cent, is far too wide. The total error of this tuning system relative to just intonation pitches can be reduced significantly if the system would be expanded beyond 12 pitches and tones per octave (expansion would be possible to the right of the bracket in Fig. 31.20 as well as to the left side). With only 12 keys/pitches per octave, the scale tuned to 1/4-meantone temperament is as displayed in Fig. 31.21.

The intervals are given in cents, which of course is a modern measure based on logarithms (for historical approaches to meantone temperaments [31.450–452]). Evidently, the pitch of the tone d, calculated as the geometric mean, is in the middle of the major third c – e (numerically, the meantone can be calculated from $\sqrt{(5/4)} = 1.11803 = 193.2$ cent), which makes d the *meantone* to c and e; by the same relation, f# is the meantone between e and g#. The scale comprises two different semitones, a chromatic (75.5 cent) and a diatonic (117.5 cent), which are suited for the highly chromatic music of the 17th century. The scale offers c#, f# and g# as well as e^b and b^b but lacks d^b, g^b and a^b as well as d# and a#; thus, the major and minor chords that can be actually played on an organ in 1/4-comma meantone tuning, with little inharmonicity of the resulting sound patterns [31.456] are C, F, G, B^b, D, A, E, E^b and c, g, a, d, e, b, f#, c# (uppercases = major, lowercases = minor). Among the intervals available in 1/4-comma meantone tuning are two augmented sixths ($e^b - c\#$ and $b^b - g\#$) that are almost 966 cent wide, which is very close to the natural seventh $7/4 \approx 969$ cent. It seems that Frescobaldi and Scheidt recognized this option for enhanced harmonic expressivity in some of their keyboard works [31.452, pp. 341–343].

It should be noted that *Fogliano* [31.457, Lib. III, Cap. 2/3] had proposed a harmonic division of the monochord, which yields a scale analogous to the harmonic scale; the fifth d – a in this scale ($10/9 \times 16/15 \times 9/8 \times 10/9 = 40/27 \approx 680.5$ cent) is one syntonic comma flat of a perfect fifth. Also, d – f is a minor third ($32/27 \approx 294$ cent) one comma flat against the just minor third ($6/5 = 316$ cent). To provide for correct intervals (the fifth d – a and the perfect fourth f – b^b), Fogliano inserted two more tones (the d above c as 9/8 and the b^b as 16/9 [31.458, pp. 70 f., pp. 106 ff.]). The 14 tones/pitches included

$$C\,\tfrac{25}{24}\,B\,\tfrac{16}{15}\,D\,\tfrac{81}{80}\,D\,\tfrac{16}{15}\,B\,\tfrac{25}{24}\,E\,\tfrac{16}{15}\,F\,\tfrac{25}{24}\,B\,\tfrac{27}{25}\,G\,\tfrac{25}{24}\,B\,\tfrac{16}{15}\,A\,\tfrac{16}{15}\,B\,\tfrac{81}{80}\,B\,\tfrac{25}{24}\,H\,\tfrac{16}{15}\,C$$

Fig. 31.22 Fogliano's monochord division

in *Fogliano*'s scale [31.457] (plate fronting fol. XXXV, tone designations are his) can be seen in Fig. 31.22.

This scale can be written (including cents [31.459, p. 94 f.]) like in Fig. 31.23.

If ordered in a tone net of pure fifth and just major thirds [31.52, p. 242], these 14 tones/pitches yield a structure similar to that shown in Fig. 31.20 except that the fifths are now perfect (Fig. 31.24).

With these 14 tones/pitches, eight just major chords (C, F, G, D, A, E, B^b, E^b) and seven just minor chords (c, g, a, d, e, f#, c#) can be played. Thus, if this system would be implemented on a keyboard instrument, with two additional keys a great improvement of the tuning and the range of just intervals and chords could be achieved. In fact, in particular during the second half of the 16th century and the first half of the 17th century, there were many attempts at developing keyboards with more than 12 keys per octave [31.450, 452, 460]. One of the reasons was to accommodate the chromatic and enharmonic styles of music aiming at a renaissance of musical genera known from Greek antiquity; another was to solve the problems left with meantone tuning. A practical solution implemented on a number of organs and also on harpsichords was to expand the keyboard by one or two subsemitonia, namely split keys that were needed for d# and e^b as well as for g# and a^b to get rid of the so-called *wolf fifth* ($g\# - e^b$ has 738.5 cent in 1/4-comma meantone temperament). The difference between the g# available in this tuning (Fig. 31.20) and an a^b needed for certain chords (a^b major, f-minor) but not available with only 12 keys is the diesis $128/125 \approx 41$ cent, which is the difference between three just major thirds and the octave (e.g., $c - e^{-1} - g\#^{-2} = 1158.9$ cent; the exponent −1, −2 indicates the pitch is one syntonic comma or two flat compared to the note of the same label in a chain of perfect fifth; see below). Consequently, to make meantone temperament workable in most or even all keys, one needs more than 12 pitches by adding from one or two subsemitonia to split keys for the five accidentals (some instruments had additional keys also for $e\# \approx f^b$ and for $b\# \approx c^b$). Otherwise, one has to restrict the gamut to a central range of keys. The gamut of keys that can be played in 1/4-comma meantone temperament with

c'	$c^{\#-2}$	d^{-1}	d	e^{b+1}	e^{-1}	f	$f^{\#-2}$	g	$g^{\#-2}$	a^{-1}	b^{b}	b^{b+1}	b	c'
1/1	25/24	10/9	9/8	6/5	5/4	4/3	25/18	3/2	25/16	5/3	16/9	9/5	15/8	2/1

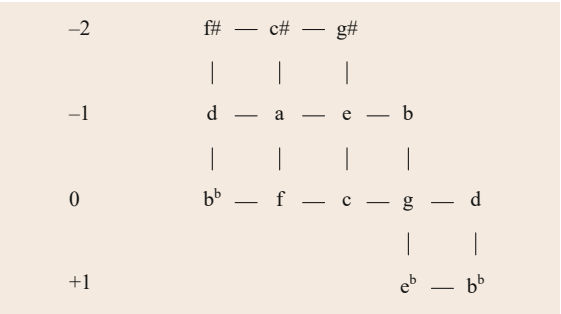

Fig. 31.24 Pitch structure derived from Fogliano's 14-tone scale

a standard keyboard (12 keys) usually is from E^{b} to A (that is, from three flats to three sharps). Most works of the era conform to this range. Some require notes that are not available, or only in some approximation that might, however, be acceptable when viewed from expressing affects such as distress and grieve by means of extreme chromaticism [31.453, p. 179 ff.], [31.451, p. 237 ff.].

Around 1680–1750, a range of *well-tempered* tunings for keyboards with just 12 keys per octave had been developed that form a compromise between tuning as many just thirds as possible (implying imperfect fifths and fourths as in quarter-comma meantone temperament) and tuning perfect fifths (implying *Pythagorean* intervals, see above). The problem is to determine pitches suited to representing intervals based on three prime numbers {2, 3, 5} in such an approximation to just ratios that all tones are usable both as melodic and harmonic intervals with the constraint that only 12 keys and pitches are available on a conventional keyboard. The number of tones/pitches needed for all intervals to be realized in major and minor keys is fairly large; the regular 53-tone temperament that was favored by *Bosanquet* [31.51] and Helmholtz offers a good approximation for intervals based on prime numbers {2, 3, 5}. If also intervals based on the prime number seven are considered, such as the natural seventh (4/7) available as the seventh harmonic on wind and brass instruments, and actually used in musical practice (from folk music of Norway, Slovakia and Switzerland to Benjamin Britten's *Serenade for tenor, horn, and strings*, op. 31), the number of pitches per octave goes up significantly [31.52]. In any event, the basic condition is $n \gg m$, where n is the number of pitches/tones required per octave for just intonation or good approximations to just pitches, and $m = 12$ is the number of keys actually available on a conventional keyboard to be tuned accordingly. Hence, *well-tempering* (from Latin temperari = to adjust, to balance) comes down to an optimization process where one must try to find *best fits* according to several criteria, among them usability of all tones in melodic and harmonic functions in as many keys as possible, along with a high degree of consonance and a low degree of roughness. Nowadays, these goals can be achieved on an algorithmic level and by means of signal processing [31.318]; by about 1680, theorists could not but calculate manually (though some did already with the help of logarithms that had been introduced, in the 17th century, into calculation of musical intervals and tunings [31.450, 451]). In practice, musicians in general had to find proper pitch assignment to the 12 keys from their professional experience in tuning organs, harpsichords, and clavichords; the temperaments implemented on keyboards had to stand an empirical test, namely that of expert listeners such as J.S. Bach taking part in examinations of newly built organs. To conclude from historical reports, sensitivity for judging by ear different tunings (and their relative deficiencies) must have been very high. The task of *well-tempering* gained urgency when compositions ventured into sharps and flats outside the gamut well covered by quarter-comma meantone (e.g., D. Buxtehude, *Praeludium in E*, BuxW 141). Proposals for well-tempering such as offered by *Werckmeister* [31.461, 462] should not be confused with *equal temperament* (ET12); a *well-tempered* tuning typically offers intervals (fifths, thirds, semitones) of different size and so also maintains differences between keys with respect to degrees of consonance versus beats or roughness. A *well-tempered clavier*, therefore, has to be distinguished from a keyboard tuned to equal temperament (ET12). There have been many hypotheses as to Bach's *recipe* for tuning a harpsichord or organ [31.463–466]. Though differing in details, these proposals all converge on a nonequal temperament for which indications can be found in the keys as well as in harmonic and melodic textures in Bach's works for keyboards (in particular, organ works [31.467, 468]). Recently, a new evaluation of Book I of Bach's Well-Tempered Clavier has been carried out [31.469] by employing dissonance calculations based on the approach of *Sethares* [31.318]. Also, organ temperaments relevant for an adequate

performance of Bach's works have been evaluated empirically [31.470].

While quarter-comma meantone temperament and concepts of *well-tempering* were in use, also equal temperament was pursued both empirically and by means of calculation. Among the empirical approaches there was Vincenzo Galilei's proposal of fretting a lute to the ratio 18/17, which leads to semitones of 99 cent [31.459, p. 57]. On a theoretical basis, there were attempts to find an equal temperament by geometrical divisions of the monochord whereby the *Pythagorean comma* (23.5 cent, the excess of a sequence of 12 perfect fifths against seven octaves, see above) was split in small proportions to each of the 12 fifths [31.451, 459]. A strictly arithmetic equation for an equal temperament (ET12) derived from a subtle compression of the fifth away from the perfect ratio can be written thus (in a modern syntax)

$$\text{Solve}[(x/2)^{12} - (2/1)^7 == 0, x]//N\,.$$

The set of solutions includes $x \to 2.996615$, the value mentioned above, and also $x \to 1.49831$, which results as a decimal from the fraction 2.996615/2. Expressed in logarithms, $1200\log_2(2.996615/2)$ is exactly 700 cent, the size of each fifth in ET12. Calculation of equal temperament was performed, in Europe, by Simon Stevin (probably 1585, or around 1605), who returned to the issue known from Euclid's critical account of Aristoxenus that the octave comprises six equal tones. After some initial attempts [31.17, Chap. 2.3], [31.451, p. 179 f.], Stevin calculated the tempered minor third from

$$\sqrt[4]{\tfrac{1}{2}}$$

and the major third from

$$\sqrt[3]{\tfrac{1}{2}}\,.$$

He came very close to exact values for all 12 semitones. His treatise though was not published before 1884. Shortly before Stevin, in China the prince Chu Tsai-yu is said to have calculated ET12 by about 1584, however, the approach he took apparently is based on proportions and divisions of string lengths while a more abstract calculation of

$$\sqrt[12]{\tfrac{1}{2}}$$

for the semitone as it seems is not stated explicitly as a mathematic formula in his works [31.471, 472].

There were several concepts of tempering a chain of fifths so that a circle could be formed [31.459, p. 156 ff.]. *Johann Neidhardt* [31.473] offered a number of temperaments, still using a monochord for divisions of strings; a criterion featured in his concept for tuning fifths and major thirds in different *circles* are beat frequencies. His final proposal [31.473, p. 50 ff.] for an equal tempered scale was still derived from proportions, to result in fifths that are all 1/12 of a Pythagorean comma narrowed, major thirds that are all 7/12 comma wide, and minor thirds all narrowed by 8/12 comma. This is in fact ET12. However, at the time ET12 had been calculated correctly, it was hardly put to practice, for several reasons. One had to do with the laborious process of retuning in particular organs, another with the results of retuning that were found musically unsatisfying. As *Mattheson* [31.474, p. 144 f.] criticized, semitones tuned to ET12 *all sound out of tune, namely, if one does not hold them as such but against the singers and instruments, in particular the trumpet* [...]. Mattheson correctly recognized that the beat frequencies in ET12 change wildly with register and interval (the term *gleichschwebende Temperatur* that was used in many German publications as a synonym for ET12 is incorrect and misleading).

The quest for ET12 around 1700–1750 has to be viewed in regard to developments in music and music theory. Concepts of modes and clausulae derived from the eight Gregorian modes (and their expansion to 12 by *Glarean*, in his *Dodecachordon* [31.475]), had been complemented with new ideas concerning major and minor. A decisive factor was the acceptance of the just major and minor third as consonances and a discussion of how to use them in triads and harmonic progressions (as elaborated by [31.448]). Though traditional concepts of *mode* lasted well into the 18th century, even with modifications (as is evident from many works of J.S. Bach), the distinction between *hard* and *soft* keys (according to major and minor thirds) inherent in a diatonic scale d – e – f – g – a – b – c was found relative because every note of the scale could be changed by alterations up and down as needed [31.476, pp. 14–15]. *Heinichen* [31.477, 478] presented a circle (*Musikalischer Circul*) as a guide to understand relationships between common major and minor keys as well as a guide for modulation between such keys in a situation where an organist needs to improvise in a preludium. He [31.477, p. 262, Sect. 6] explained that, in the genus chromaticum covering the sharps, the musically relevant extreme would be reached with H-Dur (B-major), and in the genus enharmonicum covering the flats, at B^b minor (which Heinichen saw as a *tone* (tonus, key) hardly in use anyway). Further expansion around the circle, Heinichen warned, would be of no avail; this remark does not support the idea that modulation through all 24 keys was intended or that the *Circul* of 1711 reflects ET12. The compass regarded as musically relevant by *Heinichen* [31.477] is from five sharps

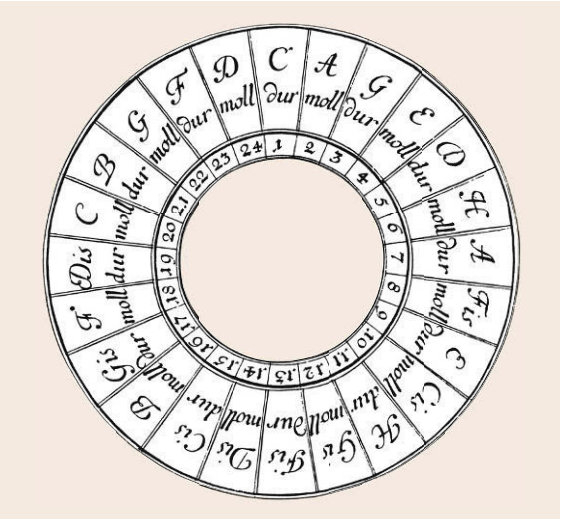

Fig. 31.25 *Musicalischer Circul* (after [31.478])

to four flats at the utmost. The circle in 1728 was closed by equating d# with e^b, and dismissing, besides e^b, keys that would have called for even more flats (Fig. 31.25 from [31.478, p. 837]).

Even though the 1728 *Circul* did not necessarily presume ET12, at least some *well-tempered* tuning close to ET12 seems implied in the circular arrangement of keys. In musical mathematics it was known that a chain of pure fifths could not be transformed into a circle and would result in a spiral instead if continued over many octaves [31.319, p. 156 f.]. However, there are concepts comparable to a *circle of fifths* outside of equal temperament like the cycle of Ṭhaṭ in north Indian music [31.366]; also Chinese historical sources from the Zhou period onward [31.479, pp. 65–67] elaborate on chains of pure fifths and fourths as a backbone of musical scale construction.

In regard to the normative interval of the perfect fifth, *Drobisch* [31.480, p. 32] described ET12 as *but one special case of the system of fifths* besides other variants (of which he reported and calculated several [31.480, 481]). However, ET12 became the standard tuning for *Western* music as played on keyboards since the fifths and fourths in this tuning system are nearly perfect and the major and minor thirds as well as the corresponding sixths are tolerable; the major third in ET12 at least is less prone to creating roughness than the Pythagorean 81/64 interval. With the spread of ET12 the *rivalry* between several prime numbers as a basis for musical intervals as encountered by Fogliano and Zarlino had been solved. But also ET12 has its cost: the *chromatic scale* in ET12 consists of 12 equal steps of 100 cent each and neither offers a chromatic (25/24 = 70.67 cent) nor a diatonic (16/15 = 111.73 cent) semitone; the very term *chromatic* thus is misleading inasmuch the distinct qualities of scales and modes based on different semitones (as are used in truly chromatic works, e.g., Sweelinck's *Fantasia chromatica*) have been eliminated. Also eliminated with ET12 on keyboards are differences in the relative consonance or dissonance of major and minor chords played in different keys that are clearly perceived in quarter-comma meantone temperament, prompting composers to express certain affective and emotional states by using different keys. Such differences were still available, to some extent, with *well-tempered* tunings, some of which can be regarded as outperforming ET12 since a gradation of keys is maintained while none of the intervals and chords sounds harsh (e.g., sixth-comma meantone, Vallotti/Young; [31.482, Chap. 18–5]). A problem introduced with ET12 on organs is the discrepancy between two tunings; while the pitches of the keyboard are now in ET12, pipes in the mixture stops are still in just intonation. A combination of both gives rise to audible beats and roughness in particular if major thirds are included in the pipe ranks (as in a historical *Terzzimbel*, which is very present in the sound of an organ).

The process of rationalization and simplification that led to ET12 has consequences for music theory, too. The development of modern major and minor tonalities in the 16th and 17th centuries as well as the chromaticism that became a formative factor demanded more than 12 (pitches/tones) per octave both in conceptualization and in musical performance. If one opted for just thirds in triads, and seeing that the just major and minor third add up to the perfect fifth (as Zarlino did), the implication is a web of pure thirds and fifths as embedded in a tone net (Fig 31.26).

–2-series	h	fis	cis	gis	dis	ais	eis	his

Fig. 31.26 Tone net from pure fifths (3/2) in the horizontal and major thirds (5/4) in the vertical

For readability, the tones/pitches are designated here with their labels as are used in Germany and neighboring countries. The series are ordered vertically with respect to syntonic commas; for example, in just intonation the tone *as* (a^b) in the +2-series is two syntonic comma higher in pitch than the corresponding tone in the 0-series while the tone *h* (b) in the -2-series is two commas lower than the tone *h* in the 0-series. The tone net shown in Fig. 31.26 of course is a section of a structure than can be extended in the vertical and in the horizontal as far as is needed (if one incorporates also intervals based on the prime number 7, the structure becomes three-dimensional; [31.52] and below).

As is obvious from the tonal relations involved, a simple cadence C – a – F – d – G – C in just intonation would require the following tones and pitches

−1 – series	d	a	e	h	
0 – series		f	c	g	d

There are two different tones for *d* relative to the center, $c = 1/1$, which have frequency ratios $9/8$ and $10/9$ that would be used in the d-minor and in the G-major chord respectively. If we consider another simple cadence in minor $c - f - B^b - E^b - f - G - C$, it is clear that the f-minor chord needs an a^b from the +1-series. The quest for enharmonic instruments in the 16th and 17th centuries [31.450] must be viewed, besides the aspect of exploring the ancient genera, as a serious attempt to give melodic and harmonic tonal relations as conceived and elaborated in compositions an adequate musical and acoustical realization. As one can hear and apprehend from cadences played on instruments like the *Clavicymbalum universale* (19 tones/pitches per octave [31.455, Cap. XL]; a replica was built by Keith Hill in 1983, now in the Organeum at Weener/Frisia), differences between chords with flats and chords with sharps are distinct and identifiable (of course, with appropriate training). In sum, the long struggle with tunings and temperaments as was pursued from about 1400–1800 would have been abandoned much earlier if differences in the tuning of scales and chords had been musically and perceptually irrelevant.

With the implementation of ET12 as a standard, the history of scales, as *von Hornbostel* [31.483, p. 13 f.] once put it, *inevitably ends*. Though chromaticism is found embedded in 19th century works written for the modern piano (for contrasting examples from Renaissance, Baroque, and 19th century music see [31.484]), it lacks the tension generated from two (or more) different sizes of semitones; the concept *enharmonic* totally changes its meaning under the constraints of ET12 in that, instead of marking a distinctive difference between sharps and flats (e.g., g# vs. a^b), both can be now substituted for each other by means of so-called *enharmonic equivalence*. Hugo Riemann, eminent music theorist, insisted that the difference between keys far apart relative to the circle of fifth (like g^b and f#) can be apprehended and even perceived (in *inner perception* that does not require actual sensory input [31.485]) from *reading* scores. *Riemann* [31.486, p. 117 f.] maintained that *orthography* is a decisive factor for music cognition, and for cognitive processing of harmony in particular while the effect of different keys taken as enharmonically identical would vanish for the listener of music. Riemann thus advocated an approach where musical textures have to be conceived (and heard in *inner perception*) in the tone system that represents pitch relations in just intonation while execution and sound production would be done in some temperament that would more or less level those differences (one of his major studies was on Beethoven's piano sonatas). Riemann, who at the beginning of his career followed concepts that aimed at giving music theory acoustical and psychoacoustic foundations as were provided by *Helmholtz* [31.28] and pursued also by *Arthur von Oettingen*, another physicist and music theorist known as a proponent of *harmonic dualism* [31.487, 488], later retreated to a dichotomy of music as conceptualized in *Tonvorstellungen* [31.489], on the one hand, and music as played and heard, on the other [31.300, 305]. In contrast, both Helmholtz and Oettingen regarded just intonation as the acoustical, perceptual and conceptual fundament of harmony, and both also owned special keyboard instruments to explore harmonic sequences in just intonation. *Stumpf* [31.490], acknowledging that the major and the minor tonality call for a *dualistic* perspective in harmony, but seeing that part of the formulations given by Oettingen and Riemann were at odds with common musical experience, tried to reconcile the sensory and the cognitive approach by stating that consonance and dissonance is a matter of sensation while conceptualization of harmonic structures is achieved in terms of *concordance* and *discordance*, respectively.

There are good reasons to take just intonation (JI) as an acoustical and psychoacoustic basis as well as a valid reference system for music theory: evidently, most of the complex sounds used in music are composed of harmonic partials so that chords combining harmonic complexes again superimpose perfectly if their fundamentals are in small integer ratios (Sect. 31.6.4). A chord played in JI has a clear and unambiguous sound structure, which in turn allows clear determination of tonal functions and harmonic relations among chords [31.52, 488]. Moreover, virtual pitches are elicited under this condition in an unambiguous way, and the difference between a major and a minor chord based on the same tone and fundamental (say, C-major, c-minor, both in *root* position, f_1 at 244 Hz) can be demonstrated em-

pirically as one of virtual pitch and not one of spectral centroid or brightness [31.305]. Therefore, if one would want to investigate concepts such as Rameau's *basse fondamentale* in a precise manner, it should be done with chord sequences realized in just intonation. JI is not advocated for obscure *numerological* speculation or a tedious effort for *purity* of intonation but for the sake of giving music theory, and in particular harmony, a valid acoustic and psychoacoustic basis as well as a meaningful reference system. Different from the time of Helmholtz, Oettingen, and Riemann when JI was awkward (and costly) to realize on keyboards, calculation of relevant pitches (see Appendix in [31.52] for a closed system of 171 pitches based on prime number {2, 3, 5, 7} ratios) and implementation as a software–hardware platform nowadays is feasible [31.318].

If no particular precision is required or wanted, for both musical performance and conceptualization, ET12 will do. It is in fact kind of a 'mean tone system' in many regards. First, the tritone in this system is calculated as the geometric mean that exactly halves the octave. Second, the semitone in ET12 is about the average between a chromatic and a diatonic semitone, and the two thirds in this system are about the average taken from the just and the Pythagorean ratios (however, with a closer approximation of Pythagorean values). So, if one assumes that intonation of singers and instrumentalists, in many if not most areas of *Western* musical practice, lies somewhere in between the two systems (Pythagorean, JI), the probability that data from measurements will approach more or less ET12 pitch values is high in particular if such data are averaged per *pitch class* (as in many publications on intonation); averaging data this way unfortunately disregards melodic and harmonic functions of tones/pitches within musical structure. What is achieved thus, is interpreting averaged intonation data referenced to an averaged ET12 system of pitches. Further, to keep things plain in terms of *categorical perception*, one may suggest that a pitch in music should be viewed as representing a diatonic scale step and its low and high alterations as well as a broad range of intonation patterns admissible for that pitch [31.55]. Such a view implies perception of pitches always can be reduced to that of pitch *categories* in a diatonic scale. To simplify things even further, one might add some assertions like the difference between a natural seventh (969 cent) and that available on a piano (1000 cent) would be within the tolerances of the ear anyway so as to justify neglecting it. If empirical data indicate otherwise [31.374, 377], one can still ignore them to keep things simple for elementary music education or similar purposes outside musical science.

Intonation in musical performance should realize certain scale types, modes and harmonic structures. Intonation can be guided (and is also limited) by sensory, cognitive, sensomotoric, acoustic, technical and other factors. For a singer or instrumentalist, a note in a conventional notation indicates f_1 of a certain tone that he or she aims to produce. However, notation often is only relative as, for reasons of convenient reading, simplifications in regard to accidentals might be made (in particular, to avoid double accidentals). In effect, of the ≈ 35 pitches that can be expressed per octave [31.50] without introducing additional symbols for intonation, often a selection is used that serves readability rather than precise intonation. If *enharmonic equivalence* is applied to accidentals, notation cannot escape ambiguity with respect to pitch information. Hence, intonation of advanced tonal music (such as string quartets, saxophone quartets, or orchestral works) requires harmonic analysis that must be done before any performance takes place. As part of such an analysis, intonation signs have to be added to the conventional notation as needed [31.52]. Musicians familiar with certain genres and their harmonic and interval framework may not need such auxiliary information, however, one has to remember that musical performance often is done in public and with the constraints of real-time execution; therefore, to reduce stress as well as notational ambiguity, auxiliary intonation signs can help. If notation is ambiguous in regard to pitch information and intonation, musicians in general try to do as good as is possible, playing or singing a pitch that they are certain fits the relevant *pitch category*, with an option to do some fine-tuning in an ensemble in particular on long-held notes. One can observe subtle pitch adjustments in chords in small ensembles performing madrigals, even of the truly chromatic and enharmonic genus (for an instructive audio demonstration, listen to the CD accompanying [31.491] as well as to recordings of madrigals from Monteverdi and Gesualdo performed by The Consort of Musicke, London). The same mechanism of pitch adjustment toward JI is observed in barbershop singing [31.374, 377] and also in string and saxophone quartets unless extensive vibrato is used by one or several players. Vibrato, which was sparingly used in Baroque music (and despised still by Leopold Mozart as a violinist), has become a means not only of operatic expression (as in belcanto singing) but also a means to disguise intonation deficiencies or insecurity. Vibrato extent measured in lyric singing can exceed ± 100 cent, on single notes [31.492]. In Fig. 31.27, vibrato of a soprano singing the word *Engeln* in Richard Wagner's Lied *Die Engel* (*Wesendonck-Lieder*) is shown. Pitch oscillates widely around B_4; detailed analysis with a gammatone filter bank revealed that the pitch shifts between ≈ 505 Hz and ≈ 585 Hz (a range of ≈ 250 cent).

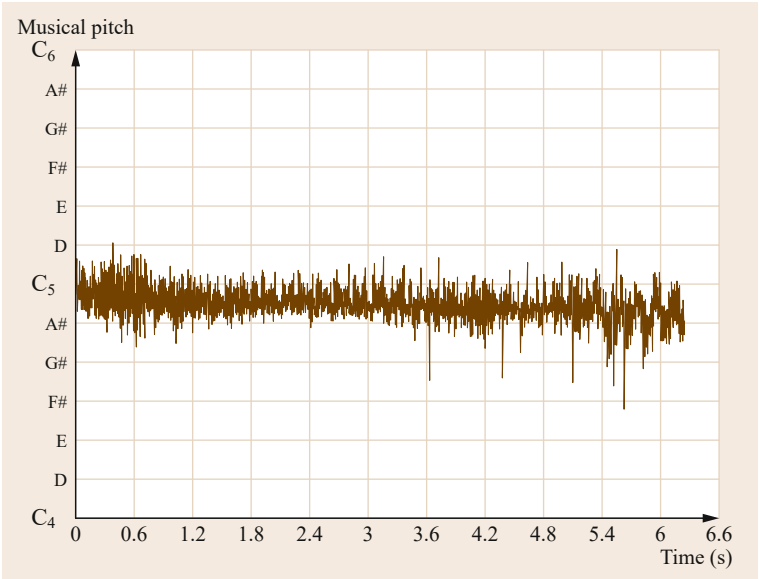

Fig. 31.27 Vibrato, soprano singing one word (*Engeln*), pitch shifts around B_4

Though listeners in general can derive a *mean pitch* from tones played with regular vibrato [31.493], vibrato to the extent shown in Fig. 31.27 blurs tonal structures. On the other hand, microtonal inflections as are produced by string bending on an electric guitar in blues and rock music often span a well-defined pitch range, and can be perceived accordingly. A musician producing precise string bendings as did the late Stevie Ray Vaughan in songs like *Texas Flood* [31.494] of course controls with his ears the sensomotoric process of fingering and applying force (increasing with pitch) to a string up to a target pitch level. Sensomotoric action and auditory pitch control are thus parts of a systemic feedback loop.

One last aspect to be included into this section is the assertion according to which a number of non-Western music cultures use scales in some equal temperament (ET). A popular view is that *gamelan sléndro* expresses ET5 and that the scale known from Thai gong chimes and xylophones (as in *piphat* ensembles) is in ET7. Hence, slendro is understood as 5×240 cent and the Thai scale as 7×171.4 cent. Also a number of African xylophones have been viewed as expressing either ET5 or ET7 (for background information see [31.93, 248, 495]. It seems that Alexander J. Ellis introduced the thesis of non-Western ET scales, unfortunately from measurements that can be called superficial at best. His argument, in short, was that there is not one *natural* scale (i. e., a scale based on small integer string or frequency ratios) but many different scales. To underpin his claim of diversity, Ellis strangely enough stressed that not only Europeans were using ET but also cultural groups as far away as South East Asia. Ellis' thesis has been reiterated time and again even though empirical data on idiophone tunings was scarce before empirical measurement could be done with suitable equipment and precision (i. e., from about 1970 to the present). Moreover, most studies on non-Western scales and tunings started from measurements of single spectral components (for example, by low-pass filtering complex inharmonic sounds) whereby frequency readings of the lowest spectral peak in each sound were taken as representing its *pitch* as well as a scale step in a certain tuning. Such an approach might hold for harmonic complex tones where one might regard f_1 as decisive for (place and periodicity) pitch, with the other harmonics reinforcing the overall periodicity (Sect. 31.4). In complex inharmonic sounds, however, there can be a number of strong spectral components in frequency ratios quite different from $f_n = nf_1$, $n = 1, 2, 3, \cdots$ (see analyses in [31.93]), which may be perceived as discrete spectral pitches. In addition, a number of strong inharmonic components in a sound can give rise to a virtual pitch at a frequency other than that corresponding to the lowest mode of vibration (as found in the spectrum). To illustrate the problem, one example shall be given. Taking a *saron ricik* in slendro tuning (a metallophone of six bronze plates corresponding to six *keys*; the instrument in question is part of the Gamelan *Kyahi Timbul*, manufactured in Yogyakarta), the f_1 components from six keys/sounds are displayed in Fig. 31.28.

Though one interval is considerably larger than the theoretical 240 cent, and another one smaller (as is typical for most slendro tunings), one could still take these differences as deviations from a *mean* scale step intended as realizing ET5. However, if the sounds from

Key	1	2	3	4	5	6
Hz	548.59	628.99	720.11	843.39	977.39	1114.04
Cents		236.8	234.2	273.6	255.3	226.6

Fig. 31.28 Javanese *saron ricik*, slendro tuning, spectral f_1 frequencies and cents

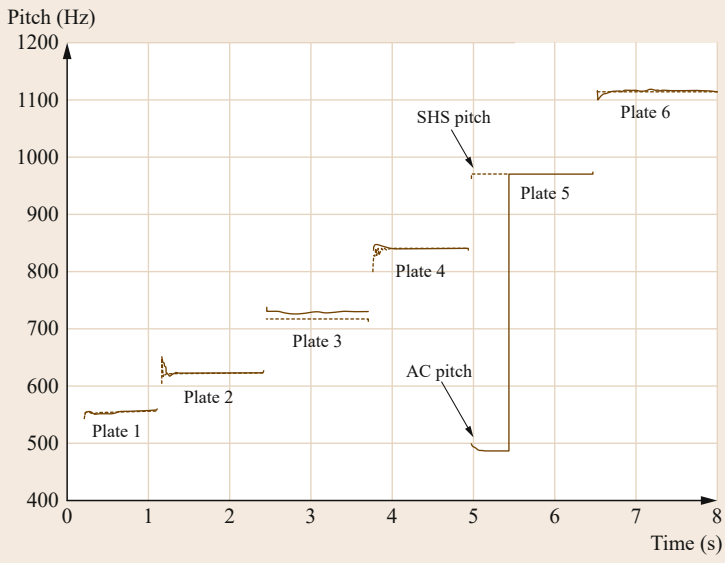

Fig. 31.29 Javanese *saron ricik*, pitch frequencies (AC and SHS). AC pitch for plate/key no. 5 at first is at 486 Hz (which is a subharmonic at 1/2 of the most likely pitch frequency). *Solid line*: AC pitches, *dashed line*: SHS pitches

Key	1	2	3	4	5	6
Pitch	554.1	621.69	717.13	841.39	970.87	1114.75
Cents		199.27	247.25	276.63	247.81	239.24

Fig. 31.30 Javanese *saron ricik*, slendro tuning, measured pitch frequencies (AC, SHS) and cents

the six plates and keys are subjected to a measurement of virtual pitches (by either AC or SHS algorithm, see Fig. 31.29), the deviations from a unit step assumed to be close to 240 cent do not disappear; instead, a scale of unequal steps becomes more likely as the five intervals between six keys are now as can be seen in Fig. 31.30.

Evidently, the octave is slightly enlarged at 1210 cent. Though the series of pitches measured does not lend to viewing *slendro* as ET5, it seems possible that Javanese musicians regard all intervals as *functionally equivalent* (the Javanese concept of *pathet* apparently combines features of *key*, *range*, and perhaps also *mode* [31.496]).

31.9 Geometric Pitch Models, Tonality

Concepts of scales and modes often involve geometrical structures (as does the very concept of a *scale*). Ordering of tones was done in a spatial arrangement at least since the time of Archytas. There are many technical terms in Greek music theory that are derived from geometry (or the other way round, geometrical concepts derived from measurement of string sections on the kanon [31.436, Part. 2], [31.443]) such as *diastema* (interval on a straight line or string) and *horoi* (endpoints of a line or string, also the two points that define an interval). That which is divided by two horoi is a *difference* (*hyperoché*), most of all, a difference in pitch. There are more terms and concepts with a geometrical background that have implications also for perception: Aristoxenus elaborates on the *topoi* of tones, which is the range within which so-called movable tones (*kinoumenoi*) can change their position while certain tones (*hestotes*, the tones framing tetrachords as well as whole steps at the bottom of the tone system and between disjunct tetrachords) are fixed in pitch [31.438].

The term topoi here refers to the positions a movable bridge or fret can take on a kanon; a change of topos means a change in the interval structure within a tetrachord, and a *difference* in pitch or pitches. According to Aristoxenus [31.438, p. 135 f.] there is a limit for the smallest difference that can be adjusted precisely on the kanon and also identified by ear (this of course is not a JND but a musically relevant interval, a small diesis that roughly is about 40 cent wide). The tones of the Greek tone systems (11, 15 or 18 tones either spanning an octave plus a fourth or two octaves [31.71], [31.438, p. 11 ff.]) can be conceived as ordered along a dimension low–high. One of the interesting issues discussed in Greek musical mathematics and philosophy is the problem of discrete entities and continuous magnitudes (as well as their distinctive differences and possible relations). The musical concepts of interval, boundaries and *difference* are part of this discourse.

One has to take the historical background into account when studying medieval sources on scales or even modern publications on pitch. In *Herbart*'s model of a one-dimensional *Tonlinie* [31.497, 498], tones are considered as points in a continuum; tones can be compared with respect to their linear distance. The idea behind this concept is that stimuli such as tones differ in certain parameter values, for instance frequency; differences are quantifiable and can be expressed as distance functions. In regard to sensation, it can be assumed that a growing difference in parameter values results in decreasing similarity or increasing dissimilarity of pairs of stimuli (Sects. 31.1, 31.7); hence, the effect on sensation can likewise be expressed as a distance function [31.93, p. 404 ff.]. *Stumpf* [31.39, p. 144] agreed to Herbart's concept, stating that the manifold of pure tones has but one dimension. The decisive argument for Stumpf was that, of any three tones A, B, C, only one can be in the medial position. Consequently, the three tones must fall on the same line. *Wundt* [31.499, p. 59 f.] added that it is *simple tone sensations* (sensations of sine tones of a given frequency) that make up the continuous manifold of but one dimension. Also *Mach* [31.500, p. 217] agreed on the one-dimensional construct, saying that the series of tones has to be viewed as an analogy to a space of one dimension, which can be conceived as a vertical line (since tones are ordered along this dimension from *low* to *high* in pitch) or as a line that runs in a median plane from front to back. Mach held that a series of tones (which are sensed as pitches) does not have symmetry; this implies there is no center or reference point. However, according to Mach sensation of a certain tone must be fixed to one distinct place in this one-dimensional tonal space.

The one-dimensional model of tones reflects aspects relevant for manifolds and continua as mathematical and physical structures; it might be recalled that Leibniz and Brentano had discussed foundations of continua while Riemann and Helmholtz contributed to differential geometry and higher-dimensional spaces [31.93, p. 404 ff.]. *Stumpf* [31.303, p. 165 ff.] underpinned the idea that one-dimensional continua of pitches (*Tonhöhen*), intensities, brightnesses, etc. are conceptual abstractions, while any tone we hear of course does have a pitch, an intensity, and a brightness as inherent properties. However, the construct of the *Tonlinie* could have been judged as unsuited for psychophysics since it disregards a basic perceptual experience, namely octave equivalence. A more appropriate model was proposed by *Opelt* who, in a preliminary booklet in [31.501] and in a more detailed publication of [31.313] offered a theory of pitch perception based on sequences of impulses and periodicity detection. He tabulated the intervals within one octave (see the Table in Fig. 31.31, no. 23) as logarithms corresponding to millioctaves, that is, $1\,\mu o = \sqrt[1000]{2} = 2^{1/1000} = 1.0006934$. The just major third 5/4 has (in rounded figures) 322 μo, the perfect fifth 3/2 has 585 μo; in ET12, the major third has 333.33 μo, the fifth has 583.33 μo, and the tritone of course has 500 μo. Opelt did not advocate ET12 except as a compromise needed for keyboard tuning. Instead, he [31.313, p. 40 ff., 66] correctly saw that ET31 would be needed as a tuning where all major chords 4 : 5 : 6 : 7 : 8 could be played with good approximation to just harmonic intonation. Since 31 tones and pitches per octave is a temperament that affords ingenuity and costs if implemented on a keyboard [31.382, 383], Opelt dismissed the natural seventh (his chord scheme thus became 4 : 5 : 6 : K : 8) and suggested 19-tone equal temperament (ET19) as a pitch and tone system relevant for conceptualizing music while, for practical reasons, ET12 would have to do on keyboards. To be sure, division of the octave in ET19 was propagated later also by *Yasser* [31.502]. The pitches and tones available in ET19 include a nearly just minor third 6/5 (315.8 cent) and an almost just major third (379 cent) while the fourth is about 7 cent wide (505.3 cent) and the fifth is about 8 cent narrowed (694.7 cent).

Opelt's approach included fundamentals of vibration and pitch, consonance and harmony, as well as aspects of rhythm perception, which are all treated from the fundamental principle of isochronous pulse sequences. It is of interest to note that he apparently was the first to offer a geometrical model of pitch in three dimensions. He first derived numerical calculations for two scales (ET19 for apprehension of music and ET12 for the limitations imposed by keyboards) along with a geometrical model that comprises the relevant sections on various (linear and logarithmic) lines (see Fig. 31.31, no. 19, included in [31.313] as plate

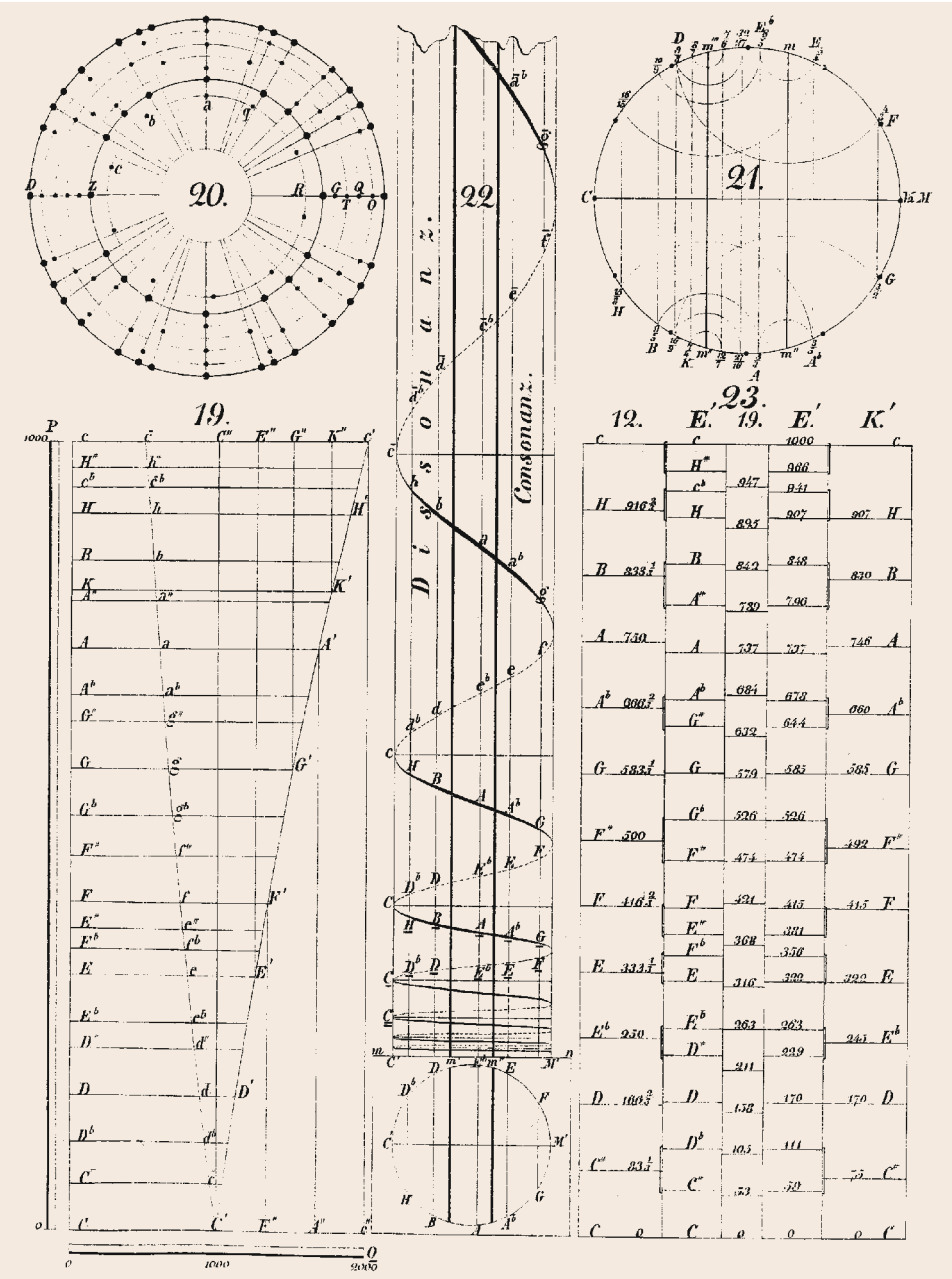

Fig. 31.31 Tone curves, tone circles and tone column designed by *F.W. Opelt* [31.313, 501]

VI). As a next step, his scales are transformed into circles (Fig. 31.31, nos. 20, 21) which also permit the finding of the pitches/tones for chords in each key. Different from later models, the cross-section of the circle (C–M in no. 21) in fact is *not* meant to yield the tritone in ET12 that Opelt considered musically irrelevant. The point M opposite the starting point C is only needed for symmetry within each octave. Finally, the logarithmic line (C′c′ in no. 19, labeled *Toncurve* = tonal curve by Opelt) representing the pitches is wound around a cylinder whose base is the circle of pitches. Complementary intervals adding up to the octave (e.g., fourth and fifth, major third and minor sixth) are found on the same ordinate. With the ascent of the logarithmic pitch scale wound around the cylinder (labeled *Tonsäule* = *tone column*; Fig. 31.31, no. 22), the scale becomes full circle after exactly one octave. The model Opelt designed nicely accounts for the rise of absolute frequency values

per octave; therefore, the helix angle of the tone curve increases in proportion to the frequency level reached in higher octaves.

Opelt's model was adapted by *Drobisch* [31.481, 503], who, however, changed the concept inasmuch as Opelt's conceptualization of just pitch relations (already simplified to ET19) is now further simplified to ET12. As a consequence, the circle of ET12 pitches is halved by f# opposite the starting tone/pitch of c. *Drobisch* [31.481, p. 35 ff.] refined Opelt's model by implementing radii from the center of the tone circle to the tones located on the tone curve wrapped around the cylinder [31.481, Fig. 3]. Thereby, he obtained a helix (like a staircase in a round tower [31.300, p. 24]).

Opelt's model of a spiral of tones/pitches wrapped around a cylinder and Drobisch's adaptation became fairly influential; *Lotze* [31.57, p. 212 f.] referred to the model and explained the musical scale phenomenon as a combination resulting from linear elevation (on the ordinate) and a declination sideways (with respect to the tone curve). From the perspective of his two-componential theory of pitch, *Révész* [31.37, p. 20] argued that a representation of the continuous element of pitch (height) together with the periodic element (tone quality) can only be achieved in a three-dimensional model like the spiral. He objected, though, on the grounds that the spiral would be ostensive yet not quite correct since its curvature does not account for the constant direction of tone height (since it rises linearly, a straight line would be more apt). *Révész* [31.56, p. 75] included a graph of the spiral wrapped around a cylinder into his account of two-componential pitch; it was, however, close to Opelt's original version and not the helix designed by Drobisch. To avoid misinterpretations, one has to observe that, in the spiral or helix model, two *components* of pitch are mapped on a geometrical construct of three *dimensions*. As has been underpinned above (Sects. 31.1, 31.7), these components cannot be regarded as independently variable (at least not in a musical situation where common instruments and vocalists generate tones).

A slightly modified construct of the *tone column* involving the spiral was presented by *Ruckmick* [31.504] who suggested a *tonal bell* as a geometrical model to incorporate another spatial attribute of sound: volume (Chap. 32). *Wellek* [31.505, 506] gave a detailed analysis of pitch and tonal attributes (height, brightness, volume, weight, density) that are variable as a function of frequency in regard to their dimensional (or, rather, nondimensional) structure. He [31.505] argued that, in musical perception and cognition, time would also be conceived spatially, and indeed is a dimension of tonal space since music and even a simple scale unfolds in time. The only other true dimension is that of low–high. In order to incorporate several components from the range of tonal attributes, a possible geometrical representation according to *Wellek* [31.505] would look like a slim cone or pyramid, however askew with the base close to the front and the peak more back in space (to account for *volume*, similar to the *tonal bell* of Ruckmick).

More recently, Opelt's spiral and Drobisch's helix have been expanded to a double helix and even more complex structures by *Shepard* [31.507, 508]. One aspect not covered explicitly in the tonal column of pitch is the relation of tones in a chain of fifth as well as its variant, the circle of (tempered) fifths (Sect. 31.8). Though it is obvious that the diatonic and the chromatic scale can be derived from a chain of perfect fifths ordered into one octave, the ascending tone curve (Fig. 31.31) does not reveal the progression in fifth as a separate *dimension*. Taking complex tones composed of sinusoidals spaced in octaves and garnered under a symmetrical spectral envelope [31.78], one can, to some extent, isolate *tone quality* by keeping the spectral centroid relevant for the sensation of both *tone height* and *brightness* of sounds constant (Sects. 30.2 and 31.1.2). With tone height and brightness kept on the same level, a scale of so-called *Shepard tones* thus is a movement in a plane circle. From the circle of tempered fifths then a double helix can be formed [31.507, Figs. 2, 3], which, together with the *chroma cycle* of ET12, results in a double helix wrapped around a torus in four dimensions. If the linear dimension of *height* is added, a five-dimensional structure incorporating the double helix wrapped around a helical cylinder results [31.507, 508].

The model is consistent in regard to certain requirements, namely, invariance under transposition, octave equivalence, and uniformity of scale steps. These requirements in general are fulfilled if one uses ET12 as is done by *Shepard* who [31.508, p. 316, Footnote. 4] also relies on categorical perception to anchor his model on the *chroma cycle* so as *to disregard the distinction between a sharp of one note and the flat of the note just above (e.g., $C^{\#}$ versus $D^{\flat}$)*. The five-dimensional model, impressive as a geometric structure, is linked to findings from probe-tone experiments [31.509], which also employed *Shepard tones*. The probe-tone method demands that subjects rate how well a probe fits to an element presented before. Elements can consist of diatonic or chromatic scales, single chords, or combinations of chords such as cadences. Perhaps the most common element is a diatonic scale in either major or minor followed by the probe tone. Also chords and cadences in major and minor have been employed in a host of experiments. The judgment done by subjects on scales of 1 (poor) to 7 (good) apparently is

one involving a goodness-of-fit estimate. For each trial one obtains a profile; for instance, 12 chromatic *Shepard tones* are presented as probes following a diatonic scale based on any of the these 12 chromatic pitches (also in ET12). Data from such experiments have been subjected to multidimensional scaling (MDS), and the findings have been interpreted as reflecting an internalized hierarchy of tonal relations [31.327, 509].

Most of the probe tone profiles obtained from such ratings exhibit a characteristic shape that is reminiscent of another profile, namely that of roughness and dissonance versus consonance as developed by *Helmholtz* [31.28] and repeated in a host of studies since (Fig. 31.12). For example, the following probe tone profile was obtained from a group of 45 students in an introductory course in music psychology (Hamburg, December 2001) for a C-major scale presented with synthesized piano-like tones (Fig. 31.32).

Since the ratings are on an ordinary scale, median values (*dashed line* in Fig. 31.32) were calculated along with the means. The highest ratings are found for C (median = 6.0, mean 6.0) and G (mean = 5.29, median = 6). The other diatonic scale tones also obtained higher mean and median ratings (E = 4.24 mean, median = 4) than the accidentals, of which C# scored lowest (mean = 2.44, median = 2). The tone B scored high at 5.58 (mean) and 6 (median), which is unsurprising since this probe tone is a repetition of the diatonic scale (C, D, . . ., B) offered before as *context*. The ratings for D, E, F, G, and A can also be explained from both the general familiarity musically trained subjects have with a C major scale and from the effect of STM in which the whole scale will be stored. Different from the short buffer available in language as a *phonological loop* [31.510], STM for tone sequences and thus scales, is much

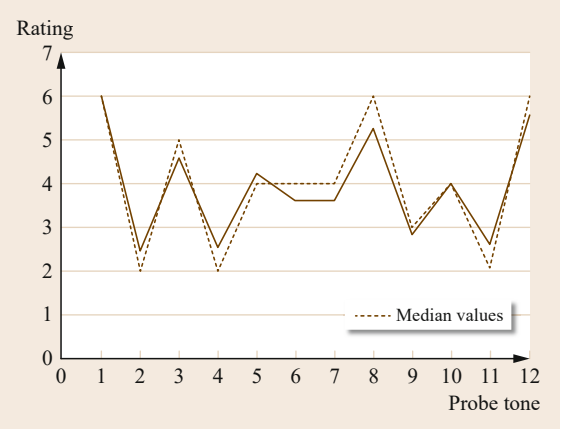

Fig. 31.32 Probe-tone profile, C-major scale, 12 probe tones C, C#, D, . . ., B based on means obtained from 45 subjects; *dashed line* = median values

greater [31.218] and can easily accommodate the *context* which, in this experiment, took about 2.7 s presentation time. The probe followed after a break of 250 ms and lasted for less than 500 ms, thereby the diatonic scale offered as context, the break and the probe add up to ≈ 3.5 s (this is a time window assigned to STM even from a conservative perspective [31.373, Chap. 4]). The probe can be compared to the complete diatonic scale to assess whether it fits from a musical point of view; probes representing diatonic scale steps thereby should receive significantly higher ratings than accidentals, what in fact they did (Fig. 31.32). In addition, there is a psychoacoustic effect if the probe is in marked dissonance with the scale and in particular with the last note of the *context*. The mean values for 12 scale tones in Fig. 31.32 correlate positively at $r_{xy} = 0.5$ with the means of consonance ratings for 12 intervals (from unison to major seventh) shown above in Fig. 31.12; since the data were obtained from two independent samples (2001, $n = 45$; 2009, $n = 51$), the correlation indicates that sensory consonance–dissonance plays a role also in probe tone ratings. *Leman* [31.511] demonstrated in simulation experiments involving a model of the auditory periphery as well as an echoic memory module that probe-tone profiles can be generated from the acoustical input (even from Shepard tones) without reference to hierarchic tonal schemes stored in LTM. Evidently, the *context* stored in STM as a sequence of pitches is sufficient for a perceptually driven comparison of the probe to the context in order to find whether or not the probe *fits*. This bottom-up processing approach is corroborated by findings from event-related potential (ERP) studies, which show that musicians are faster in encoding a regular sequence (*Neuhaus* [31.512] condition P^oD^o) than nonmusicians. Apparently, musicians need about three tones to make preliminary inferences as to the structure that is processed. Such inferences seem to involve expectancies about the direction in which a sequence is likely to continue as well as the shape it might adopt (there are indications that a frontal N300 component occurring in a time range of ≈ 300–600 ms after onset relates to expectancies with respect to sequential processing; see discussion in [31.513]). While processing of auditory input stored in STM seems feasible for rather short and simple tone sequences in regard to feature extraction and comparative tasks (e.g., an estimate of the goodness-of-fit of a probe tone), more complex structures call for the involvement of LTM. Consider, for instance, identification of modal structures in music where listeners have to analyze a melodic-diastematic formation in order to recognize which tones carry certain modal functions (like repercussa, finalis, confinalis [31.435, 514]). Guido (*Micrologus*, cap. xi) remarked that we can only

identify a mode beyond doubt after the very last note has been heard. One of the reasons is that a scale at the base of a mode can be different in upward and downward direction (as is often the case in Arab and Turkish Maqām/makam and in Indian Rāg [31.365, 366]). To provide even expert listeners with some *aide-mémoire* to recall complex modal structures interwoven with characteristic melodic patterns, Arab and Turkish classical music offer the Taqsim/taksim (as a fairly extended introduction to a maqām/makam) and North and South Indian classical music likewise offer an Alap in a similar function to introduce the Rāg succeeding it. Recognition of extended modal structures embedded in elaborate melodic-diastematic formations of course requires that listeners can reactivate their knowledge stored in LTM.

Finding the *tone center* or even the *key* of a piece of music has been achieved algorithmically, in a number of studies many of which used artificial neural networks (ANN [31.328, 329, 515–517] and [31.327, Chap. 4]). Experimental data suggest that the tone center, like pitch in general, is an emergent property that appears if a processing unit (an ANN or possibly a human) is exposed long enough to appropriate sound stimuli. Apparently, there are processes of self-organization in ANN (once they have been trained) capable of determining relationships between chords and keys organized in the ET12 circle and to store the results as schemata [31.518, 519]. Moreover, it has been shown in many experiments that ANN can accomplish a broad range of classificatory tasks from pitches and keys to meter, rhythm, timbres, and even genres and styles (see, for example, articles collected in [31.520]).

The causal approach to *tone semantics* [31.328–330] can draw on features inherent in tonal sequences and chordal patterns (in particular if realized with complex harmonic tones in JI). The normal cadence I–IV–I–V–I in Western harmony can be conceived as combining three triads related by perfect fifths and fourths; the consonance of fifths as well as identical tones in pairs of chords accounts for the perceptual affinity of chords within such a cadential schema. (In a *probe chord* experiment conducted with 45 students in 2001 in our institute, the G-major chord played with complex tones following a C-major chord as a reference did yield a mean of 4.47 on a scale of 1−7; SD = 1.29.) Human listeners familiar with *Western* music of the 18th and 19th century will make inferences as to a *tonal center* (or a sequence of several centers in a symphony or sonata) of a work they listen to from the occurrence of certain chord progressions, cadential schemata, as well as from the metrical accents and formal structure in which parts are arranged. For example, in a short and fairly simple piece like Chopin's Prélude in A-major the tonic occurs on the first quarter of the first bar, to be followed by the dominant seventh (bars no. 1, 2) and recursion back to the tonic in bars 3 and 4, etc. Thus, the center is clearly marked by the $T - D^7 - T$ progression that is a standard feature of indicating *tonality* and/or *key*. The only mildly *surprising* part of the work in question comes in bar 12 where a phrase ends on a $F\#^7$-chord. The note f# of this chord relates to the tonic by a minor third; $F\#^7$, as a seventh chord, can be conceived as the dominant of B (which, in turn, is the *secondary* dominant (in Riemann's terminology, *Wechseldominante, DD*) to A). The harmonic tension thus generated, however, is *released* in a plain progression of major chords $F\#^7 \rightarrow B \rightarrow E^7 \rightarrow A$ based on relations of fifths and fourths, respectively. Listeners familiar with Western harmony will have no difficulty in finding the tonal center and to apprehend harmonic functions of chords in musical textures like this. One could argue that the Prélude mentioned makes use of tonal schemata that demonstrate a *natural* as well as a *logical* organization; both aspects played a role in music theory from Zarlino to Riemann, and beyond [31.521, Chap. 16], [31.52, 300, 305]. *Riemann* [31.486, 522] developed an elaborate system of tonal relations and harmonic functions that reflects their *logical* character (in terms of *propositions* involving thesis, antithesis, and synthesis) as much as their *natural* foundations (the graded affinity of tones due to different degrees of consonance). This system can be condensed into a geometric structure (Fig. 31.33) where c is the center [31.523].

Riemann's system of harmony was devised to analyze and describe works composed between, roughly, 1700 and 1850. He devoted special studies to the piano sonatas of Beethoven, among other subjects. By the time of Beethoven, tonal harmony had evolved into advanced modulations while the fundamental cadential schemata familiar to listeners were still in use. A study of Western tonality of course cannot dispense with the historical background that is suited to reveal the very gradual transition from modal polyphony to functional harmony in music and music theory, between circa 1400 and 1750 [31.458, 524, 525]. For this process one can find a sample of *typical* and also a number of rather *untypical* cases both in theoretical writings and in musical compositions. Take, for example, one of Josquin des Prés' so-called *gospel motets* (*In principio erat verbum*) marking the transition from the 15th to the 16th century. In this work (recorded by, among others, René Clemencic and Musica Antiqua and Prague Madrigalists), one may observe many features known from modal techniques [31.526] while the cadences exhibit also strains already pertaining to major–minor tonality. In contrast, there are works written in the 20th century that fully ex-

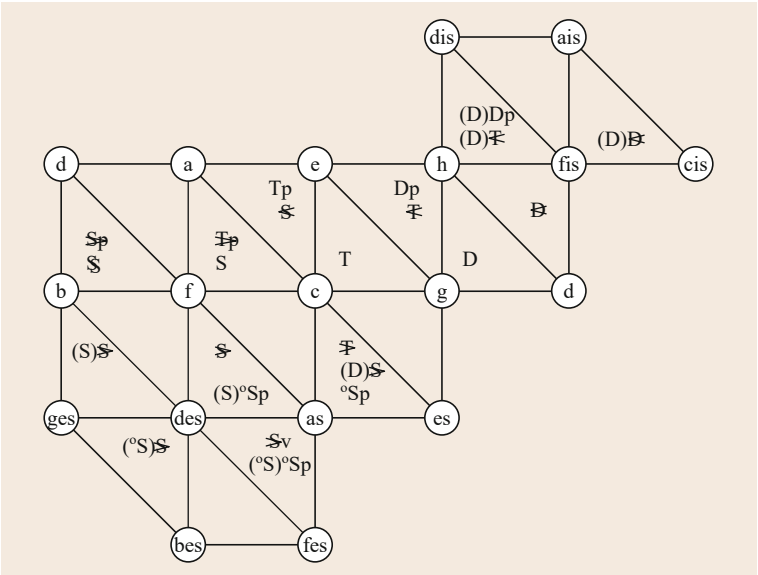

Fig. 31.33 Riemann's system of tonal relations and tonal functions (after [31.523, p. 81])

plore harmonic tonality and also incorporate elements known from modality (e.g., Vaughan Williams' *Fantasia on a Theme by Thomas Tallis*). To account for the harmonic structure of works such as Vaughan Williams' *Fantasia* or complex chordal textures as offered by Wagner (as in the *Tristan-Vorspiel*) or Strauss (in *Salomé* and other works), resorting to 12 *pitch classes* and a circle of 12 *chromatic* tones conceived in ET12 (by analogy to the 12 keys of a piano) is inappropriate. For example, in the *Fantasia* the so-called *five-chord motive* (based on a progression $G-F-g-A^{b}-G^{b}$) alone calls for 12 different tones/pitches. Even a composition clearly written for keyboard like the first *duetto* from part III of the *Clavier-Übung* by Bach (e-minor, BWV 802) according to the notation supervised by Bach has 17 pitches; this is a fact to be considered as evidence in an analysis of the melodic and vertical interval structure and, consequently, in regard to intonation. If one concedes this duetto can be played on a keyboard with but 12 keys and pitches, it is likely that by such a reduction some ambiguous intonation and a loss of the distinctness of intervals used in both melodic progression and simultaneity will be introduced.

The point that seems decisive for music theory and psychology is whether tonal relations embedded in interval and chord structures of musical works open to analysis shall be realized acoustically as pitch structures so that a correspondence between the two is achieved (within close limits). This is an issue that has led to debates and practical solutions as early as the Renaissance (for instance, Vicentino's 1555 treatise and his attempts at practical realizations of enharmonic music [31.450, 491]) and ever since. In the 19th century, *Helmholtz* [31.28], *Bosanquet* [31.51], *von Oettingen* [31.487, 488] and *Shohé Tanaka* [31.527] were among the leading scholars who advocated JI along with enharmonic keyboard instruments capable of rendering audible tonal structures far beyond diatonicism. Of course, such instruments were difficult to master and useful rather for demonstrating how specific chord progressions and modulations found in certain works of music were conceived, and should be apprehended, in analytical listening. One of the means of analysis that was recommended to be used in combination with enharmonic keyboards was the so-called tone net of perfect fifths and just major thirds proposed first by the mathematician *Leonhard Euler* [31.528] as a means of describing tonal relations in a clear and comprehensive way. The physicist and music theorist *Arthur von Oettingen* [31.487, 488] took up this concept [31.529]. He argued that, with respect to a tonal center defined by a certain tone and pitch (say, c), the tones and intervals shown in Fig. 31.34a are perceived as related.

The tones closely related to the center are the major third above and below this tone and the fifth above and below the center tone (the relations establish two symmetry axes). Also related to the center (but to a lesser degree) are the major third above and below the two fifths above and below the center. In sum, there are eight tones connected in this way to each center. To be sure, similar schemes adopted by Eitz and some other researchers reduced the number of tones related to the center to six (two fifths, two major thirds, two minor thirds).

Riemann [31.489, p. 19 ff.] adopted the reduced version of the tone net; the reason was that he saw

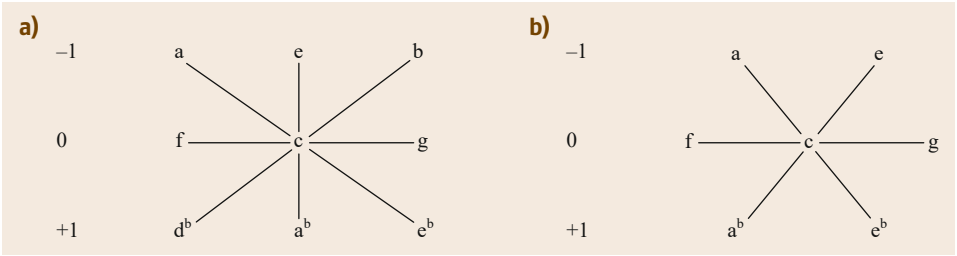

Fig. 31.34 **(a)** Tone center, related tones and symmetry axes (after [31.488, p. 386]), **(b)** Reduced tone net (adapted from [31.488, p. 384])

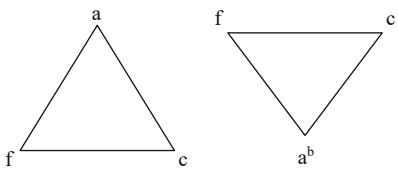
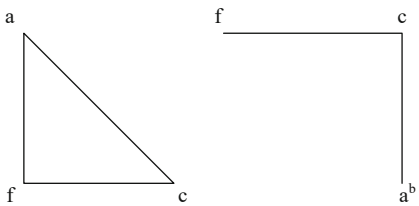
a constant shape of three tones forming either a major or a minor chord.



However, a constant shape also results from the more refined version of the tone net offered by *Euler* [31.528] and von Oettingen (one may either use triangles or open lines).



More advanced versions of the tone net were developed by *Fokker* [31.382, 530] who, following ideas already issued by Christiaan Huygens on incorporating intervals based on the prime number seven, pointed to the possibility of a three-dimensional structure. *Vogel* [31.52, 529] further elaborated this concept and developed a three-dimensional lattice structure (Fig. 31.35) that incorporates sequences of perfect fifths in the horizontal, sequences of just major thirds in the vertical, and the natural seventh (4/7 and 7/4) above and below each tone in the third dimension.

The main reason to represent tonal relations as geometrical structures in a tone net is clarity and comprehensibility. For example, the *distance* between certain chords and keys can be found by common geometrical operations (shift, translation), and such distances can be used for assessing perceptual and cognitive issues (the tone net allows quantification of chord progressions and of the *affinity* several chords or sonorities may have for musically trained listeners). In a historical perspective, the tone net is a late consequence of developments in music and music theory that started in about 1500 when (a) just major and minor thirds as well their complementary intervals were frequently used in musical compositions and when (b) the harmonic division of the octave, of the perfect fifth, of the just major third and even of the whole step yielded a range of musical intervals (3/2, 4/3, 5/4, 6/5, 9/8, 10/9, 16/15, 25/24) that could not be accounted for with a chain of perfect fifths (as in the Pythagorean tradition [31.451, 458]). Both aspects can be studied in works of music and in theoretical writings such as published by *Fogliano* [31.457] and *Zarlino* [31.448] where tonal relations include those of the prime numbers 2, 3, and 5. Further steps in the ongoing exploration of tonal relations include various cadential schemata (already in the 16th and more so in the 17th century), the dominant seventh chord as a means of *closure* based on tension and relaxation (in the 18th century and massively in the 19th century), harmonic chord progressions based on relationships of major and minor thirds, and finally harmonic textures involving septimal relationships between sonorities (as in Wagner's *Tristan* [31.52]). These developments included various types of chromaticism and even enharmonic tonal structures. In sum, musical composition diverged more and more from the diatonic scales and modes that were fundamental in church and secular music before 1500. By about 1850–1910 even functional harmony was expanded to the very limits (as in works of Wagner, Reger, Strauss and some of their contemporaries). In view of these developments, music theory could not adequately deal with complex harmony on the basis of diatonicism and its curricular correlate known as *Stufenlehre*. *Riemann*'s theory of harmonic functions [31.486, 522] was a serious attempt to deal with the shortcomings and failures of diatonic *Stufenlehre* and to supply more appropriate tools for music analysis and harmony. *Riemann* [31.50, 486] regarded JI as useful for conceptualizing tonal relations (intervals, chords) but as a pitch system unnecessary for musical practice. He [31.486, 489] instead opted for an approach where the music theorist should carefully *read* the score in order to apprehend the tonal relations unfolded in works of music as *tone images* (German: *Tonvorstellungen*). Correct *tone images* then

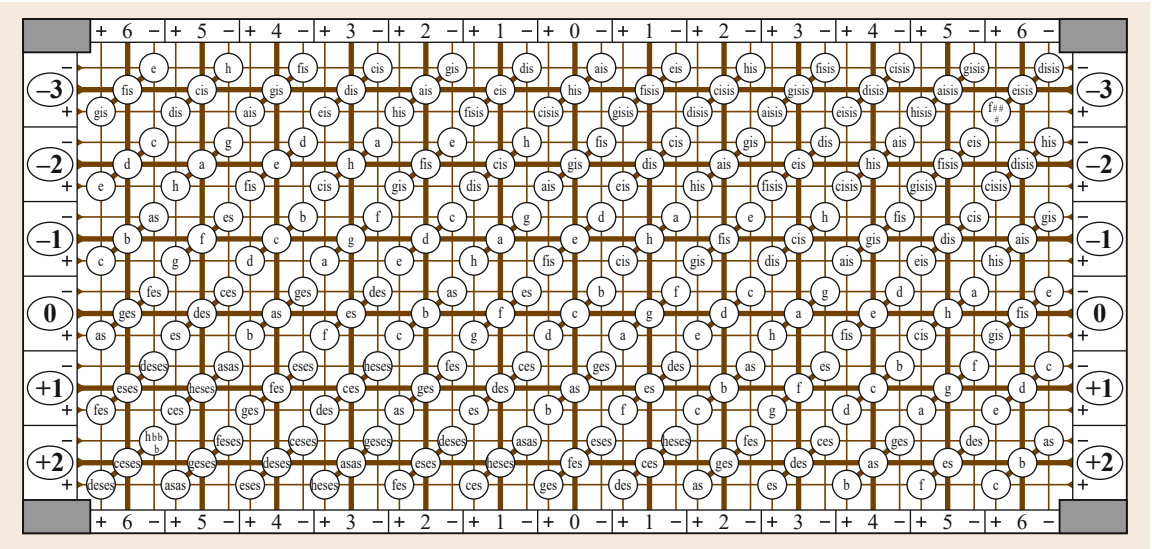


Fig. 31.35 3-D (three-dimensional) tone net (after [31.52, 529])

would gear our perception of actual music as played so that we, cognitively, would *hear* correct pitch relations even if intonation was deficient. Though such a process of *pitch correction* (within limits) governed by apperception of tonal relations plays a role for listeners, the alternative of matching correct intonation of tones/pitches to an appropriate melodic and harmonic analysis of musical works seems reasonable.

Among the scholars who, in the 20th century, worked on advanced systems of harmony as well as on the development of musical instruments suited to musical performance in tunings close to JI were the composers and musicologists *Siegfried Karg-Elert* [31.531] and *Eivind Groven* [31.532] (see articles in [31.533]), the physicist and music theorist *Adriaan Fokker* [31.382, 383] and the musicologist *Martin Vogel* [31.52].

32. Perception of *Timbre* and *Sound Color*

Albrecht Schneider

This chapter deals with perception of *timbre* or *sound color*. Both concepts can be distinguished in regard to terminology as well as to their historical and factual background even though both relate to some common features for which an objective (acoustic) basis exists. Sections of this chapter review in brief developments in (traditional and electronic) musical instruments as well as in research on timbre and sound color. A subchapter on sensation and perception of timbre offers a retrospective on classical concepts of tone color or sound color and reviews some modern approaches from Schaeffer's *objet sonore* to semantic differentials and multidimensional scaling. Taking a functional approach, acoustical features (such as transients and modulation) and perceptual attributes of timbre as well as interrelations between *pitch* and *timbre* are discussed. In a final section, fundamentals of sound segregation and auditory streaming are outlined. For most of the phenomena covered in this chapter, examples are provided including sound analyses obtained with signal processing methods.

32.1 Timbre and Sound Color: Basic Features

32.1.1 Terminology: *Timbre* and *Sound Color*

Timbre is a French word that denotes a stamp (e.g., *timbre fiscal* = revenue stamp), a brand, a sound or a sound color. The French Encyclopédie has an entry *timbre* (T. 16, 1765, 333) that contains several musically relevant annotations, namely *timbre* as referring to snare strings on a drum skin, timbre as the resonant state of a bell, timbre of a voice or of a musical instrument. In his article on *son* (tone, sound; Encyclopédie, T. 15, 1765, 345; for historical aspects see [32.1, 2]), Rousseau had used the term timbre as covering a third property of sounds besides tone height (*le degrè d'élevation entre le grave & l'aigu*) and intensity expressed as the degree *de véhémence entre le fort & le foible*. Timbre then is the quality of a sound that results from an evaluation in regard to dullness – shrillness or softness – brightness (*du sourd à l'éclatant, ou de l'aigu de doux*; the scaling of timbre thus is from sourd and doux to éclantant and aigu). The term timbre as it occurs in textbooks on orchestration [32.3, 4] denotes an integral quality of sound as produced by, and attributed to, certain instruments. These were classified, first by *Mahillon* [32.5–8] and then by *Hornbostel* and *Sachs* [32.9], according to physical principles of sound production, in the first place. The classification offered by Mahillon, based on the huge collection of instruments housed in the Brussels Conservatory of music, comprised:

1. Autophones
2. Instruments à membranes
3. Instruments à vent
4. Instruments à cordes.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_32

Hornbostel and Sachs have the same four classes (labeled idiophone, membranophone, chordophone, aerophone), however, in a different order (and with significant differences of grouping within each class) that reflects the physical principles involved more clearly. In general, idiophones viewed as vibrating bodies consist of three-dimensional structures (rods, bars, plates, shells), membranes such as drum skins are – ideally – two-dimensional (neglecting their thickness), and thin strings have been treated as one-dimensional in the seminal work of Bernoulli and Euler so that longitudinal, transversal and torsional vibration can be covered by second-order differential equations [32.10, 11]. Finally, aerophones such as flutes, for the lack of shearing forces between molecules in air columns, only allow longitudinal vibration.

Referring to the principles and materials of sound production, *Gevaert* [32.3, p. 5] for example states that the timbre of wind instruments (instruments à vent) is determined by the geometry (length, diameter, bore profile) of the tube, on the one hand, and by the mechanism by which the air inside the tube is set to vibration, on the other. Gevaert correctly points to a regular sequence of pulses (*battements*) necessary for making the air column vibrate, and he also mentions three basic types of pulse generator (edge tone, valves formed by either beating reeds or the lips pressed into a mouthpiece) as are used for sound production in flutes, reeds, and brass instruments respectively. Further, he attributes the *timbre moelleux* (soft timbre) of the French horn to the conical shape of the mouthpiece. *Gevaert* [32.3, p. 18] found that bowed strings are *the soul of instrumental music* since they have a *timbre pénétrant et riche*. *Berlioz* [32.4, p. 21] judged that the *sons harmoniques* of the lowest (fourth) string of a violin *ont quelque chose du timbre du Flûte; ils sont préférable pour chanter une mélodie lente*. The point of interest here is that timbre is regarded as a unique and integral quality (e.g., *timbre du Flûte*), though this may be limited to a certain register or to tones played on a certain string. In this respect, *Forsyth* [32.12, p. 480], in his textbook on orchestration, argues the D (second) string of the cello, *of all the soft, silky sounds in the orchestra, it is the softest and silkiest*.

The unique and consistent timbre attributed to certain instruments or to their parts such as individual strings or pipe ranks (as in organs) is expressed, in the English language, by terms like tone quality, tone color or sound color. Likewise, these terms are used in German (*Klangfarbe*, *Tonfarbe*). Timbre is often used synonymously for *sound color* though there seem to be some differences between the phenomena covered by these terms in that *sound color* predominantly refers to a certain spectral structure while timbre, at least in more recent research, can cover spectral as well as temporal aspects (Sect. 32.1.2). Fundamental to both terms is the experience that sounds can have a distinct sensory quality that, though perhaps not independent of other qualities, in particular pitch and loudness, cannot be accounted for as a *function* of either pitch or loudness alone or as a simple combination of both. Consequently, there seems to be information encoded in the sound structure that gives rise to sensations of *timbre* in addition to information pertaining to *pitch* and to *loudness*.

32.1.2 Objective Basis of *Timbre* and *Sound Color*

In line with the realist and causal perspective taken in Chaps. 30 and 31, timbre and sound color are regarded as sensory experiences deeply rooted in natural foundations. These are physical, on the one hand, and anatomical as well as physiological, on the other. In an evolutionary perspective, various animal species (from insects and amphibians to birds and mammals) show remarkable diversity in regard to organs suited to perform sound production as well as sound perception (articles in [32.13–15]). Many vocalizations serve to communicate information (*Tembrock* [32.16] and articles in *Witzany* [32.17]). The degree of structural and functional complexity reached in birdsong [32.18, 19] and in whale songs [32.20] is particularly striking in regard to the large and diverse song repertoire of certain species involving learning and memory as cognitive capacities as well as communication networks operated by two or more members of a certain species. In addition, interspecies sound communication is known from bioacoustical observations. The songs of birds and whales comprise complex sound patterns (take, for example, songs of the nightingale and of the humpback whale), which vary considerably in spectral content over time. In this respect, it can be said that these sounds make use of timbral qualities as a means of communication. There are parallels in human speech and singing in that different phonation (resulting in different spectral energy distribution and formant structure) can convey different emotional states as well as the intentions of a person speaking or singing [32.21].

Sound production and sound perception in animals (including humans) is based on acoustical principles [32.21–23] even though these are implemented into organic biosystems. In fact, one can give a description of the vocal tract of humans in terms of anatomical structure and functional aspects of muscles, nerves, etc. in the phonation process. Further, one may go into the acoustics of phonation in terms of generator and resonator geometry, air flow and pulse sequence

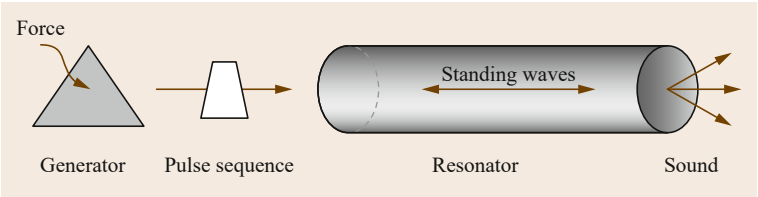

Fig. 32.1 Model of an aerophone (pulse generator coupled to a tube-like resonator)

generation at the vocal folds as well as resonance phenomena taking place in the mouth cavity [32.21, 24] etc. Quite obviously, there are also parallels between the structure and function of the human singing voice and a host of musical instruments classed as aerophones. *Gevaert* [32.3] rightly attributed the timbre of wind instruments to a combination of a valve-like pulse generator and a resonator in which an air column is set to vibration. Taking the general model of such a generator coupled to a resonator, the scheme in Fig. 32.1 can be drawn.

In this basic model, a source (a person breathing air) drives a generator by supplying a force, which in this case is air flowing at a certain speed and with a certain pressure. The flow is periodically interrupted either by a small jet of air being bend inward and outward of a sharp edge (e.g., the labium of an organ flue pipe), or by valves that are (partially or completely) opened and shut to produce pulses of air released into the resonator. A single reed (as in the clarinet) or double reeds (as in the oboe) or the lips pressed into a mouthpiece (as in the trumpet, trombone, French horn, etc.) can serve as the valve in the generator. The sequence of pulses traveling through the length of the resonator (a cylindrical or conical tube) partially is reflected at the end opposite the generator so that standing waves are formed inside the tube where natural modes of vibration are excited. Without going into details, which are intricate because the generator parameters include quite many nonlinearities [32.11, 25], one can see that the behavior of such a generator-plus-resonator system depends on the geometry of its parts, on the input parameters (input impedance of the valve, blowing pressure and speed, air flow through the valve, input impedance of the tube, etc.) and on the coupling of the generator to the resonator. The interaction between the two maintains the regeneration cycle needed for continuant tones. In regard to the geometry of resonators, it has been demonstrated [32.26] that a resonator treated as a Bessel horn produces a series of natural mode frequencies so that higher mode frequencies are multiples of the lowest only if the Bessel function J^x yields either $x = 0$ (cylinder) or $x = 2$ (conical tube). The clarinet has a cylindrical tube almost closed at one end by the valve so that the resonator predominantly responds to odd harmonics; the clarinet overblows into the twelfth, which is the fifth above the octave (the third harmonic [32.27, p. 115–125]), while the oboe (where the bore is close to a cone slightly truncated near the reed generator) overblows into the octave. For the tones in between, finger holes are provided on both instruments. Since also the number of modes excited in the resonator differs between woodwinds (for the same pitch played with similar force of excitation applied), different spectral energy distributions result that are perceived as differences in *sound color* or timbre. For instance, sounds recorded from a number of woodwinds playing the same note (C_4) with moderate force of excitation have spectra that differ in the number and strength of partials (Fig. 32.2).

The sounds analyzed with a phase vocoder algorithm (equivalent to putting the sounds through a bank of band pass filters tuned to f_1 of the sounds [32.28]) are samples of the following instruments (left to right): bassoon 1, bassoon 2, bass clarinet, clarinet, oboe, concert flute. The spectral centroid (Sect. 30.2) for these sounds varies from ≈ 680 Hz (bassoon 1) and 880 Hz (bassoon 2) to 2.4 kHz (bass clarinet) and 2.55 kHz (clarinet); the centroid for the oboe sound is 1.42 kHz while, for the flute, the centroid is identical with f_1 (261.6 Hz). Thus, for a performer or listener the sounds in question differ significantly in brightness when playing the same note. What distinguishes tones produced by different instruments such as the bassoon, the clarinet, the oboe, etc. in the steady-state portion of sound after the transient part is the shape of the spectral envelope and, thereby, the distribution of spectral energy covered by the envelope. The spectra of wind instruments controlled by a valve as pulse generator have been said to approach a cyclic structure with maxima that can be interpreted as formants [32.29–31]. A condition necessary for a perfect cyclic spectrum would be a series of rectangular pulses with a duty cycle of τ/T (τ = pulse width and T = pulse period) that yields small integer ratios; amplitudes of partials then conform to a sinc function $(\sin x)/x$ where zeros are at $n\tau/T = 1, 2, 3, \ldots, k$ [32.32, p. 40 f.] (Fig. 32.3).

Spectra approaching a cyclic structure to some degree can be recorded from reed instruments such as the oboe; in Fig. 32.4, the spectrum of the tone C_4 played (*mf*) on a baroque oboe is shown. In addition, the spectral envelope calculated from a formant filter analysis

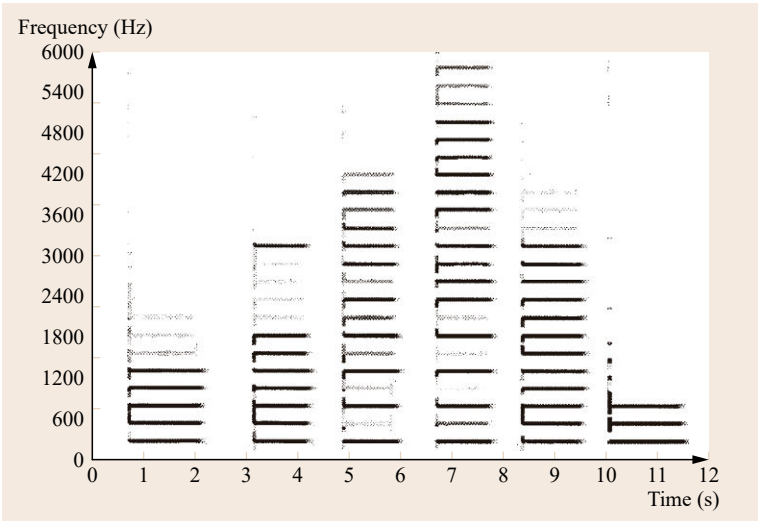

Fig. 32.2 Spectra of various woodwinds (from left to right: bassoon 1, bassoon 2, bass clarinet, clarinet, oboe, flute) all playing the note C_4 (phase vocoder analysis, base frequency = 261.6 Hz). Relative amplitude of partials indicated by grayscale (*white* = low, *black* = high amplitude)

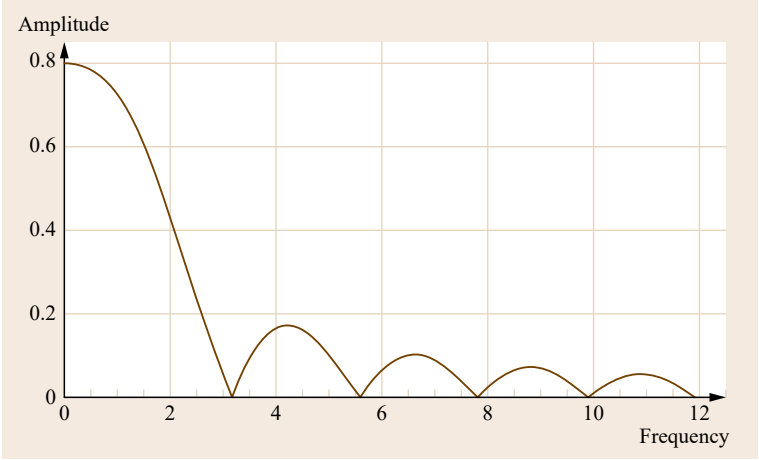

Fig. 32.3 Sinc function as a model for the envelope of a cyclic spectrum

is plotted in the same graph. One can see three groups of partials at $\approx 0-1.8$ kHz, 1.8–3.6 kHz, 3.6–6.6 kHz separated by relative minima; these groups are covered by peaks of the formant filter envelope. Also, a formant analysis performed with the Burg algorithm [32.33] yields several tracks of formant frequencies as a function of time. In this respect, one may assign a formant-like quality to this sound (as well as to sounds from other reed instruments [32.34]). Even closer approximations to a cyclic spectrum can be observed in organ reed pipes [32.35] and also in sounds recorded from plucked strings in a harpsichord where in particular the string velocity reflects the pulse train and the spectrum of the string velocity consequently is fairly periodic [32.36]. Hence, the pulse generator imposes the shape of a spectrum on the resonator, which is fixed in geometry, in organ reed pipes and in the harpsichord, while in reed instruments such as the oboe the length of the air column vibrating in the bore can be modified by means of finger holes.

The generator-plus-resonator model can also be viewed as a generator producing a source signal fed into a filter, that is, into the resonator (for source-filter processing see [32.37, 38]). In terms of linear systems [32.39, Chap. 5] and [32.40, Chap. 9], a filter of low-pass or bandpass characteristic has a certain frequency response as well as an impulse response; the transfer function $H(\omega)$ of a filter determines the amplitudes and phases of the frequency components in the output spectrum relative to the input spectrum. Relating bandwidth to response time, the filter response time τ of a symmetric bandpass to an input signal with rapid onset is

$$\tau = \frac{2\pi}{\Delta\omega} = \frac{1}{\Delta f} .$$

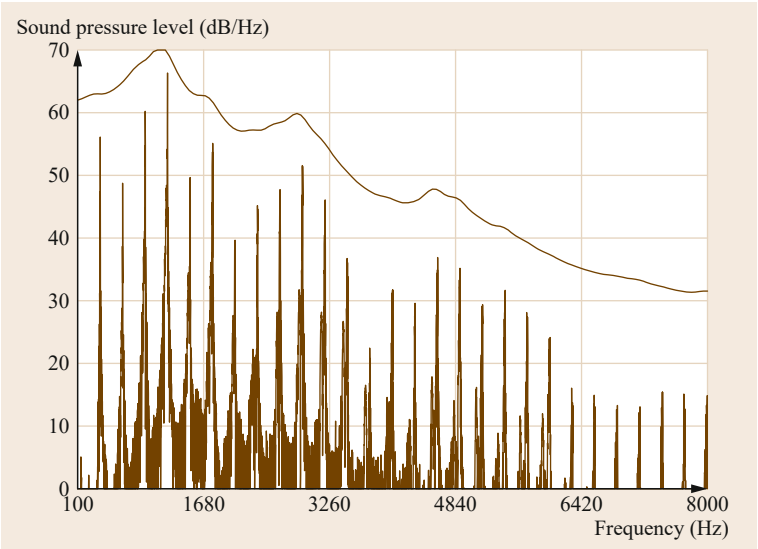

Fig. 32.4 Baroque oboe, spectrum of tone C_4 (*mf*) and formant filter envelope

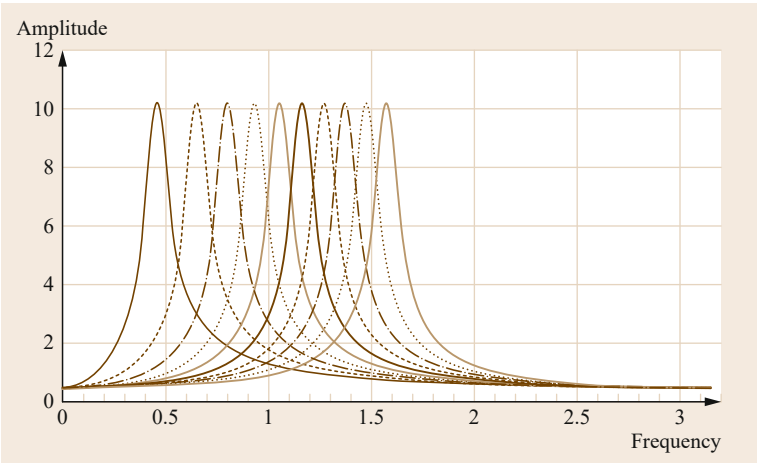

Fig. 32.5 Bank of bandpass filters as analogue of resonance peaks in instruments

Hence the response time is the inverse of the bandwidth. The transfer function of the resonator can be modeled by taking the resonances of the tube as the center frequencies of a chain of bandpass filters (Fig. 32.5).

If we conceive of a digital filter where $x(k)$ is the input signal and $y(k)$ is the output signal, convolving the input signal with the impulse response of the filter, $h(k)$, yields the output sequence $y(k) = x(k) \times h(k)$. The poles of the filter in the complex z-plane are equivalent to the resonance maxima in the resonator (e.g., the tube of an organ flue pipe). It is in physical modeling of musical instruments that such concepts have been implemented in signal processing codes.

In regard to the temporal behavior of the system, it takes some time before a pulse sequence fed into a tube resonator builds up standing waves, which is the condition for sound production and radiation. This process is particularly evident in large organ flue pipes (of 16′ and 32′ size), but can be observed also in smaller pipes (of 8′, see Figs. 30.17, 30.18 and [32.35]), in large duct flutes like the Slovak *Fujara* (of ≈ 160 cm tube length [32.41]), and even in large reed pipes where higher modes build up at their correct harmonic frequencies only after several hundred ms. In Fig. 32.6, the onset of the tone B_2 ($f_1 \sim 122.3$ Hz) recorded from a bassoon played with medium force (*mf*) is shown. One can see that mode no. 2 (corresponding to partial f_2 in the spectrum) is building up early while mode no. 1 needs more time and mode no. 3 as well as higher modes start with broad spectral lobes meaning a stable regime of vibration has not yet been established for these modes. Also, there is some noise in the transient signal in a frequency band above ≈ 1 kHz. The steady state of the tone as defined by clear spectral peaks

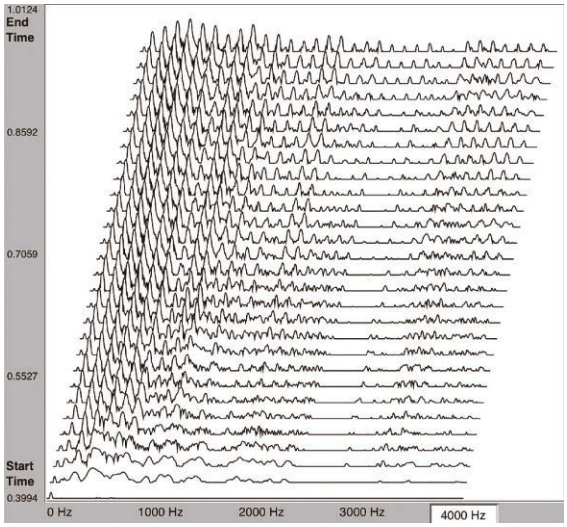

Fig. 32.6 Bassoon, onset of sound for a tone at $f_1 \sim$ 122.3 Hz; 29 spectra (FFT: 4096 pts, Hanning, hop ratio 0.2)

marking harmonics as well as by a small degree of spectral fluctuation is reached only after $\approx$ 300–400 ms. However, a clear pitch conveyed by a number of low harmonic partials as well as the period of the temporal envelope can be perceived much earlier (within $\approx$ 100 ms from onset).

The sounds from organ pipes analyzed in Sect. 30.2 and the bassoon sound (Fig. 32.6) demonstrate that, in particular in aerophones but also in plucked and bowed chordophones, a transient part precedes the steady state; the transient part results because the vibrating system (air column, string) has a certain input impedance and exhibits inertia. Since the input impedance for a cylindrical tube filled with air is

$$Z = \frac{p}{q} = \frac{p}{v\,A}\,,$$

where p is the pressure and $q = v\,A$ is the acoustical volume current (for a plane A and particle velocity v), pressure has to build up beyond a certain threshold before a stable vibration pattern with standing waves and radiation of a periodic sound signal is achieved. Consequently, the transient part contains noise in the signal in addition to the restricted number of harmonic partials resulting from such modes that respond to the excitation right from the onset. In plucked strings, as in the harpsichord, the transient comprises both a longitudinal wave preceding transversal motion as well as a short noisy segment resulting from the interaction of the plectrum with the string [32.36]. In strings excited with a small hammer, one can observe a short noisy precursor signal followed first by the longitudinal wave and then by transversal motion of the string (for measurements of a Stein-Conrad Hammerflügel from 1793 that has delicate small hammers, thin strings and a fast action see [32.42]). The precursor signals are quite short (usually, $t < 10$ ms) yet are of perceptual relevance (Sect. 32.2.3).

32.1.3 Organology, Electronics, and Timbre: Some Historical Facts

Humans evidently recognize and value different sound qualities given the immense number and diversity of musical instruments in use in various cultures and ethnic groups around the world. Exploration of the field known today as *sound color* and *timbre* was begun, on an empirical level, by musicians and craftsmen when making flute, reed, brass and string instruments. Historically, highly developed instruments such as the bronze lurs from Scandinavia [32.43] and bronze bells from China [32.44] testify instrument makers and musicians must have had a regard for sound quality already in antiquity. Timbre as related to certain materials played a significant role in Chinese tradition of instrument classification [32.45, p. 67 ff.]. Differences in sounds were also discussed in Greek writings on music theory (as in chapters of Aristoxenos' treatise on music, see [32.46]). In Roman times, several brass instruments, because of their powerful (as well as *horrible*) sound, were employed for military purposes while the first organs (the organum hydraulicum, said to have been invented, in Alexandria, by Ktsebios) appeared as instruments suited to fill a theater or arena with sound [32.47]. From the Middle Ages onward, mensuration of organ pipes perhaps led to a basic understanding of the interdependence of *pitch* and *sound color* in flue pipes. Musical instruments such as shawms, bagpipes and the hurdy-gurdy are mentioned quite frequently in medieval and Renaissance literature including remarks on sound properties. The development of bagpipes as well as the medieval bladder pipe not only provided players with a continuous sounding instrument but also with a *sonorous* sound quality (both chanter and drone(s) employed single or double reeds). Similarly, the hurdy-gurdy (which appeared in Europe around the 13th century [32.48]), offered a performance style based on continuous drone accompaniment plus distinct melodic pitch sequences as well as a specific sound (resulting from the interaction of the turning wheel with the strings, where the speed of the wheel and thereby the *attack* on the strings can be varied). Organ dispositions of the 14th century indicate that several instruments already offered a contrast of two sound concepts, namely diapason (*Prinzipal*) and organo pleno (*Grand orgue* [32.49, p. 10 ff.]). By the end of the 15th century,

the wall profile for the minor-third bell was discovered; a good example is the *Gloriosa*, Erfurt, cast by Geert (Gerhardus) de Wouw, in 1497. The minor third in this particular bell has ≈ 280 cent (the Pythagorean minor third has 294 cent), which suggests bell founders had an understanding of how to produce a certain spectrum by shaping the profile of the bell's wall. A detailed account of the instruments in use by about 1600 was provided by *Praetorius* [32.50]. The broad range of instruments (in particular reeds) developed in the Renaissance and the concept known as *Spaltklang* (split sound) realized in organ dispositions (as reported in [32.50]) as well as in ensembles demonstrates a keen sense of timbre. In modern times, *sound color* (German: *Klangfarbe*) became an essential feature in Western art music as reflected in orchestration (for a comprehensive survey, see [32.51]) growing increasingly more complex in works of the 19th and 20th century respectively. Composers demanded rare or newly invented instruments (such as the celesta employed by Tchaikovsky in *The Nutcracker* or the Heckelphone in Strauss' *Salomé*) as well as unusual ways of playing (as in many works of modern music after 1945) in order to have unique or even perplexing sounds at their disposal. It should be noted that the temporal and spectral characteristics of tones played on most orchestral instruments vary considerably in regard to dynamics (from *pp* to *ff*), to the effect that the radiation pattern and hence, the directivity of sound also changes a lot with dynamics (for a comprehensive survey of facts and data, see [32.52]). In this respect, the timbre is by no means constant (besides the variation of spectral energy distribution observed when instruments are played in different registers).

The advent of electroacoustic music brought technical sound sources (generators, oscillators) and devices to combine and modify sources (e.g., ring modulator, vocoder) into play [32.53–56]. The analogue (voltage-controlled) synthesizer and digital instruments that became available for common use in the 1970s and 1980s respectively, offered even more choices for creating complex sounds [32.56–58]. Digital synthesizers (like the Yamaha DX 7) as well as digital samplers (like the Akai S 1000 and the Emax II) in fact are music computers based on signal processing technology. The computer had been used for sound generation, by Max Mathews and other pioneers, for about two decades before digital audio became a standard in sound recording and music media (the CD was standardized as a digital format around 1979–1980 and introduced to the commercial user market in 1982). Special techniques like frequency modulation (FM) synthesis [32.59–61] allowed both to replicate the timbre of many existing instruments, among them idiophones like xylophones, gongs, etc. and to create sounds with complex, time-variant harmonic and inharmonic spectra, which were unprecedented. Such sound material led to compositions that transcend borders between the common categories of *pitch* and *timbre* (like *Stria* [32.62] by John Chowning, *Bossis* [32.63] and Sect. 32.2.4).

In addition to electronic and digital sound synthesis, all kinds of environmental and technical sounds were put to use in *musique concrète*, which, as one of its goals, considered aperiodic noises and periodic waveshapes as a continuum to be exploited for sound collage techniques [32.64, 65]. A far-reaching, more generalized concept of *sound* evolved in areas of electronic and computer music as well as in studio productions of pop and rock music when room acoustics, multichannel recording and reproduction and a host of audio effects (such as artificial delay and reverb, phasing, flanging, chorus; see articles by *Dutilleux* and *Zölzer* [32.66]) were integrated with orchestral and electronic instruments as well as with analogue and digital sound samples. In consideration of these developments, it became customary already in the 1960s to speak of, for example, *the sound of Mantovani* (multiple bowed strings deeply embedded in reverb) or *the wall of sound* produced by Phil Spector in pop music recordings, for which the recipe was to have many instruments played simultaneously in a rather small studio so that their sounds overlay and are hardly recognizable individually since Spector added, moreover, amounts of reverb and compressed the mix dynamically so that indeed a very dense *wall of sound* is audible in recordings like *Be My Baby* [32.67]. Later on, there was *psychedelic sound* in which time-axis manipulation of signals such as phasing and flanging as well as stereo panning effects figured prominently (e.g., Tomorrow: *Revolution*, 1967, Jimi Hendrix: *All Along the Watchtower*, 1968), and then *disco sound* (with huge concentration of spectral energy at the bottom end of the audible frequency range and typical patterns of percussion and bass in regard to meter and rhythm), etc. In all these *sounds*, timbre played an important if not decisive role. However, sound in this respect rather is a conglomerate of natural and artificial sound sources, effects, production and reproduction techniques while *timbre* traditionally (as in treatises on orchestration [32.12, 51]), has been assigned to single instruments or to the voice of certain male and female singers.

32.1.4 Research on *Timbre* and *Sound Color*: A Brief Retrospective

Though elements of acoustics can be traced in Greek antiquity (for example, the observation that the tension of a string determines whether the tone it pro-

duces sounds dull or sharp), a more systematic approach was pursued in the 16th and 17th century when empirical research was established along with mathematical treatment of problems. Knowledge concerning sound structure improved a lot when Beeckman and Mersenne understood the nature of harmonic vibration that led to the discovery of partials in strings (for which Sauveur gave a detailed description in the years 1700–1713 [32.68–70]). From Sauveur's published lectures, *Rameau* [32.71] saw that musical tones comprised a fundamental and its harmonics. By about 1800, it was clear to acousticians like Chladni that musical sound in general was a mixture of harmonic or inharmonic partials. The explanation *Chladni* [32.72, p. 241 ff.] gave was that elastic bodies can undergo very many vibrations at the same time, which would correspondingly activate many different parts of the inner ear without hampering each other. Thereby, sounds from different instruments could be perceived simultaneously. *Chladni* [32.72, Sec. 248] attributed different sound qualities to the different materials of elastic bodies consisting of organic or inorganic material (e.g., wood, brass, iron) and the microstructure of vibration inside such bodies as well as in the media (fluids, solids) through which sound propagates. *Opelt* [32.73, Sec. 7] held that the quality of sounds (e.g., strings, trumpet, flutes) or the *so-called sound color* (*Klangfarbe*) depends on different kinds or shapes of pulses reaching our ears. Opelt argued pulses and vibrations must be complex since, in a musical instrument, all parts vibrate; that is, strings vibrate coupled to resonance plates and air columns vibrate coupled to the tubes and bells of wind instruments. The resulting sound embedded in complex tones thereby is *an aggregate of several isochronous pulse sequences* having their origin in various parts of the instrument. Moreover, the mechanism of excitation (plucking or bowing a string, hammers in keyboards, etc.) would result in different *sound colors*.

When Helmholtz, in the 1850s, began his work on musical acoustics and psychoacoustics, he had tuning forks and resonators as well as sirens for sound analysis. Sets of precise tuning forks driven electromechanically for continuant tones provided kind of an early synthesizer (Rudolph Koenig, ten forks, $f_1 = 128\,\mathrm{Hz}$ [32.74, p. 329 ff.]) for complex sounds such as vowels. Koenig, himself an acoustician who cooperated closely with Helmholtz, also constructed a mechanical wave analyzer with a set of resonators. In the 19th century, some elementary tools for recording sound waves had become available [32.75] before Edison developed his improved model of the phonograph (issued in 1888) that was used in many investigations of sound. Among the objects of study was sound production in the human voice, and in particular the nature of vowels [32.74, p. 367 ff.]. In the second half of the 19th century, the quest for finding a specific resonance mechanism that could explain the production of vowels led to theories of *formants* (a term coined by the physiologist Ludimar Herrmann in the 1880s who contributed greatly to empirical sound research [32.34]). Sound research gathered further momentum when, after about 1920, continuous recording of sound on film labeled *phonophotography* [32.76, p. 10 ff.], [32.77] and analysis of the sound wave both in regard to periodicity and spectrum became widespread as lab techniques. Pitch had been calculated as fundamental frequencies from the periods of vibration (by $f = 1/T$) even before and spectral analysis had been done with the aid of tuned resonators, notably by Helmholtz. However, spectral analysis by means of filters [32.78] not only allowed identification of spectral components but also investigation of transient behavior. Using octave sieves where the impulse response is short due to the rather broad filter bandwidth one could see modes of vibration and corresponding spectral components building up over time before a stable (quasistationary) regime was reached [32.79, 80]. Still, *sound color* rather referred to the quasistationary regime of vibration and its corresponding spectrum showing the amplitudes of spectral components at their (harmonic or inharmonic) frequencies while transients were addressed as the short section at the onset where the sound wave often lacks clear periodicity (Sect. 32.1.2; for a survey of research on transients in nonpercussive instruments, see [32.31]).

Significant progress in musical sound research was made when an improved model of the analogue Sona-Graph became available for musicologists in the 1960s. The Sona-Graph, first issued in the late 1940s for research in phonetics (*visible speech*), allowed a spectral and temporal representation of sound in a quasi-three-dimensional (3-D) format (time as abscissa, frequency as ordinate, and energy of partials indicated by degrees of a grayscale). The Sonagraph Model II offered several bandpass filter settings and was used to explore sound structures in Western and non-Western musics [32.81] including characteristics of the singing voice [32.82]. In the 1980s, digital spectrum analyzers (such as the B&K 2032 model) allowed FFT-based spectral analysis of complex sounds [32.83]. Since the 1970s, a number of special codes for sound signal analysis had been developed including linear prediction, autoregressive models, and pitch tracking [32.33, 84]. From about 1990 on, powerful workstations suited for digital signal processing (DSP) became available. Software packages (like sndan, based on phase vocoder analysis/synthesis, introduced in 1993 [32.28]) allowed users to perform high-resolution sound analysis and synthesis/resynthesis. With the new tools (both hardware and

software) it was possible to study temporal and spectral structures of sounds recorded from Western and non-Western (e.g., Indonesian *gamelan*) instruments in great detail [32.85, 86]. At the same time, approaches to sound synthesis and resynthesis were refined further when wavelets, granular synthesis, digital waveguides and other techniques had been developed (there are collections of many relevant articles in [32.28, 66, 87, 88].

Summing up this paragraph, it seems obvious that exploration of musical timbre depended significantly on the tools available to researchers for sound analysis and synthesis at a certain time and place. There is a line of progress leading from mechanical to electrical devices and finally to computer-based algorithmic modeling of sound and sound-producing instruments and to ever more fine-grained analysis. Not only did acoustical and musical sound research benefit from computerized tools. As will be seen in the following section, also psychological research into timbre and sound color took new directions when computers and software for advanced statistics became available for many institutions. Meanwhile, toolboxes for sound research have been set up including audio descriptors applicable to musical timbre [32.89].

32.2 Sensation and Perception of *Timbre* and *Sound Color*

32.2.1 Classical Concepts of Tone Color or Sound Color

Helmholtz [32.90] ascertained that the pitch of a simple or complex harmonic tone depends on the period of vibration and that sound intensity depends on its amplitude. He attributed sound color to the microstructure within each period of vibration as well as to the fine structure of the resulting sound wave. He stated that each different sound shape calls for a distinct shape of vibration whereas several different waveshapes might bring about the same sound color. Different sound colors according to Helmholtz result from different patterns of harmonic partials added to the fundamental frequency (f_1) determining the pitch of the sound. Hence, differences in the sound color of complex sounds result from the number and amplitudes of partials above f_1 while phase differences between partials, *Helmholtz* [32.90, p. 194] declared, can be neglected. This view is in line with his resonance theory of hearing, which posits the inner ear would perform a Fourier analysis whereby a number of partials would become audible as constituents of a harmonic complex. From his observations *Helmholtz* [32.90, p. 97] argued that strong partials suited to activating a resonator would also be audible as an individual harmonic (*Oberton*), and that no *Oberton* was audible in the case where no response from a resonator had been observed. Though Helmholtz considered also sounds with inharmonic partials, his main concern was the harmonic type since most of the instruments assembled in an orchestra are chordophones and aerophones.

Stumpf [32.91, p. 520 ff.] stated that, from a phenomenological perspective, human subjects assign three basic attributes to sounds, namely pitch (*Höhe*), intensity (*Stärke*), and extension (*Größe*). While sensations of pitch and intensity can be directly traced to physical properties of sound (frequency and period as well as the amplitude of the sound wave reaching the ear), extension as implying some spatial interpretation is a more complex concept that can incorporate several sound features and sensory attributes. In his book on speech sounds, *Stumpf* [32.92, Chap. 15] also elaborates on his concept of instrumental sounds in detail. He distinguished *inner* and *outer* moments of sound color, where the latter depend mostly on temporal factors (transients, envelope, modulation) while the inner structure of sounds depends mostly on spectral composition and energy distribution [32.34]. Both taken together perhaps embrace what the term *timbre* seems to denote: an intricate combination and interplay of temporal, spectral, and dynamic features of sounds that, in normal sensation and even in an analytical mode of hearing, are often difficult to analyze and hard to separate from each other. *Stumpf* [32.91] argued that, in actual sensation and perception, even basic attributes are not completely independent since the pitch of pure tones can vary to some extent with intensity, and both combined give rise to differences not only in *tone height* but also in brightness, density, and volume. *Köhler* [32.93–96] and some other researchers pointed to the similarity between pure tones played from low to high frequencies and the sequence of vowels *u-o-a-e-i*, resulting in an attribute often labeled *vowel quality* (also termed *vocality*).

The phenomenal description of tonal attributes and their interrelations had been addressed, from an empirical descriptive approach including auditory tests with musically trained and untrained subjects, by *Stumpf* [32.91, 92, 97–99] and by several of his coworkers [32.93–96, 100] as well as by other researchers. For example, *Rich* [32.101] had proposed the attribute of *volume* to mark the spatial extension or diffusion of low tones against high ones imagined by listeners in addi-

tion to other such attributes like brightness or density. *Stevens* [32.102] found that even pure tones evoke sensations of *volume* (*bigness*, *spread*, [32.103]), and that this attribute relates to both the frequency and the intensity of tones. Since pitch to a small extent [32.104] and loudness attributed to pure tones also depend on both frequency and intensity, *Stevens* [32.102] warned *that no psychological dimension need be a simple correlate of a single dimension of the stimulus*. In fact, several attributes covary positively or negatively with frequency and intensity; an increase in frequency from low to high brings about sensations that covary positively with frequency, namely pitch (if taken as *tone height*), brightness, and density. Brightness increases also when intensity is raised within certain limits, and the same holds true for density as a phenomenal attribute of sound. Further, increases in intensity for pure and complex tones in the treble frequency range ($\approx 6-10$ kHz) can turn sensation of brightness into unpleasant sharpness. While tone height, density and brightness increase with frequency, the volume of tones seems to be larger at low and smaller at high frequencies (provided constant sound pressure level (SPL)). *Lichte* [32.105] confirmed that, besides pitch and loudness, complex tones have *at least three attributes. These are brightness, roughness, and one tentatively labeled fullness* (which corresponds to *volume* in other studies).

Stimulus parameters and attributes of sensation that had been described in a range of studies [32.92, 100, 103, 107–109] were given a detailed interpretation by *Albersheim* [32.106]. Ordering tonal properties that have objective correlates in physical parameters as well as tonal attributes (these are phenomenal descriptions of sensations) in regard to their mutual relations, he derived a scheme for pure tones and another scheme for complex tones of which slightly adapted versions (to account for differences between the original German terms and English translations) are shown in Fig. 32.7a,b.

Likewise, *Albersheim* [32.106, p. 268] condensed his discussion of the stimulus parameters and sensory attributes of complex tones into the scheme shown in Fig. 32.7b.

The term mixed color denotes the phenomenal quality of a sound resulting from the composite effect of fundamental frequency and spectral energy distribution. Different spectral patterns varying in the number and strength of partials determine the sensation of brightness as well as the similarity such complex sounds may have with vowels in speech and singing, on the one hand, and timbres known from musical instruments, on the other. In addition, the phenomenal quality of a complex sound can change when it is shifted up and down a musical scale. The term *mixed color* expresses

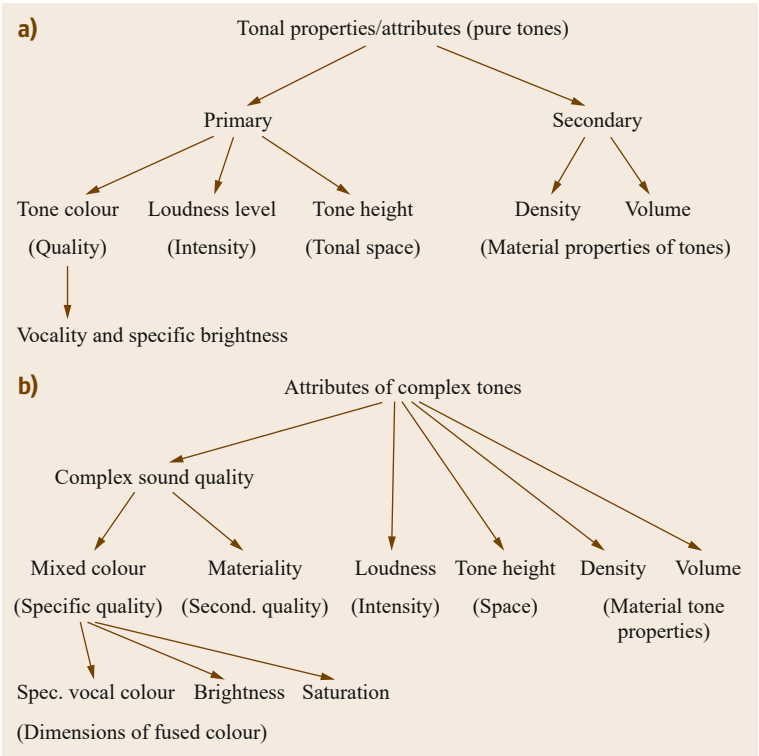

Fig. 32.7 **(a)** Tonal properties and attributes for pure tones (after [32.106]) **(b)** Properties and attributes of complex tones (after [32.106])

the combined effect of all these factors. Materiality (German: *Stofflichkeit*) denotes material properties of a sound one can *touch* and *feel* (analogous to haptic sensation), for instance, roughness or smoothness of sounds. *Albersheim* [32.106] devoted a significant part of his monograph to phenomena and categories known from the study of phonetics and voice quality in regard to their applicability to musical sound, addressing aspects like *specific vocal color* of complex harmonic tones. Vowels had been covered by *Köhler* [32.93–96, 100] and given systematic treatment by *Stumpf* [32.92] on the basis of many experimental findings.

In contrast to the elaborate descriptions of tonal attributes provided by Stumpf, Hornbostel, and Albersheim, the cognitive psychologist *Ebbinghaus* [32.110, p. 306] gave a neutral definition of sound color when he said the *sound color* (*Klangfarbe*) of tones is understood as that which distinguishes them in sensation, at identical pitch and intensity, when produced from different instruments or voices. This statement implies that there are distinct sound properties giving rise to (at least three) basic sensations: pitch, intensity, and sound color. However, the nature and perceptual *content* of sound color were left out of this definition which, much later, resurfaced in nearly identical shape as that of *timbre*, issued by the American Standard Association ([. . .] *the attribute of sensation in terms of which a listener can judge that two sounds having the same loudness and pitch are dissimilar* [32.111]).

32.2.2 Modern Approaches: From the *Objet Sonore* to Multidimensional Scaling

As is evident from the preceding sections, approaches to the classification of sounds in regard to sound color or timbre originally started from fundamentals of vibration, sound production and radiation as realized in certain instruments (including the voice). As far as sensation and perception is concerned, the basic concept was that of psychophysics where one seeks for a physical input parameter causing an output in sensation that is measurable (and possibly scalable in some unit, Sects. 30.1.2–30.1.4). This view was gradually but steadily changed when, in the descriptive and analytical studies published by Stumpf, Rich, Hornbostel, etc. the experience of subjects in perceiving sound played an increasingly greater role. Though physical and physiological facts known from measurements and observations were still taken into account, the focus in music psychology was on tonal *attributes* relevant for perception. The phenomenological paradigm reflecting the experience of musically trained subjects is clearly evident in the monograph *Albersheim* [32.106] devoted to attributes of tone and sound.

In the following, a number of approaches to the study of timbre and sound color will be discussed in regard to developments in music and media technology as well as in empirical research methodology. For obvious reasons (given the large number of publications on timbre, and on *sound* and perceptual aspects of sound in general), the survey must be selective.

Developments in Audio Technology

Technical production and reproduction of music as sound began after the phonograph and the gramophone had been introduced to the public [32.112]. Radio transmission followed in the 1920s when electric amplification and recording on the basis of vacuum tube technology was developed, and solid-state technology (the transistor was invented in 1947/48) came into use during the 1950s. By about 1930, the *Trautonium* (a kind of early synthesizer) had been invented, followed soon after by its polyphonic expansion, the so-called Mixtur-Trautonium; these instruments were used by composers of modern music (P. Hindemith, H. Genzmer). Also in the 1930s, the Hammond organ became available in several models (making use of rotating tone wheels and electromagnetic pickups for sound generation). Shortly before and during World War II, the modern tape recorder was developed (even in stereo, by AEG). The vinyl LP (12″, 33 1/3 rpm) was issued in 1949. Evolving technology offered new possibilities to creative artists engaged in what became *electronic music* [32.53]. Institutions like the Studio for Electronic Music at Cologne (part of the public radio station, NWDR, later WDR, and home turf of composers Herbert Eimert and Karl-Heinz Stockhausen) offered technical facilities including a range of sound generators, filters, ring modulators, and tape recorders as well as electronic keyboard instruments (for technical information and musical aspects, see [32.113]). *Moles* [32.114, Chap. IV] elaborated on sound according to physical (time, frequency, SPL) and psychoacoustic parameters (envelope, spectrum, level and dynamics, pitch, timbre), which can be used for both analytic description of existing *sonic objects* as well as for the creation of new ones. His main idea was that music as is performed, recorded on tape or other medium, and perceived by listeners consists of *objets sonores* that can be distinguished from one another, and can be decomposed into cells in a frequency/level plane representing the area defined by lower and upper limits of human hearing. *Moles* [32.114, p. 118–119] considered such cells (he uses terms like *cellules* as well as *quanta sonores*) as carriers of information, thus relating to concepts of communication developed in a more formal

approach by *Gabor* [32.115] and by *Shannon* [32.116]. Moles also offered rules of how to work with sonic objects. The acoustic and psychoacoustic description of sonic objects met the scientific spirit encountered in electronic music circles. The tape recorder became instrumental in collage and montage techniques employed not only in electronic music but also in *musique concrète* that made use of a broad range of natural and technical environmental sounds [32.64]. The idea to expand sound material from tones and chords as well as complex sonorities into *musical noise* had been propagated by Italian *Futuristi* [32.117] and had been pursued by some composers in Europe and overseas.

Schaeffer's Typology of Sonic Objects

An attempt to deal with the huge range of sonic and musical objects serving as material for contemporary music was the comprehensive *solfège des objets musicaux* prepared by *Pierre Schaeffer* [32.118, pp. 387–597]. *Schaeffer* condensed his considerations into a scheme [32.118, pp. 584–587], which is formally organized like a matrix (*m* rows, *n* columns). The rows contain what he calls criteria of musical perception (critères de perception musicale); the criteria are masse, dynamique, timbre harmonique, and profil mélodique, profil de masse, grain, allure. These terms refer to volume (in the sense of Stumpf, Rich, Stevens), dynamics, and spectral as well as tonal structure in sonorities. Since Schaeffer's scheme is not confined to single sounds, and in fact tries to establish a typology of musical objects, he includes basic types of melodic contour (like the *podatus* and *torculus* known from Gregorian chant and neume notation). Grain (on the level of sounds) refers to the *surface* (which can be rough or smooth), and allure means the envelope, which can be regular (with or without vibrato) or irregular, etc. The columns comprise qualifications (types, classes, genres) and evaluations according to *species* (espèce, which also can designate a sort or a kind) in regard to the *height* (hauteur), intensity, and duration of sonic objects. To be sure, the typology offered by Schaeffer was a bold attempt which, however, is based on personal experience and description rather than on systematic treatment backed by empirical data. As a typology, it serves to order phenomena according to certain aspects even if it is not consistent in every respect (the matrix has some empty cells). Like in the phenomenological description of tonal attributes [32.106], the perspective is that of the appreciative subject perceiving sound and music.

Semantic Attributes of Timbre

Though subjects experience sounds as sensations characterized by certain qualities and intensities, perception can involve verbalization when judgment based on sensory data includes an act of predication [32.119]. Since sounds and their timbres allow for verbal description (and, moreover, can convey a musical or extramusical meaning), people speak of a *rumbling thunder*, *gurgling water*, *whistling wind* as well as of a *whining violin* or a *blaring trumpet*. Most languages contain very many adjectives used to characterize certain sounds or their timbres, and one can find a host of such adjectives in reviews of concerts and recordings as well as in other publications on music. In psychology, sets of adjectives were used to characterize expressive qualities of musical pieces or phrases in order to disclose their affective mood and their *meaning*, in regard to listeners [32.120].

The study of semantic meanings that things or persons or ideas have for various people was pursued by *Charles Osgood* et al. with a methodology known as semantic differential [32.121] and also as *polarity profile*, in areas of psychology. The goal is to measure attitudes and preferences of people as they value or dislike certain things, persons, ideas, etc. Osgood et al. conceived of a *semantic space* in which various concepts (this term was used instead of *stimuli*) could be placed according to the judgments subjects give on lists of adjectives (or nouns) ordered so as to form bipolar pairs (like soft–hard, good–bad, fast–slow). In between such polar adjectives, a scale is inserted for which *Osgood* et al. [32.121, p. 85] proposed seven alternatives. These can be expressed by numbers or by verbal qualifications suited to indicating a scale. The technicalities of scale construction are in fact as important for the outcome and the reliability and validity of experiments as is the selection and the arrangement of adjectives (some critical issues are discussed in [32.122–124] and [32.125, p. 73 ff.]).

A semantic differential or polarity profile usually comprises from about 30 to 70 pairs of adjectives, which are the variables used to characterize a number of items (*concepts* in Osgood's terminology), by a sample of subjects. The resulting data (blocks of variables × items × subjects) is subjected to the calculation of descriptive statistics (means, variances, etc.) and of intercorrelation matrices, on which in many studies factor analysis (FA) with respect to PCA (principal component analysis, usually with varimax rotation) has been performed. Without going into details of FA (besides PCA, there are several other methods and models in use), it should be noted that the methodology involves a load of vector and matrix algebra as well as the representation of the variables and the factors calculated from the variables in a *k*-dimensional vector space [32.126]. To be stable as topological constructs and reliable and valid in regard to interpretation, fac-

tor models must conform to geometrical axioms and principles. *Osgood* et al. [32.121, p. 91] suggested to conceive of distances between *concepts* in the semantic space in terms of linear geometrical distances. To calculate these distances without violation of geometrical axioms (and minimizing the risk of artifacts), the raw data should be interval or ratio scaled. However, this is a condition rarely fulfilled in studies based on semantic differentials. Moreover, these seem to comprise two different kinds of scales as the adjectives selected for the polarity profile in many studies are either denotative (descriptive in regard to features and attributes of items) or connotative (associative in regard to features of items); some adjectives are in between these categories. Consider, for example, sounds recorded from various orchestral instruments (strings, woodwinds, brass, percussion) that differ in temporal envelope and spectral structure (Sects. 30.2 and 32.1.2). On the denotative level, one could offer adjectives such as soft–loud, dull–bright, smooth–rough, transparent–dense. Further, there are adjectives such as *nasal* that are widely used but may refer to more than one acoustic property [32.127]. In addition, there are adjectives that may denote timbre qualities more indirectly. For instance, the sound of a trumpet appears *shining* to many listeners; the objective basis for this is spectral energy distribution and centroid. Then there are adjectives that express connotative rather than denotative meanings associated with certain timbres like *doleful*, *exciting*, *gloomy*, etc. The problem is that the scales used for denotative attributes can be regarded as rating scales (subjects try to estimate a certain quality and/or intensity on the basis of a sensation) while the connotative adjectives rather call for an emotional appraisal or associative guess (consider, for instance, a pair like *dreamy–awake* in regard to the violin sound of Isaac Stern playing the opening measures of the Adagio in Bruch's violin concerto).

The semantic differential (often coupled with FA) has been used in the study of musical and other sounds [32.128–132]. In *Osgood* et al. [32.121, p. 36 ff.], the *standard* solution obtained from FA consists of three factors, the first of which was interpreted as evaluative, the second as a *potency variable*, and the third as *activity*. Such a solution restricted to three factors seems plausible if the factors allow for a rather wide interpretation and thus can embrace a larger number of variables (in this case, pairs of adjectives). It should be noted that *Wundt* [32.133] had proposed a three-componential model of emotions based on three polar pairs (pleasure–displeasure, excitement–inhibition, tension–relaxation) from which a number of additional emotions were derived as combinations (e.g., joy is derived from excitement, pleasure, and tension). In a factor model consisting of three independent, that is, orthogonal factors, these fit into a three-dimensional space so that the items can be conceived as *points* (relative to coordinates x, y, z in Euclidean space) and the distances between items (as well as between subjects) calculated as Euclidean distances where the linear distance between pairs of points ($a = x_i, y_i, z_i$; $b = x_j, y_j, z_j$) is interpreted as a measure of phenomenal similarity or dissimilarity respectively. Finally, three factors in many empirical studies suffice to explain a substantial percentage of the variance in the data. However, the factors derived from FA again are vectors that do not always lend themselves easily to factual or perceptual interpretation in regard to the items and/or subjects. Also, the interpretation calls for some *label* that will be attached to a factor. *Rahls* [32.129] found for 20 sounds and 47 pairs of adjectives a four-factor solution of which the first three were interpretable: the first as an *evaluative* factor, the second as one that involves *activity* and the third viewed as *potency* (see above). In *Jost*'s [32.130] study of clarinet sounds, one factor pointed to *volume* as an attribute, and a weak factor indicated the specifics of the clarinet timbre.

In contrast, *von Bismarck* [32.131] found for his sounds (sine tones, complex tones, noise) a strong factor accounting for 44% of the variance that relates to spectral energy distribution and presence of energy in higher frequency bands. This factor, which quite clearly reflects a sensory attribute [32.134], was labeled *sharpness* (German: *Schärfe*). In an experiment taking up some of Bismarck's pairs of polar adjectives as *differentials* but using dyads played from wind instruments, *Kendall* and *Carterette* [32.132, p. 455] found that *sharp is not a good discriminator across wind instrument dyads* since *sharp* in English refers to *pitch* rather than timbre. The problem encountered with such terms as *Schärfe* $\neq$ *sharpness* of course is one of semantics. Many of the terms used in description of sounds, even if denotative in essence, are taken from other spheres such as optics (brightness) or haptics (roughness, smoothness). Certain attributes are intermodal in regard to sensation as is the case with brightness [32.135] and apparently so with roughness (which is scalable both as an auditory attribute of sound and as tactual experience; *Zwicker* and *Fastl* [32.136, Chap. 11], *Stevens* and *Harris* [32.137]). Also *Schärfe*, which one could tentatively translate as *stridency* can be addressed as an intermodal attribute. The German *Schärfe* refers to the condition of a blade of a sword or knife that has been sharpened; the word also denotes the sharp outer edge of a swinging or carillon bell profile. Thus, the original meaning is in the tactual and haptic area of sensation. The term can be applied to sounds sensed as glaring, strident, penetrating and perhaps even *hissing* if they contain a strong proportion of energy in higher parts of the audible fre-

quency range. Such sounds can be easily generated in harmonic complexes when amplitudes of partials increase in proportion with harmonic number [32.138]. Another method simply is bandpass or high-pass filtering of harmonic or inharmonic complexes or noise bands so that energy is concentrated in the frequency range corresponding to higher critical bands (CBs) of the auditory system.

The problems involved in verbalizing sound and musical phenomena in general are complex and difficult to solve. In certain ways (reflected in a number of essays by *Charles Seeger* on fundamentals of musicology [32.139]), it would be recommendable, though perhaps not always practical, to communicate in the medium of music about things musical instead of using speech. From the viewpoint of empirical methodology, it seems wise to reduce semantic ambiguity in verbal descriptions of sound as far as possible, which can be done by selecting such adjectives and nouns that denote certain sound characteristics rather than using connotative adjectives (where subjects in a sample often have ideas as to their meanings that differ widely). Also, verbal descriptors should be checked in experiments for consistency relative to various sets of stimuli as well as for their strength of differentiation between items (one of the issues with semantic differentials is the lack of standardization [32.122]).

In order to avoid pitfalls that can happen with the methodology of semantic differential and FA interpretations, the use of adjectives combined with unipolar scales and a robust method of data analysis such as hierarchical cluster analysis seems advisable. This approach was chosen by *Thies* [32.140] in an attempt to find fundamental categories for a descriptive classification of sounds that could bring Schaeffer's more intuitive scheme to a systematic and formal typology. Starting from the German vocabulary which, in regard to sound and its attributes, offers some 1600 descriptive and connotative words, he selected 51 *general* classifiers (e.g., loud, soft, rough, smooth, high, low) and 382 more *specific* (like nasal, creaky, buzzing, pulsating, whispering). In experiments offering musical and environmental sounds as stimuli, subjects were asked to judge which of the classifiers applied to certain sounds, and if so, to what extent. Cluster analysis found groups of adjectives that represent basic descriptive sound categories. From these groups, pairs of adjectives (like tonal–noisy, dark–bright, soft–hard) representing fundamental spectral and temporal features and sensory attributes (tonalness, brightness, loudness, etc.) were considered as fundamental classifiers to be used in a first-level analysis and classification while, on the next level, more specific classifiers are used for a fine-grained classification and typology.

The problem of semantic meanings adjectives have with respect to properties of sounds and attributes of timbre may aggravate if viewed from an inter-language perspective. Inasmuch as languages reflect cultural norms and experiences shared by ethnic and language groups, it is likely that cultural differences manifest themselves in different concepts and terminology even though acoustic properties of sounds and also parameters of auditory perception are identical among such groups. In a comparative study with subjects having either Greek or English as their native tongue, the convergence of descriptive adjectives was tested with the verbal attribute magnitude estimation (VAME) method [32.123, 141, 142] which avoids semantic differentials by putting adjectives against their negation (e.g., dull–not dull, sharp–not sharp). This comparative study [32.143] employed various methods of data analysis (cluster analysis, FA, correlational techniques) and also feature extraction from the stimulus sounds (23 musical instrument tones). The data analysis resulted in three common dimensions labeled luminance, texture, and mass, where luminance refers to attributes like brightness and sharpness (to include, however, depth/thickness in the Greek sample) while texture was interpreted as related also to spectral energy distribution, and mass possibly referring to spectral density and flux. The results demonstrate that a set of sound stimuli presented to subjects from different culture and language groups may elicit responses that converge to a certain extent due to acoustic stimulus features while there are also differences in conceptualized attributes derived from descriptive adjectives. In a Swedish study on the timbre of the steady state of alto sax sounds also employing adjectives along with VAME, *Nykänen* et al. [32.144] found a combination of rough and sharp (seemingly included in the Swedish adjective rå ≈ raw, bleak), soft, warm as well as a vowel quality o-like to describe the sounds best. There was a correspondence to psychoacoustic parameters in that the attribute *rough* could be predicted from the model of roughness used by *Aures* [32.145, 146] combined with the model of sharpness proposed by *von Bismarck* [32.131, 134].

Similarity Ratings of Sounds

Another approach to timbre research is that of similarity ratings. Detection of similarity in objects conveyed as sensory input is an experience basic to humans and other species. There are several theories of similarity some of which emphasize extraction of features from sensory input that are used for comparison while others underpin the cognitive evaluation process underlying similarity judgments [32.147, 148]. In regard to the problem of verbalization addressed in the previous paragraph, one might assume that the recognition

of similarities driven by sensory input works without verbalization while an analytic cognitive evaluation of input rather would involve such. Assuming a hierarchical model that leads from sensation to perception and apperception (Sect. 30.1.2), different levels of processing would likely be reflected in shades of awareness of such processes.

In the field of sound and music perception, *Stumpf* [32.149, Sects. 6,7] especially argued that different degrees of similarity as perceived by subjects can be expressed as differences in distance, which implies similarity is scalable and differences in similarity can be translated into some distance measure. Scaling of similarity has been a paradigm for a long time, for which a standard methodology usable in psychophysics and other areas was developed [32.150, 151]. Since phenomenal similarities between a set of objects often rest on several or even many properties, the geometric concept according to which perceptual *similarity* ≡ *proximity* has led to a multidimensional perspective where objects can be represented as points in a k-dimensional space. The interpoint distances relative to a number of dimensions then express the *similarity* or *dissimilarity* between n objects on m dimensions ($n \gg m$). In addition, one can calculate and geometrically represent similarity judgments of different subjects in a sample to compare their perceptions. The methodology to carry out such empirical studies is multidimensional scaling (MDS), also termed multidimensional similarity structure analysis [32.152, 153]. There are some ideas and concepts shared by both FA and MDS, namely the idea that a subject's responses to complex stimuli comprising several or many variables can be explained and/or predicted from a small number of factors or dimensions as well as the concept to represent relations between high-dimensional (multivariate) stimuli in a rather low-dimensional geometrical space. This space, spanned as factor configuration or MDS model derived from empirical data in several steps, is assumed to reflect perceptual and also cognitive evaluations of subjects. It should be noted that the metric-dimensional approach to *similarity* perception has been challenged on methodological and factual grounds [32.147] and has also been defended as a basis valid for the study of similarity as well as recognition and identification processes [32.154–156]. Though MDS (and, likewise, FA) can be used for data reduction from a larger number of variables presented to subjects in experiment to a few metavariables labeled *factor* or *dimension*, its main function is to help shape hypotheses concerning the dimensionality of complex structures. Like in FA, MDS models can be derived in a precise manner (for Euclidean space and distance functions) if the input consists of interval- or ratio-scaled data. However, similarity judgments are ordinal as subjects find two objects (say, two sounds recorded from any two instruments at the same pitch and presented at the same loudness) are *not similar*, *somewhat similar*, *similar*, *very similar*, *highly similar* or even perceptually *identical*. To allow for a so-called nonmetric MDS, one can assign numbers to such degrees and turn them into proximities from which, in an iterative process (minimizing errors and adjusting interpoint distances between objects or other items), the *final* distances in a k-dimensional space are calculated. The distances of n objects relative to m dimensions are regarded to reflect the perceptions and judgmental decisions of the subjects. The type of metric (Euclidean, city block, Minkowski [32.152]) that is chosen for the model expresses different cognitive decision strategies. If the similarity judgment is decomposable into several more or less separate evaluations of similarity along dimensions $(a, b, c, \ldots, k)$, a so-called city-block metric reflects the additive process. In case a direct and overall estimate of the similarity between objects is performed, a Euclidean distance model sums the differences on the contributing dimensions. When dimensions have different salience for individual subjects, a weighted Euclidean distance model seems apt (though this technique requires certain precautions). A Minkowski r-metric can be chosen if, in a decision process with respect to similarity, one stimulus feature is predominant so that the dimension to which it relates seems supreme against all others. The goodness-of-fit that various models yield with respect to their metric, number of dimensions, error score, as well as the coefficient of determination in relation to the dataset, can be used in a cautious interpretation of the evaluation and decision processes involved in the perception of phenomenal similarity.

Since about 1970, computer software for metrical and nonmetrical MDS has been available, which has spurred many experiments also in the field of sound and music perception [32.157, 158]. Some of the now *classical* experiments on timbre were performed at Stanford [32.159–161]. Grey worked with 16 synthesized sounds that emulated those of orchestral instruments since one task of his research project was to explore computer-based analysis-synthesis techniques. Data from an experiment with 20 musically sophisticated subjects judging the similarity of the 16 sounds were subjected to nonmetric MDS, which did yield three dimensions interpretable in terms of acoustic properties of sounds. The first dimension quite obviously relates to spectral energy distribution and spectral envelope; the second was interpreted as relating

> *to the form of the onset-offset patterns of tones, especially with respect to the presence of synchronic-*

ity in the collective attacks and decays of upper harmonics. [32.159, p. 61]

The third dimension was also viewed as temporal and related to the energy distribution in the attack of tones.

Studies of sound and timbre in most cases have confined their MDS analyses to three or even two dimensions [32.132, 159–168], [32.169, Chap. 6] one of which seems almost notoriously related to spectral energy distribution, centroid and brightness [32.170]. The second often has been interpreted as related to onset characteristics (hard or soft attack, percussive or rather mellow sound) or to the temporal envelope in total. A third dimension sometimes has been viewed in regard to spectral flux which, in most sounds, is considerable at the onset of sound because of the transient portion and becomes small once the steady state is reached. Spectral flux (SF) can be calculated from digitized audio signals where SF expresses the rate of change in spectral composition from one frame of analysis to the next [32.171]. Some studies could not confirm the interpretation of a third dimension as expressing SF [32.158, 167] though in fact most natural sounds exhibit some or even considerable variation in both spectral frequencies and amplitudes over time. In case composite waveshapes are used as stimuli, one dimension can be interpreted as spectral energy distribution (sparse harmonics–rich harmonics) and another in terms of the *surface quality* of sounds; since a sawtooth with many harmonics in zero phase has steep slopes in every period, the sound appears comparatively *rough* while a triangular wave appears quite *smooth* [32.168].

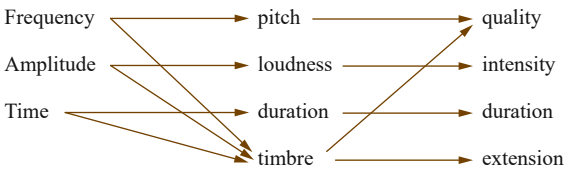
Incorporating a third dimension in a MDS model can be useful to account somewhat better for the variance in the similarity data; however, one might be confronted with a certain trade-off since, with a third dimension in a MDS model, as with a third factor in FA, one often may explain a higher percentage of the variance, on the one hand, while the interpretation of a third dimension or factor can be arduous, on the other. Not only does each factor or dimension need to be given a *label* (the verbalization problem is encountered again, if on another level), but its interpretation must also account for the factual *content* and perceptual effect of stimuli weighted in the light of the *k*-dimensional model. In general, interpretability seems to diminish with the number of factors or dimensions respectively. This can be possibly explained in regard to conditions under which similarity judgments are mostly made in real life, on the one hand, and processes of categorization, on the other. Concerning conditions, one has to take the huge amount of environmental information arriving at our senses as possible input into account. From an evolutionary perspective, *survival* makes very fast recognition of objects imperative. In a first and probably pre-attentive step, recognition involves some overall and provisional categorization in which comparison of a possibly new object to previously learned *prototypes*, *schemata* (or whatever the template is called) is performed. For an instantaneous comparison which, with respect to *survival* behavior, may trigger further sensory processes as well as motor responses, restriction to a few salient features seems pertinent. Adopting either a feature detection approach or that of dimensional metric as in MDS, reduction of the processing load is inevitable in fast estimates. The goal can be achieved successfully through exclusion of irrelevant as well as dimensional reduction of usable sensory input [32.172]. Even in many instances where the time factor is less critical, overall judgments of similarity apparently still seem restricted to a few salient features or a small number of dimensions respectively. Apparently, such suffice for a rough perceptual ordering of things into categories; listeners hearing music in a concert or from the radio can perform at least a tentative classification of sounds representing, for example, strings, brass, and percussion instruments. This can be done with reference to very few acoustical features and perceptual attributes, a fact corroborated from computer-based classification of musical sounds with respect to sources [32.173]. Many of the two-dimensional MDS models of *timbre similarity* in fact relate to the temporal and the spectral envelope as fundamental components of complex sounds; the two most common dimensions *centroid/brightness* and *onset/envelope* (see above) apparently suffice to categorize a host of sounds according to their timbre, at least in a gross mode. A closer inspection then may reveal further details needed for a finer classification. In this respect, timbre can be viewed as an emergent perceptual quality [32.174]. Of course, learning plays a role in such processes as recognition and identification of timbres where trained musicians usually perform faster and more reliably than nonmusicians. For example, it needs no expertise to assign a certain impulsive sound one hears to a class of instruments (say, membranophones) while one must have some experience to judge what the type of drum from which the sound comes could be (size, single- or double-headed, beaten with hand or stick), and it is certainly demanding to decide whether a drum sound correctly identified as that of a frame-drum belongs to a Moroccan *bendir* or to an Irish *bodhran*. However, in experiments involving synthesized FM sounds (TX 802) most of which emulated familiar instruments, differences in performance between subjects in three subclasses of musical expertise (professionals, amateurs, nonmusicians) were not just as great as one might have expected [32.167].

32.2.3 Acoustical Features and Perceptual Attributes of Timbre

Schouten [32.175] saw five acoustical parameters defining timbre:

1. Tonalness versus noise
2. Spectral envelope
3. Time (or temporal) envelope
4. Change in spectral envelope or in pitch
5. Onset characteristics, which he labeled *acoustic prefix* of sounds.

These in fact are interrelated in a number of ways, as are the four fundamental qualities of pitch, loudness, duration, and timbre that are constitutive for auditory perception. It is evident that one cannot perceive a *pitch* from a tone unless it does have a duration and sound intensity. Likewise, loudness as based on intensity and frequency [32.176] and variable also with the duration of stimuli presented to subjects calls for a sound that must have some frequency content with nonzero duration and amplitude(s). In this respect, parameters are not totally separable even though one can study the relative weight they can have in sensation and perception of complex sounds. The idea that parameters might be separable and decomposable into *dimensions* perhaps owes to classical concepts of psychophysics (Sect. 30.1.4) where sensations were studied with respect to quality, intensity, duration, extension, etc. Taking acoustical sound parameters, on the one hand, and perceptual dimensions, on the other, one can set up the following scheme:



Of course, pitch can be explained also in the time domain (Sect. 31.4), and loudness depends not only on physical intensity of the sound but to some degree on spectral energy distribution as well as on presentation time and temporal integration (Chap. 33). Further, timbres can be perceived as distinct qualities in case they offer salient features.

The view according to which pitch is separable, in principle, from timbre is not identical with that advanced by *Helmholtz* [32.90] on separability of pitch and sound color (Sect. 32.2.1). Taking the Fourier-based resonator model of Helmholtz, a harmonic complex simply is decomposed, on the basilar membrane (BM) level, into partials along a log frequency axis where the lowest partial (f_1) accounts for the sensation of pitch, and the remainder of the spectrum for *sound color*. The concept indeed implies that a sound, well-defined as to its pitch through f_1 (as well as its inverse, the period $T = 1/f$), gains some additional *coloring* from the spectrum above f_1. In this respect, sound color is a more or less stable quality corresponding to the steady state of a sound [32.177]. Further, sound color can be viewed in regard to *extension* where the number and strength of partials define spectral width, density, and centroid (for a given f_1 of, say, 110 Hz, the centroid shifts upwards in frequency with the number of additional partials). This effect is easily demonstrable with an analogue synth where a tone (say, A_2), when played with a sawtooth wave, gains in *color* as well as in brightness from sweeping the cutoff frequency of a low-pass filter toward higher frequencies. In early works on orchestration [32.3] the term *timbre* also referred to a sound quality largely determined by spectral structure while the temporal aspects as yet were of little concern. Since the 1920s and 1930s, when onset characteristics and temporal fluctuations of sounds could be studied with electroacoustic equipment at hand, transients in particular in aerophones and chordophones have been a topic of research (for a survey, see [32.31]). With computerized sound analysis, transients were investigated as dynamic time-frequency structures from which information relevant for auditory perception can be drawn [32.178]. In the following, the parameters discussed by *Schouten* [32.175] will be examined further in the light of research data.

Transients and Onset

The transient part of a sound reflects a vibrating system immediately after excitation, which can be effected by a single impulse as in many idiophones (e.g., xylophones, gongs, bells, cymbals) and membranophones as well as in plucked strings, or by a sequence of pulses as in aerophones (Sect. 32.1.2) and in bowed chordophones where excitation continues with energy supply to the generator. The transient portion of a sound can be defined as that from the absolute onset of vibration (the time point or sample where the amplitude is nonzero) up to a point where vibration becomes either periodic with small fluctuations (as in aerophones and chordophones) or where the peak amplitude is reached and the decay of the envelope begins (as in idiophones and membranophones excited by a single impulse). The transient portion of a sound is the most *interesting* part in terms of information (see [32.25] for concepts describing information structure of sounds) since information depends on entropy and the rate of change per time unit. *Shannon* [32.116] gives a formal proof that white noise has the maximum possible entropy. In comparison to the almost periodic regime of vibration in the steady state, the onset often lacks clear periodicity and

can even appear *chaotic* (as indicated by the limit cycle for the time series of a vibration or sound in a phase space). The onset of many sounds recorded from natural instruments includes noise in the transient portion; a well-known phenomenon observed in organ flue pipes is the *spitting* response to air pulse sequences before a standing wave is established (Sect. 30.2 and examples in [32.179, Chap. 5]).

For the listener, the rapid changes that the wave shape and spectral content undergo in a short time result in a high rate of information delivered to the perceptual system. In contrast, the flow of information saturates once the steady state is reached. For example, for identification of clarinet sounds it was found that scores do not improve after 0.5–0.6 s of presentation time [32.180]. In regard to detection and identification of onsets and transients as well as of changes in spectral envelope over time, there are temporal and dynamic thresholds as well as several integration constants that have been reported from experimental findings (for an overview of research, see [32.31]). Further, there are forward and backward masking effects (for a detailed discussion, see [32.181]). Some of the relevant integration constants concern the very limit of auditory temporal discrimination between two events and the threshold of temporal order between events. The limit of temporal discriminability has been given as 3–5 ms (as in experiments on gap detection), however, the absolute value depends somewhat on sound level and other conditions. Other time constants concern just noticeable differences in onset asynchronicity and the threshold of temporal order. Onset asynchronicity between instruments playing notes simultaneously typically is in the range of 0–20 ms; asynchronicity within this range (and approaching its upper limit) supports identification of instruments [32.182]. Onset, in this respect, means the sensory and perceptual *event* that of course is dependent on the vibration pattern of sounds yet is not identical with the SPL measured at a certain time. The perceptual onset for tones in succession will be detected when the amplitude of vibration and the SPL of the sound radiated from a source exceed a certain threshold, which has been given as 6–15 dB below the maximum level of a tone [32.183]; this threshold is variable with respect to the absolute SPL of the stimulus and is also variable due to masking effects if several tones/sounds are played in close succession or nearly simultaneously. Two tones played in succession become clearly discriminable as *auditory events* when their perceptual onsets are about 40 ms apart; the threshold for audible single reflections of sound from walls to be perceived as *echoes* is in the range of 40–50 ms so that several early reflections occurring within a shorter time span ($t < 30$ ms) typically *smear* into one sensation. Given that ≈ 50 ms mark the time difference between events to be perceived as an orderly sequence and that complex tones in general are identified in regard to their pitch, timbre and loudness in a time window of ≈ 100–200 ms, it follows that the number of notes in music that are clearly identifiable as a melodic and diastematic structure, plus conveying a certain timbre and loudness, is limited per time unit.

Onsets can be very short as in swinging and carillon bells where, after the energy is transferred from the clapper to the bell (contact time ≤ 1 ms [32.184]), a large number of modes is excited within a few ms since the wave speed in bronze is ≈ 4400 m/s for longitudinal and ≈ 2160 m/s for transversal waves. The sound radiated from the bell or from a similar idiophone struck with a hard mallet contains many strong harmonic and inharmonic partials as a complex mixture [32.85, 86, 185] from which the auditory system must derive pitch and timbre information [32.186]. The onset of such sounds (which fall into a time window of 20–50 ms) usually is perceived as *clangorous* due to considerable spectral inharmonicity as well as high-frequency content, and assignment of a single pitch to the onset segment often is not possible. If idiophones struck with a mallet are at one end of a scale measuring the acoustical transient portion of a sound, there are some instruments on the other where the transient is long and can last for several hundred milliseconds as, for instance, in a double-bass played softly with a bow [32.187] or in large organ flue and reed pipes [32.35]. Also, some folk instruments such as the Slovak duct flute *Fujara* (of ≈ 160 cm tube length [32.41]) are slow in the buildup of modes. However, the dynamics of the onset of a sound is much dependent on playing technique as well as the dynamics of the musical context in which instruments are used. In works of modern music, notation might prescribe dynamics from *fffff* to *ppppp* and might include verbal instructions that range from *tutta la forza* to *morendo*. Also, composers in the decades after 1950 demanded instrumentalists (and also singers) to produce sounds in often uncommon ways, which could bring about, for example, quite percussive sounds from wind and string instruments. The variability of onsets due to playing technique and context notwithstanding, subjects familiar with music and orchestral instruments make use of the onset of sounds as information bearing to the classification and identification of such instruments.

For listeners, the transient part of sounds serves to distinguish various instruments as well as to mark the onset of notes. Transients such as the *spitting* of organ pipes, the prerunner sound in harpsichord strings (when the plectrum touches the string before lifting and plucking it [32.188, 189]), the *raspy* attack of a bow set to

motion on a cello string (in particular the C- and the G-string), the plosive attack in a trombone or trumpet tone, are such *prefixes* (to use Schouten's term) to the steady state that make sounds characteristic of certain instruments or families of instruments. Some instruments also have a peculiar decay or have markers at the end of a tone; for instance, in most harpsichords one can hear the jack fall down when a key is released, an effect that is prominent when full chords are played. In an ensemble performance, the *prefixes* from individual instruments can help listeners to notice the onset of the tones they play (listen, for example, to Hindemith's *Kleine Kammermusik für fünf Bläser,* op. 24,2). If attack transients and the final decay to zero amplitude are removed from natural instrument tones, identification scores drop significantly even for musically trained subjects where the effect is greatest for the attack removed [32.190]. Conversely, in an MDS study [32.166], similarity ratings for onsets from natural instruments presented in isolation did not differ much from complete tones, indicating that the onset contains most of the relevant information [32.25]. Removing perceptual cues like the transient at the onset means an increase in confusability of stimuli. Apparently, the effect can be compensated, to some extent, by playing technique. For example, instruments typically played with vibrato (flute, violin) are less affected by such removal since the vibrato then may substitute the cue needed for identification [32.191].

Time (or Temporal) Envelope

Isolated sounds from various instruments can be distinguished with respect to their temporal envelope, which can be segmented into characteristic parts (as in the attack, decay, sustain, release (ADSR) model Sect. 30.2). For instruments excited by a single impulse (many idiophones, most membranophones) a rapid attack is followed by a fast decay. Large bells have a long sustain, however, when sound is radiated on a low level for tens of seconds. In aerophones, tones die away quickly once the air supply to the generator is stopped. In plucked and bowed chordophones, sustain can be quite long after excitation has stopped because parts of the resonator and the air enclosed in the box still vibrate (due to a storage of energy). For the tone G_2 played on the open string of a cello (staccato, forte), the sustain lasts for ≈ 3 s after the bow has been lifted from the string (Fig. 32.8; the sound was recorded ≈ 0.5 m away from the instrument in a *dry* studio).

In this tone, the rapid attack and the long sustain are perceptually salient envelope features. In general, there are certain shapes of envelopes which, combined with spectral patterns, probably make up *timbral prototypes* for listeners. Changing the temporal and/or the spectral envelope means part of the information does not match a certain type of instrument. For example, reversing a natural complex sound affects both cues since, even though the total energy contained in the sound is the same when played forward or backward, the order in which relevant features become audible is reversed, which makes identification of natural sounds reversed in time difficult. The effect of time reversal of sounds was used quite extensively in the 1960s, in recordings of *psychedelic* music, where usually one electric guitar track previously recorded and then played backwards provides lead guitar lines in an otherwise normal mix (listen, for example, to The Byrds: *Thoughts and Words*, recorded in December 1966). An important factor for sensation and perception of temporal envelopes is modulation. Regular amplitude modulation (AM) can result from narrowly spaced spectral components, which would give rise to a sensation of roughness

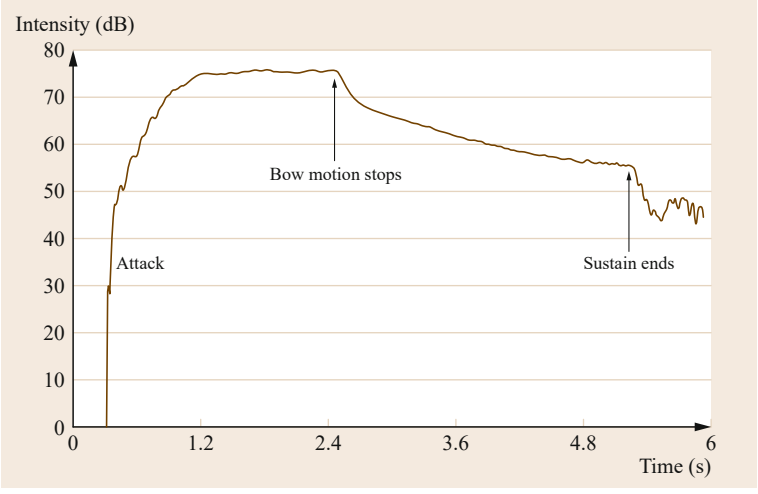


Fig. 32.8 Cello, open G-string (G_2), staccato, forte, steep attack, long sustain

(Sect. 31.6.2) in addition to the amplitude fluctuation. Quite regular AM with very little FM of f_1 and without introducing roughness can be produced also by modulating excitation parameters such as the blowing pressure in a flute [32.192].

Tonalness versus Noise

Tonalness usually is understood as a sensory attribute dependent on spectral harmonicity as well as its equivalent, periodicity of the time signal. Tonalness is one factor, besides roughness, sharpness (or stridency, Sect. 32.2.2: *Semantic Attributes of Timbre*), and loudness in a psychoacoustic model of *sensory euphony* [32.145, 146]. In regard to spectral harmonicity ≡ temporal periodicity (consequent to the Wiener–Khintchine theorem, Sect. 30.2), the steady state of a tone from an aerophone or chordophone played with medium force of excitation is basically tonal while the transient onset can contain noise in significant quantity. Some noise also results from the motion of the bow on a string or from the flow of air in wind instruments (there are playing techniques for flutes and saxophones emphasizing a *breathy* sound). In order to make synthesized sounds appear natural to listeners, their transient part needs to be shaped and noise must be added to sinusoidals in a harmonic or inharmonic complex [32.193, 194].

Spectral Envelope

Perhaps the most important component in timbre perception (and the defining criterion for *sound color*) is the spectral envelope. Additive or subtractive synthesis as was implemented in a host of electronic organs of the 1960s produces sounds which, though lacking characteristic onset and decay of natural instruments, at least are indicative of certain classes and types of instruments (those organs usually offered a selection of *flutes*, *reeds*, and *brass* sounds in more or less fair imitations of the originals). Spectral envelopes for these classes often were derived from filtering a complex (e.g., rectangular) waveshape so that concentration of energy in a band from 1−2 kHz resulted in a more nasal (*reed*) sound while emphasis on energy in low partials and in higher bands (2−5 kHz) should indicate a *brass family* sound. Flutes simply were imitated by low-pass filtering with the cutoff frequency set for a *mellow* sound. Since such synthetic steady-state sounds after a short while are experienced as *static* by listeners (for the lack of fresh information, see above), most electronic organs offered some AM (*Tremolo*) unit modulating amplifier output level while some had facilities to enrich the sound (for instance, by pairs of oscillators slightly detuned against each other so that organ stops with double sets of pipes such as *vox coelestis* or *unda maris* were imitated).

The concept according to which certain instruments or families of instruments distinguish themselves by spectral structure and the shape of the spectral envelope owes much to the source-filter model (Sect. 32.1.2). According to empirical findings [32.169, Chap. 6], timbre is essentially determined by the absolute frequency position of a spectral envelope, which suggests the perceptual attribute of timbre has a physical correlate in formant-like spectral energy distribution. Given that many instruments (aerophones including the singing voice, chordophones) are driven by pulse sequences fed into a resonator [32.195], the sound radiated from the instrument depends significantly on the geometry of the resonator. The size and shape of the resonator largely determines the spectral envelope (assuming the instrument is in its normal register, and played *mf*), which is sensed as a peculiar *sound color* [32.177]. This concept of approximately constant tone or sound color is behind organ pipe stops where different stops (or ranks) of flue and reed pipes distinguish themselves by their sound color, for pipes of the same pitch (determined basically by pipe length, measured in foot, e.g., 8′, 4′, 2′). To maintain a given sound color (e.g., diapason, salicional, flute, trumpet) over several octaves, organ builders follow certain mensuration rules [32.196, Chap. 3]. For example, for two flue pipes an octave apart, the ratio of the pipe lengths is 2 : 1 while the pipe diameters should have a ratio of 1.682 : 1 (and the cross-sectional areas should be in the ratio of 2.828 : 1). That is, approximate homogeneity of sound color from one pipe tone of a given rank to the next is achieved by means of scale factors [32.11, 196, 197]. Correct scaling ideally would produce almost identical spectral envelopes for all the tones within the gamut of several octaves; the envelope then simply is shifted along the frequency axis with rising f_1 of each tone. To illustrate the case, formant filter envelopes of three organ tones recorded from the same stop are shown in Fig. 32.9. The tones are C_2, C_3 and C_4 from a trumpet 8′ stop of the historical organ at Hollern. The envelopes are fairly similar given that the microphone distance relative to the three pipes was not identical and that some reflections of sound inside the organ case may have occurred (sound levels were normalized to −6 dB fs for analysis).

A scale factor that preserves the relations within a specific geometry can also be used for peals of (swinging or carillon) bells where the scaling of size and mass determines the pitches but should (ideally) not affect the sound color. Further, the same principle can be applied to *families* of instruments that cover different registers (soprano, alto, tenor, baritone, bass) but share the same basic sound color [32.195] in the steady-state portion of sound when playing conditions are kept almost constant. A violin, a viola, a cello and a double

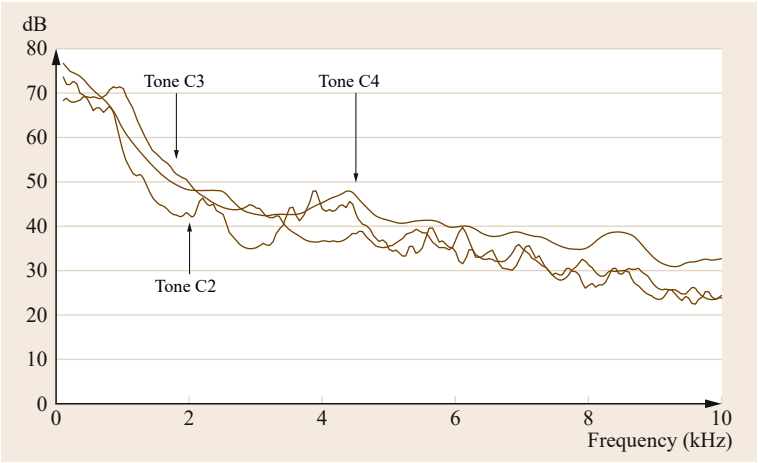

Fig. 32.9 Formant filter envelopes for three tones (C_2, C_3, C_4) of one organ stop (trumpet 8′)

bass are recognized as members of the *bowed strings family* notwithstanding differences in register and variation in spectral fine structure. If types of instruments can be distinguished (and possibly identified) by their respective spectral envelopes sensed as *sound color*, a hypothetical explanation is that the spectral energy distribution in the sound corresponds to a specific excitation pattern along the BM that is learned as representing a certain sound source, and is stored as a template or profile in long-term memory (LTM). However, one has to take the variation in sound color into account, which may occur in different registers of a single instrument, or even within one octave of its playing range. Also, factors such as the strength of excitation (usually from *ppp* to *fff*), dependence of spectral energy distribution and of the directivity pattern of radiation on sound level as well as room acoustics (absorption, reverberation) all influence the *timbre* one perceives of a given instrument [32.52, 198], [32.169, Chap. 6]. The problem of how homogeneous timbral qualities are relative to the tones of a musical scale within one octave, and more so if scales extend into another octave, has been studied empirically. Research on this topic involving MDS was done by *Marozeau* et al. [32.199] who concluded that pitch differences of tones within one octave had but little effect on timbre dissimilarity judgments. With respect to wind instrument sounds, data from musically naive subjects suggested timbre is perceived as identical for tones within one octave [32.200]. A replication of the experiment showed, however, that musicians can make reliable judgments beyond that range [32.201].

Change in Spectral Envelope and Pitch

A close inspection of many musical sounds reveals that both the period length of the complex waveshape and the frequencies and amplitudes of spectral components vary with time. For the steady state of complex harmonic sounds recorded from aerophones and chordophones played without vibrato, the variance of period length T (ms) or its inverse, the fundamental f_0, can be quite small, so that no pitch modulation is audible (in line with autocorrelation function (ACF) analysis). Pitch shifts, however, will be encountered in case tones are played with vibrato, which is customary nowadays for flute and violin performances, especially for the repertoire of the *romantic* era. Vibrato is also used extensively in belcanto singing (Fig. 31.27). Vibrato is performed, for instance on a violin or other bowed string instrument, rolling the cup of the finger up and down on a string whose vibrating length is thereby varied periodically. Vibrato thus produces FM; the modulation frequency usually applied by violinists is about 5−8 Hz and modulation of f_1 and higher partials can reach or even exceed ±35 cent. Vibrato can also give rise to AM of harmonic partials when their frequencies move in and out of the narrow resonance zones of the resonator [32.202]. Consequently, the spectral components in general show periodic AM along with the FM from the vibrato, however, individual components can be affected differently dependent on their position relative to the resonance zones. In sum, the pattern of FM plus AM resulting from vibrato may deviate somewhat from strict periodicity. To illustrate the case, a small segment from the recording of a professional violinist playing the note c#5 (over a chord provided from soft piano accompaniment) is shown in Fig. 32.10.

One can see that the violin partials undergo FM while they exhibit AM to different degrees; some of the tracks marking partial frequencies shift between strong and weaker amplitudes as indicated by black and gray color respectively. Players of the modern concert flute learn a special technique of breathing and chest muscle control [32.203] that enables them to produce FM vibrato and AM tremolo effects. Periodic variation of

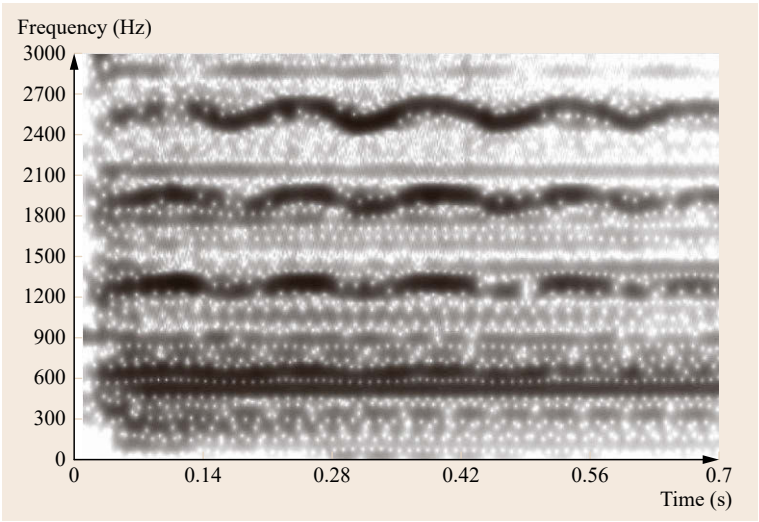

Fig. 32.10 Violin, note C#5 ($f_1 \approx$ 554 Hz), vibrato, FM and AM effects

blowing pressure results in a tremolo without significant FM [32.192]. Changes in blowing pressure means the force of excitation is varied over time, which results in different numbers of natural modes that are excited in the resonator. Also, amplitudes of partials contained in the sound radiated from the instrument vary as a function of blowing pressure. In general, higher levels at the input of the system produce more partials so that the spectrum broadens toward higher frequencies. Consequently, the spectral centroid also shifts upwards in frequency, which can be sensed as an increase in brightness. Further, subjects are sensitive to changes in timbre evoked by phase shifts between harmonic partials [32.162]. The effect is strongest for harmonic complexes where partials are either in sine or in cosine phase as opposed to partials alternating in sine and cosine phase; the strength of the timbral difference depends on f_1 of the complex and varies markedly between subjects. For $f_1 = 294.4$ Hz the maximal effect of phase on timbre for a sample of eight subjects was equal to changing the SPL by about 2 dB. A possible explanation is that the peak amplitude per period and the crest factor are higher for harmonic partials in cosine phase compared to partials in alternating phase. For harmonic complexes consisting of five partials with $f_1 = 200$ Hz and amplitudes decreasing by -6 dB with harmonic number, the difference is ≈ 1.7 dB.

Summing up this section, *timbre* was found to depend on several temporal and spectral properties of sounds, which often combine into complex spectrotemporal patterns that are analyzed into constituents in perception in order to distinguish individual instruments or other sound sources. Modeling sensory analysis as carried out in the auditory periphery, the concept of CBs usually is implemented by chains of bandpass filters suited to perform spectral analysis as a basis for perception of pitch (Sect. 31.5). Such an approach can be followed also for timbre and loudness though in particular the transient part of sounds requires high temporal resolution, which means a conventional Fourier-based analysis may fall short of the performance of the auditory system, which is superior in regard to the *uncertainty relation* $\Delta f \Delta t$ [32.204]. For the steady state of most sounds, spectral envelope and centroid have proved to be good descriptors of sensory attributes (see above and also *Barthet* et al. [32.205] for clarinet tones). Viewed in terms of CBs, patterns of spectral energy distribution code pitch and timbral information as well as loudness (*Pollard* and *Jansson* [32.206], Sect. 32.2.4 and Chap. 33). Applying time constants relevant for auditory perception, timbre can be approached as a sequence of *windows* or *frames* that contain spectral energy distributions. If there is not much change from one frame to the next, a more or less stable spectral profile evolves, which can represent a *sound color* that in turn may indicate a certain instrument or *family* of instruments [32.195]. However, identification of instruments or other sound sources is facilitated when temporal cues are offered along with spectral information. Experiments have shown that attack time is an important cue where either soft onsets or steep slopes (Fig. 32.8) help to categorize sounds. In addition, the overall shape of the envelope can indicate whether sounds are percussive rather than continuant. Further, modulation (AM, FM; regular, quasiperiodic, or irregular) can be used as a cue for timbre perception and categorization. Sounds undergoing modulation (AM and/or FM) might appear *raspy* or *blurred*; some sounds appear *shimmering* or *clangorous* or *ringing* due to spectral inharmonicity and modulation. The actual

effect on sensation depends on modulation parameters (depth, frequency) as well as on how many spectral components are modulated and if modulation is conjoined for these components or not.

32.2.4 Interrelation of *Pitch* and *Timbre*

In concepts of tone perception developed in psychophysics [32.74, Chaps. 9–11], [32.176, 207] the pure tone figures prominently since it allows the establishment of a close correspondence between physical and sensory magnitudes. In regard to pure tones, it is feasible to address pitch as depending on the frequency of vibration, and loudness proportional in some way to the vibration amplitude and intensity of radiated sound. Duration does not pose a problem assuming time is a linear process (equivalent to the constant motion of a mass point in 3-D-space [32.208]). This leaves sound color or timbre as the perceptual quality that relates to several physical parameters (Sect. 32.2.3). As has been argued above, sound color constitutes a quality complementary to pitch if one adopts the perspective of Helmholtz based on Fourier and Ohm, which allows the decomposition of a harmonic complex into the fundamental (f_1) carrying all or at least most of the pitch information, and the remainder of the spectrum conveying the sound color that may characterize a certain instrument or family of instruments. Such a view might hold for the steady state of a harmonic complex where f_1 is dominant and the amplitudes of the other partials roll off at a certain rate (dB/oct) in the spectrum so that the pitch is unambiguously related to the fundamental. However, there are musical sounds in particular from idiophones and also membranophones where this model fails to capture relevant structures. For example, in *Western* swinging bells and carillon bells there are some partials close to harmonic frequency ratios while other spectral components are clearly inharmonic ([32.185] and Sect. 30.2). Typically, complex bell sounds give rise to more than one spectral or virtual pitch [32.104, Chap. 11], [32.186], and these sounds often show marked AM due to interaction of narrowly spaced components. Spectral inharmonicity and spectral modulation are features also found in non-Western idiophones, in particular in Javanese and Balinese *gamelan* [32.85, 86, 209, 210]. The combination of pitch ambiguity, spectral inharmonicity and modulation, which is characteristic of sounds from bells, gong chimes and other metallophones, is not compatible with the additive (f_1 pitch + spectral sound color) concept sketched above for harmonic complexes. Rather, such sounds are sensed as spectrotemporal conglomerates that are not easily analyzable into constituents by ear even though musically experienced subjects can assign pitches to many sounds by singing or humming a tone (or several if they sense more than one pitch per sound). Also, subjects make comments on the *clangy* or *metallic* onset and the *shimmering* decay of such sounds, which thus can be described verbally in terms of timbral attributes. However, for many complex inharmonic sounds there is even less a demarcation between the perception of *pitch* and that of *timbre* than might exist for harmonic complexes.

The issue of whether pitch and timbre are two distinct or two interrelated qualities that subjects perceive when listening to sounds such as synthesized harmonic complexes or tones played on certain instruments has been discussed on the basis of empirical data [32.211–213], [32.104, Chaps. 10–12]. In regard to criteria elaborated by *Garner* [32.172] for *integral* and *separable* dimensions of perception, there seem to be indications for both points of view. From common experience, one could argue that musically trained subjects are capable of assigning two labels to musical tones presented in isolation, one denoting a pitch and the other denoting a timbre that is characteristic of a certain instrument or at least a type or a *family* of instruments. The two judgments implied in such a labeling task are *categorical* in that the stimuli have to be ordered into discrete categories. Such a task can be accomplished if the cues available to subjects intending to identify both the pitch (in terms of musical denominations, e.g., F_3, B_4) and the instrument type (e.g., tenor sax, trombone, cello, electric bass) are unambiguous and salient. However, in experiments on possible interactions of pitch, timbre, and loudness involving synthetic sounds, subjects seemed unable to attend to one dimension or attribute while disregarding the other (two experiments coupled timbre and loudness as well as timbre and pitch [32.211]). If the task is discrimination of small changes in either pitch (with respect to f_0) or timbre (defined by spectral centroid) of synthetic harmonic complexes, musically trained subjects showed smaller difference limens (DLs) for pitch than nonmusicians but were similar in their respective spectral centroid DLs [32.213]. In addition, performance differed significantly between congruent (changes in f_0 and spectral centroid were in the same direction) and noncongruent conditions (which, in natural sounds such as produced from wind and string instruments, is unlikely). While some experiments suggest pitch and timbre can be perceived as independent of each other [32.212], interference of pitch and timbre has been reported as well. A possible explanation for conflicting evidence may be sought in different experimental designs, stimuli, and tasks. If the stimuli are tones from familiar musical instruments (or synthesized tones close in timbre to natural sounds), in particular

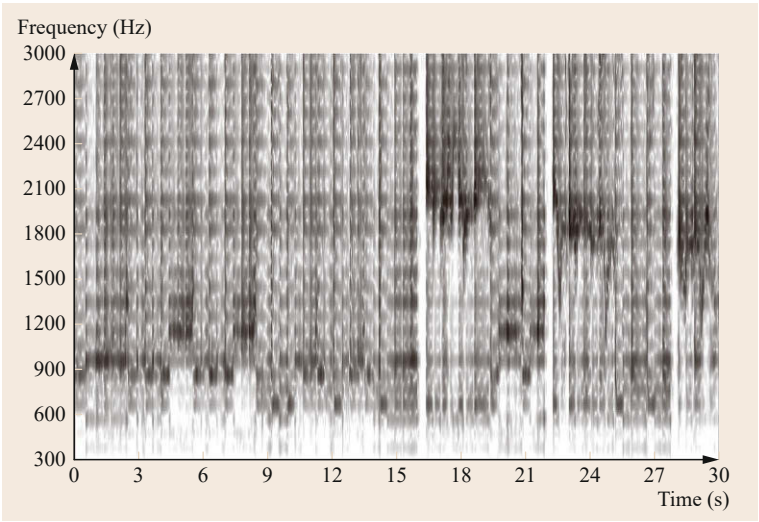

Fig. 32.11 Spectrogram 300 Hz – 3 kHz, Jew's harp melody, Opal Shuluu (Tuva)

musically trained subjects will have little difficulty in tracking both pitch changes and watching for changes in timbre (for example, shifts in centroid and brightness evoked through spectral filtering or by means of phase shifts between partials). Subjects thus can focus on one parameter at a time and quickly shift their attention between two parameters; such a strategy may be effective for essentially *independent* processing of pitch and timbre information. However, the structure of sound stimuli and of the sensory input used for processing has to be taken into account (Sects. 30.2, 31.1–31.6). For complex harmonic sounds such as radiated from aerophones and chordophones, BM filtering and auditory neural processing conveys pitch information both in place and in temporal code. Resolved partials and groups of unresolved partials all contribute to periodicity pitch while they also convey information concerning spectral energy distribution and spectral profile, which result in perception of sound color and the changes it may undergo in the course of presentation. Major changes in spectral structure and energy distribution can also have effects on perceived pitches. For instance, attenuation of the odd harmonics as well as phase shifts of partials in a complex can bring about a shift in perceived tone height by an octave or even several octaves while not affecting the *chroma* component of pitch ([32.214] and experiments reported in [32.215]).

The interdependence of pitch and timbre in harmonic complex tones is evident from music realized with instruments where a generator is put into the mouth that functions as resonator as well as with styles of vocal music where the mouth cavity serves as a bandpass filter. Such techniques can be observed in musical genres of various cultures where the Jew's harp (also: jaw's harp, trump) or the mouth bow are in use, or where styles of overtone singing are practiced. Figure 32.11 shows an excerpt of a melody played by Opal Shuluu (Tuva) on a Jew's harp [32.216, Track 31]. The spectrogram shows that each vertical sonority contains quite many components in the most relevant band (300 Hz–3 kHz), many of which are nearly harmonic and appear as multiples of a virtual pitch (autocorrelation, AC) at ≈ 96.1 Hz; the melody is filtered out by changes in the resonator (mouth cavity) so that certain components become more prominent in the spectral energy distribution per time frame. It is a typical mixture of melody against a drone, or, put in terms of Gestalt psychology [32.217, Chap. 7], of a figure against a ground.

With inharmonic sounds, separation of pitch and timbre is much more difficult since there is no strict periodicity relevant for f_0 pitch perception, and spectral structure may be also quite irregular. This hampers pitch perception for individual sounds from bells, gong chimes, or other metallophones [32.218]. Further, sequences of inharmonic sounds representing a scale or a melody may differ considerably in spectral energy distribution from one sound to the next as can be observed, for example, with bells in historic carillons. Spectrograms of sounds (cut to the initial 3 s) recorded from bells no. 1–3 of the Brugge carillon (Joris du Mery 1744, [32.186]) in Fig. 32.12 demonstrate that, notwithstanding essential components of a minor third bell that can be identified in all three segments, there is no homogeneous *sound color* since distribution of spectral energy varies markedly between these sounds. Further, the spectral component lowest in frequency (*arrows* in Fig. 32.12 marking the so-called *hum note*) in each of these three bell sounds is weak in intensity, which implies it will hardly elicit an individual spectral

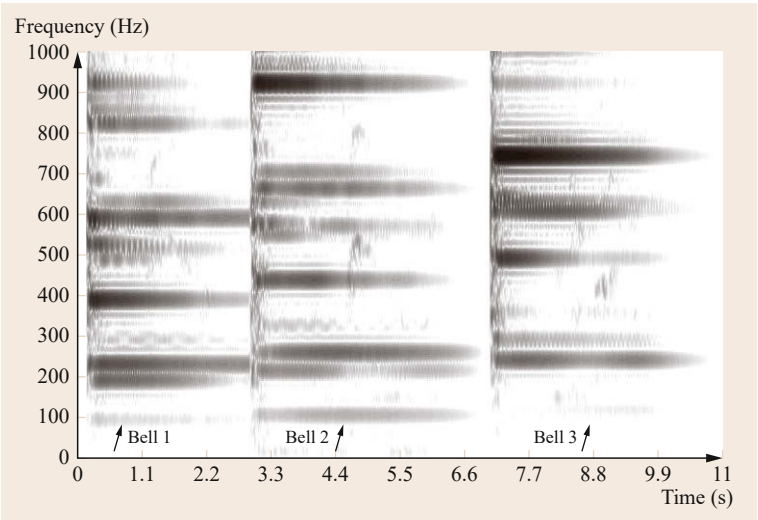

Fig. 32.12 Brugge carillon, sound segments from bells no. 1–3, spectral components 0–1 kHz, *fundamentals* (hum notes) marked by *arrows* are weak in these sounds

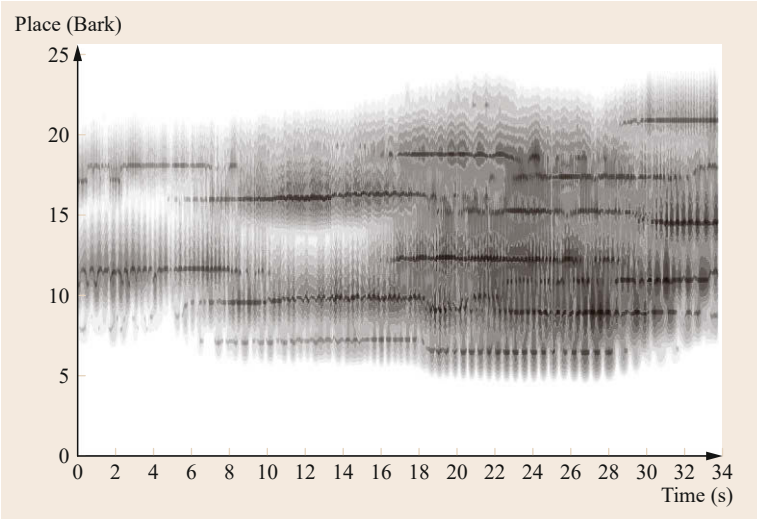

Fig. 32.13 John Chowning: excerpt from *Phoné*, left channel, cochleagram

pitch. Unlike the fundamental f_1 in a harmonic complex, which is reinforced by the sum of partials contributing to f_0 ($f_1 \equiv f_0$), virtual pitches in inharmonic complexes must not converge with the lowest spectral component. In bell sounds, the most prominent virtual pitch (the strike note) often is close to, but not identical with, the second spectral component. If this is fairly strong, it can be sensed as a spectral pitch besides the strike note. Pairs of adjacent spectral and virtual pitches cause ambiguity in perception.

The ambiguous nature of inharmonic sounds has been explored in compositions of computer music where textures of harmonic and inharmonic complexes are interwoven as in works of John Chowning who made use of the FM sound generation technique he had developed [32.59, 219]. In one such work, *Phoné* (1980/81), sequences of complex sounds, which at times resemble formant structures of the human singing voice, are distributed on two stereo channels (in the CD mix [32.220]). Though the listener can detect tonal elements in the complex sounds from both channels, spacing of spectral components is quite dense and energy distribution covers much of the audio bandwidth. A cochleagram (Fig. 32.13) shows an excerpt from *Phoné* (left channel only); one can see several strong components per time unit that are relevant in regard to spectral and/or virtual pitches interspersed with broad bands of energy. The perception resulting from both channels is a complex mixture of *timbral* elements with faint pitch structures in between. The vertical structure of these complex sonorities thus differs from traditional compositions where, typically, several *voices* can be

distinguished, which interact in polyphonic settings or combine into chord-like formations.

Electronic music based on analogue technology had already lifted the boundaries between *voices* and *timbre*. With digital technology, one can create complex sonorities of many kinds. Also, interpolation between various spectra chosen from natural sources can be effected (spectral interpolation is different from cross-fades between sounds as are available in most samplers, *Arfib* et al. [32.221]). The approach to sound generation based on digital FM opened new perspectives since, taking the basic concept of FM, that is, carrier and modulator frequencies, one can combine several modules that produce either carrier or modulator frequencies in a network that can generate arbitrary spectra, which again are modulated in frequency (or in phase) and in amplitude over time. Such sounds in fact can contain several inharmonic and/or harmonic complexes at any given time. Implementation of this concept became available in digital synthesizers suited to daily use in the studio, and even on stage, in 1983 (DX 7 and follow-up models like TX 802, TX 81Z). With digital FM sound generation one can set parameters so that octaves in a scale do have frequency ratios other than 2 : 1 (e.g., the *golden mean*, 1.618 : 1, which Chowning employed in *Stria*, 1976/77, [32.63, 219]). Further, FM technology enables composers to create scales, melodic sequences and chord-like sonorities that appear paradoxical in certain respects, and may be perceived like *auditory illusions* [32.222]. In compositions like *Stria* and *Phoné*, textures and mixtures of complex sounds may still evoke perceptions of *pitch* and *timbre*, however, the flow of sonic objects that are heard, moreover, moving in a 3-D space (the original version of *Stria* is quadraphonic), transcends traditional categories of *tone*, *pitch*, *voice* (in the sense of harmony and counterpoint), and *timbre*.

Composing with complex sounds rather than with musical tones is an approach realized in electronic and computer music as well as in such orchestral works where *clusters* of tones are equivalent to complex spectral structures. In regard to perception and musical syntax, an issue much debated is whether sequences of complex harmonic and/or inharmonic sounds may constitute a *scale* similar in function to a scale of pitches we perceive when hearing a sequence of harmonic complex tones. Some exploratory studies suggested a hierarchical organization of timbre similar to that of pitch would be feasible, at least in principle [32.164, 165, 223].

The issue whether sound sequences could be constructed in which shifts in timbre is the parameter equivalent to pitch shifts like in a musical scale, apparently was nourished from some sketchy ideas on the possibility of a *Klangfarbenmelodie* that *Schönberg* [32.224, p. 471] had added to his textbook of harmony. Schönberg seems to suggest that sounds might be varied in *sound color* so that identifiable sequences more or less analogous to pitch sequences would result. Schönberg did not go into detail except noting that, as he saw it, *Klangfarbe* was a more general concept comprising *Klanghöhe* as one dimension, referring to a sensation of relative height evoked by one complex sound when compared to another. His idea then was to vary *Klanghöhe* in such a way that sequences similar to a melody would be perceived. To be sure, *Klanghöhe* is not identical with *tone height* defined by linear frequency in two-componential models of pitch. A likely interpretation of Schönberg's short remarks is that *Klanghöhe* can be taken as equivalent to the spectral centroid. Consequently, operations on sounds that would shift the centroid up and down like on a pitch scale while maintaining the shape of the spectral envelope might be suited to create a *Klangfarbenmelodie*. Schönberg's own approach to this concept as manifest in his op. 16/III was that he had five tones in a complex sonority changing so as to produce noticeable changes in brightness over time [32.225]. Sensory brightness of a sound is largely dependent on the centroid resulting from spectral energy distribution.

If the spectral envelope would be identical for all the tones played by one particular instrument in different registers (see above), a near-constancy of sensational quality could be expected for listeners as the spectrum is virtually shifted up or down in frequency without changing the amplitude relations between partials. There have been considerations of how operations such as transposition and inversion (known from operations on melodic pitch sequences such as canons) could be applied to sounds with respect to the sensory and perceptual quality of *sound color* [32.177]. The problem, however, remains that shifts of the spectrum, while maintaining a more or less identical sound color, might not be perceived as such, yet rather as interacting with pitch structures since pitch, in particular for musically trained subjects, appears to be the more fundamental perceptual quality. Consider for example the sounds from 31 diapason pipes per octave as are available on the organ that has been built for the Huygens–Fokker tone system [32.226]. Playing the tones of this quite unusual scale, one after another (the difference in f_1 between adjacent pipes is 38.71 cent), musically trained listeners will perceive a sequence of tones distinctive in pitch and almost homogeneous in sound color. If one conceives of timbral sequences based on complex inharmonic FM sounds (see above) meant to constitute a *timbre scale*, it is likely that listeners with a musical background may still be inclined to infer pitch relations from such sequences though they may also perceive

a concept of *order* among sounds varying in certain timbral parameters.

Of course, in music and musical instruments there are interrelations between pitch and timbre in many respects. For example, mixture stops in pipe organs were introduced to expand the spectral width and to strengthen the brightness of organ sounds as well as to reinforce the pitch of tones that were played with fundamental stops (such as the diapason or Prinzipal). There is a combination of spectral and virtual pitch effects if the tuning of the keyboard matches that of pipes in mixture stops as close as possible. Also, interrelations of pitch and timbre have played a significant role in regard to musical composition and orchestration since composers knew from experience which instruments would *fuse* well in a homophonic texture and which instruments would be suited to support perception of individual voices in a polyphonic setting. Viewed from acoustics and psychoacoustics, there are factors such as formant-like concentration of spectral energy, partial spectral masking between instruments and sensation of roughness caused by spectral interaction in dissonant sonorities that need to be considered [32.181, 227]. Spectral fusion versus spectral roughness as well as emphasis of formants in singing styles are also relevant in vocal music, as for example folk music idioms can differ significantly in this respect [32.228].

32.2.5 Sound Segregation and Auditory Streaming

The performance of the auditory system in mammals is striking in several respects:

1. Sensory processing is fast and quite precise with respect to locating sound sources and extracting features from complex sounds.
2. The auditory system is capable of integrating related information into entities that become perceivable as *objects*.
3. The auditory system can distinguish between several concurrent sound sources and objects so that these can be identified and categorized accordingly.

This section will provide basics on hearing conditions in environments and will then survey some of the principles underlying formation of auditory objects, on the one hand, and their segregation when occurring simultaneously, on the other. Since in particular auditory stream segregation has been the subject of comprehensive monographs [32.217, 229], the following paragraphs will only cover some of the relevant points.

Listening to music in a concert hall or in front of an audio system (which may be stereophonic, quadraphonic, or ambiophonic) means a quasicontinuous stream of sound waves propagating through a medium (Sect. 30.3) reaches both ears of a subject who may try to identify sound sources and *objects* within this stream. In this respect, binaural hearing is the normal situation. Depending on the environment (which may be a concert hall, an open air concert, or one's living room), the ratio of sound energy emitted directly from the source and the sound reflected from hard surfaces may vary. In open spaces unbounded by reflecting surfaces, a free field condition prevails. If music is presented on stage in a concert hall, listeners typically have the orchestra or band in front so that most of the sound energy is transmitted directly, with a certain portion of lateral energy reflected from the side walls; in addition, energy might be reflected from a hard ceiling (for room acoustics and their effects on auditory perception, see [32.230–232]). In effect, in rooms bounded by hard surfaces, there is a mixture of direct sound and diffused sound between which a delay can be measured. The interaural cross-correlation [32.230, Chap. 3] between sound signals fed into both ears is a parameter suited to measure the degree of diffuseness. There are several more parameters (such as clarity, reverb time, coloration, distinctiveness or *definition*) that are of relevance for perception. For sound sensed binaurally in a free field (or in other spaces with negligible reverberation), mammals can use the interaural time difference (ITD) and the interaural level difference (ILD) as primary cues for spatial hearing and source localization [32.233, 234]. A model widely accepted is that the interaural time difference (ITD) is processed at the level of the inferior colliculus (IC), in pooled neurons [32.235]. Acuity is extremely high in that the just-noticeable difference (JND) for ITD seems to be close to 10 µs for a 500 Hz tone. In addition, the interaural level difference (ILD) serves as a cue for localization [32.236]. Though both ITD and ILD are restricted to certain conditions and ranges, taken together they can provide sufficient information to subjects for localizing sound sources. In regard to prerecorded music reproduced from audio systems, listeners are mostly confronted with a stereophonic setup where sources are *panned* on a left–right axis while 5.1 and other surround sound systems simulate a 360° panorama. Wave field synthesis [32.237] can even improve spatial representations of sources from prerecorded music that are perceived as if distributed in a natural 3-D environment.

Patterns of sound waves entering the auditory system binaurally can be extremely complex according to musical and physical parameters encoded. Consider, for example, performances of symphonic works rich in harmonic textures and instrumentation where also the dynamic range may vary considerably over time. Hence, listening to music requires fast processing

with sufficient resolution to allow for feature extraction and overall categorization of the input. Fast extraction of stimulus features necessary for sensory and motor responses in afferent-efferent feedback loops affords distributed processing along stations of the auditory pathway (AuP) (Sects. 31.2–31.4). As expected, there are indications that much of the processing relevant for pitch and other features is done subcortically, and in parallel up to the IC [32.238–240]. However, if processing is hierarchical and distributed, one would expect some neural network capable of integrating related information so that one perceives *objects* or even *complex wholes* and not just a bunch of features. This problem has been discussed quite extensively, in psychology and neuroscience, as one of *binding* [32.241, 242]. Though many studies on *binding* are concerned with visual perception as well as with language, formation of auditory objects also calls for a neural system suited to integrate spatial and temporal information gained from the various stages of analysis in the cochlea and along the ascending AuP. In the following, temporal and spectral criteria relevant for *fusion* as well as for *fission* of components in individual sounds and for fusion or segregation of concurrent sounds will be reviewed. Cues for identification of sound sources such as instruments and voices as well as for perceiving sonic objects embedded in a quasicontinuous stream of waves are temporal, spectral, and dynamic.

Fusion and *Fission* of Spectral Components in Individual Sounds

Evidently, we can hear a harmonic complex tone played on an aerophone or chordophone (e.g., oboe, trumpet, cello, sax) as a coherent whole notwithstanding that a number of low partials of such tones will be resolved in the BM filter bank, and also groups of higher partials will be segregated according to the CB auditory filter model [32.243–245] In a nonanalytic listening situation, individual harmonic partials and groups of partials falling into different CBs will be perceived as *fused* into one complex that, because harmonic partials join into a common period, gives rise to a distinct pitch and can convey a sensation of a certain timbre. The section of a sound that appears as *fused* into one object is the steady state while at the onset individual harmonics may be audible because, in particular in aerophones, some modes can reach a stable regime of vibration earlier than the bulk of modes making up the spectrum [32.204]. Of course, one can adopt an analytic stance and try to *hear out* some of the low partials in, for example, a harmonic complex comprising ten partials ($f_1 = 200$ Hz) with amplitudes rolling off at 3 dB/oct. Also, a nonharmonic component included in a harmonic spectrum most likely will be detected (if strong enough in level) as a separate component not fitting to the main body of partials constituting the perceptual object (a complex harmonic tone). Consider, for example, a harmonic spectrum where the third partial is detuned to a frequency ratio of 2.55 to $f_1 = 100$ Hz while the other components are in small integer frequency ratios. Using ten components with amplitudes decreasing at -3 dB/oct, the waveshape plotted in Fig. 32.14 results. The basic periodicity of 10 ms corresponding to f_1 as well as to f_0 resulting from partials 1, 2, 4–10 is still dominant; however, the inharmonic component obstructs a regular waveshape to repeat per period.

Separation in this case is effected by means of two concurrent pitch percepts, one based on the spectrum and periodicity (f_1 and f_0) of the harmonic complex, the other on the frequency and period of the inhar-

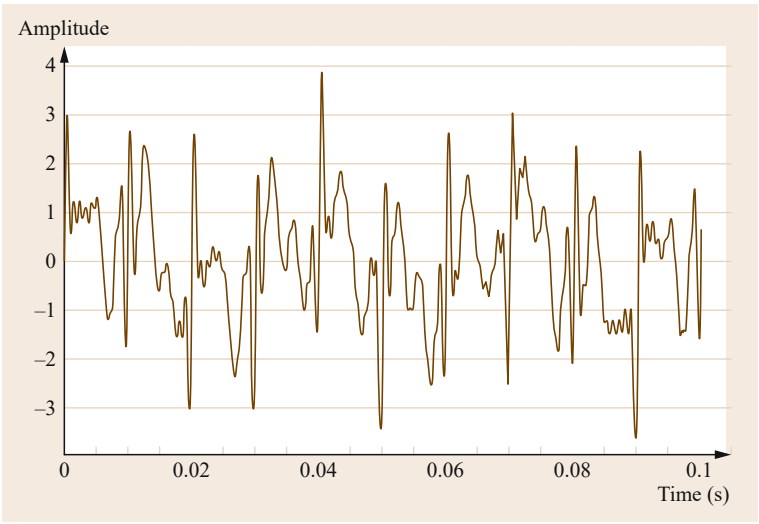

Fig. 32.14 Waveshape, harmonics 1, 2, 4–8 of $f_1 = 100$ Hz; partial no. 3 detuned to 255 Hz

monic component that *stands out* against the complex. Such a situation basically occurs with bell sounds where several partials may *fuse* quite well while in particular the minor third often is clearly detectable as a strong component (Fig. 32.12). Most sounds from carillon and swinging bells as well as such produced from gong chimes or by means of FM technique (see above) are ambiguous not because they would lack pitch and timbre information but because this information does not integrate easily into representing a single, coherent sound object. Rather, subjects in experiments tend to assign two or even more pitches to one complex inharmonic sound and in addition may find the timbre variable with time [32.85, 86, 209, 246–248].

Onset Synchrony versus Asynchrony of Concurrent Parts and Sounds in Music

Theoretical onset times and durations of notes in works of music can be calculated from notations in case a certain metronome value is prescribed. Absolute tempo (measured in beats per minute, BPM) in many recordings of pop music is evident from drum computer or sequencer tracks. In music performances not bound by notation and/or absolute tempo set by a machine, onset times of various instruments may be measured relative to some *time keeper* (for instance, a regular sequence of fast notes the drummer plays on the ride cymbal). Jazz and also rock musicians seem to have opinions of what may contribute to a good *groove* in a musical performance. One aspect often alluded to is that onsets of certain instruments should be slightly ahead or behind those of the time keeper. For instance, the bass may *drag* the tempo a tiny bit ahead of the time keeper while the snare drum is a tiny bit late, and then is perceived as somewhat *heavier* relative to the beat marked by a regular sequence of pulses (e.g., the attack of strokes on the ride cymbal). In such perceptions, two factors seem to be of relevance. One relates to temporal order and precision relative to an audible or imagined pulse, the other perhaps to effects of masking. If all onsets were synchronized so that sounds from different instruments in an ensemble would converge as much as possible, it would be difficult to distinguish their notes, in particular if instruments similar in sound color (see above) are playing notes in consonant chords. Of course, this is a situation wanted in certain musical contexts such as homophonic settings where maximum fusion of parts (as well as of partials) is desired. However, in polyphonic or multipart music, it is often necessary for listeners to follow individual parts (or *voices*) in order to apprehend musical structure as based on themes, motives, and voice-leading. For example, many works written for string or saxophone quartet require listeners capable of perceiving individual parts as well as the interplay of such parts in simultaneous chords or other vertical sonorities. Experimental data suggest that even musically trained subjects have difficulties in keeping track with multipart music if the number of voices exceeds three and when timbres for all voices or parts are relatively homogeneous [32.249]. Since timbre may not suffice to distinguish sources within *families* of instruments such as bowed strings or saxophones, and partial spectral masking can occur in particular if parts are relatively close in the pitches of their respective notes [32.181], temporal and dynamic factors come into play as a means to keep parts or voices apart. As has been reported by *Rasch* [32.182], subjects showed higher scores in correctly detecting the direction of intervals in quasisimultaneous concords formed of two complex tones when their onsets differed by 0–20 ms. *Rasch* [32.250] also tested the role of onset asynchrony in small ensembles where he found that those instruments that play the main melodic line tend to lead by about 30–50 ms. Onsets as in performed music seem to vary considerably relative to a grid one may calculate from notation, or may impose from a reference instrument. Onset asynchrony helps the listener to segregate voices in polyphonic music. In polyphonic keyboard works of the Baroque era (such as fugues written by D. Buxtehude, N. Bruhns, J.S. Bach), different voices (assigned to the right and left hand of the performer respectively) often do not begin aligned but with one voice starting on the beat and another kept apart by a quaver or semiquaver rest preceding the entry of that line.

Coordinated Modulation of Spectral Components as Marker of a Source

There are many reports on the effects modulation has on source segregation and identification. In particular, coordinated modulation of spectral components so that their frequencies vary in parallel has been stressed [32.251]. In experiments with synthesized vowels presented in combinations at different pitches, subjects judged the prominence of a modulated target vowel higher than unmodulated vowels [32.252]. In a musical situation such as when a solo violinist is backed by an orchestra in a violin concerto, there might neither be much difference in averaged (root mean square, rms) sound level between the solo violin and the orchestra nor in the timbre of the solo violin as compared to the string section of the orchestra. Parameters suited to effect acoustic and auditory segregation of the solo violin against the orchestra then can be strong onset attacks in nonlegato phrases and the use of substantial vibrato in legato phrases comprising long-held notes. In fact, this is observed in many performances. Detection of modulation has been found an efficient cue for computerized scene analysis [32.253].

Segregation of Harmonic Compounds as in Single Consonant Chords

As has been explained in Sect. 31.6.4, there are certain conditions for perceiving harmonic complex tones and combinations of such tones in terms of consonance, fusion, and *Verschmelzung*, which means sounds such as Stumpf's *ideal concord* (Fig. 31.15) are perceived as highly coherent while being also apprehended as a configuration of tones related by certain intervals. In order to apprehend structural relations between several pure or complex tones, a listener should be able to segregate a chord or other harmonic compound into its constituents. This requires that a sound is present for a certain time, and that the listener has some experience in analytic listening. The task is to find how many pure or complex tones are contained in a chord or other sonority, and to identify the relations between the components. Consider for example the final chord in a work of organ music like the *Praeambulum primi toni a 5 in d* by Matthias Weckmann where five voices join into a long-held chord comprising the notes D_2, D_3, A_3, $F\#_4$, A_4, D_5 (the note D appears tripled to emphasize the key of the piece). Since works like this *Praeambulum* are usually played with several stops at $16'$, $8'$ and probably also at $4'$ and $2'$, spectral energy relevant for pitch and timbre perception as contained in many partials should cover a frequency range from D_1 to at least three octaves above D_5, that is, ≈ 4.7 kHz. In the recording used here for analysis (Wilde–Schnitger organ of 1683, Lüdingworth near Cuxhaven), one of the stops is a $16'$ dulcian reed pipe that produces very many harmonic partials per tone. Figure 32.15 shows a spectrogram 0–2 kHz and the f_0 of the chord derived from AC and subharmonic summation (SHS) analyses as well as the output of a Bark filter analysis with the center frequencies spaced closer (ratio 0.85) than in the usual Bark scale to emulate CB bandwidths as observed in auditory peripheral filtering. These data-driven analyses demonstrate that segregation of constituents according to features (pitch-relevant partials, other harmonics, onsets, temporal fluctuations of spectral components in frequency and amplitude) is possible, at least to a certain extent.

Hearing the chord live in the church, one may try to use spatial information since the pipes sounding the chord are distributed in the organ (with the pedal stops housed in two towers flanking the main organ case). In regard to pitches, which are often the strongest cue for auditory analysis, one can hear the *fundamental* at $D_1 \sim 38.8$ Hz (the organ is tuned to $A_4 \sim 466.3$ Hz), which is the f_1 spectral component of two of the $16'$ pipes employed as well as a periodicity pitch (f_0) that is confirmed by both AC and SHS analyses (Fig. 32.15). Of the remaining tones, several can be identified by their pitch intervals relative to D_1, especially A_3, $F\#_4$, and D_5. Neglecting small fluctuations in frequency and amplitude (Fig. 32.15), the D-major chord to one's ear offers a high degree of *Verschmelzung* notwithstanding small tuning deficiencies (the organ is in meantone tuning, implying the $F\#_4$ is a just major third but the A_3 and A_4 are flat by 5.5 cent respectively). Auditory analysis in this case is not too difficult because the chord lasts for almost 5.5 s.

Segregation of Auditory Streams

In 1649 and 1654, *Jacob van Eyck*, a famous Dutch carillonist and flutist, published two volumes of a collection of some 150 tunes, many of which were part of the popular repertoire of his time [32.254]. These tunes, which can be performed with a single soprano

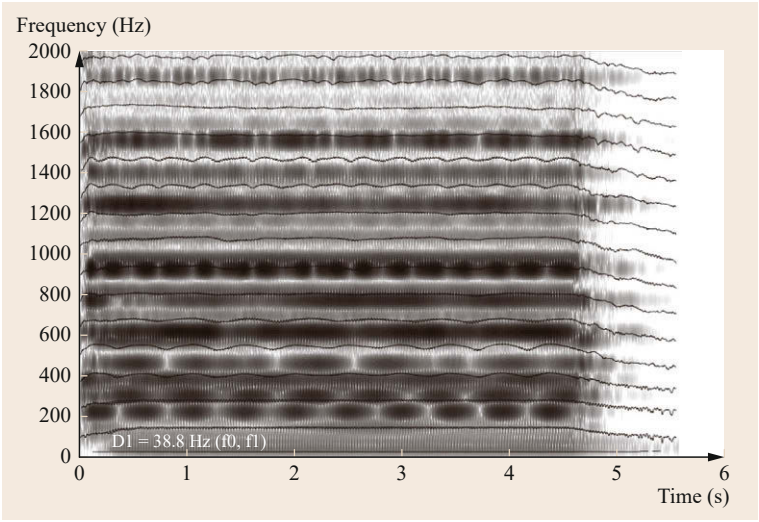

Fig. 32.15 M. Weckmann, *Praeambulum*, final D-chord, spectrogram 0–2 kHz, AC and SHS pitch analysis, Bark filter analysis 0–2 kHz (15 bands), extraction of f_0 (identical with f_1), detection of strong components and of (frequency, amplitude) modulation effects

recorder, are elaborated in variations, which include embellishments such as figurative elements as well as short notes inserted into the somewhat longer notes of the tune. In effect, if played at a lively or even fast speed by a skilled flutist (as van Eyck was), the impression on a listener is that the music, though not truly polyphonic (which would rather call for two or more independent voices), is not monophonic either. The type of setting found in van Eyck's anthology has been labeled pseudopolyphony; it was a technique employed also by J.S. Bach in his works for violin solo and cello solo (BWV 1001-1006; 1007-1012) where, however, simultaneous intervals and even full chords are included as these are playable on a bowed string instrument that offers four strings. In Fig. 32.16, a small section from the performance of one of the tunes adapted by van Eyck (*Wat zalmen op den Avond doen? Van Eyck* [32.254]; Marion Verbruggen, recorder) is shown, which demonstrates the style of a pseudopolyphony where two voices played on a single recorder seem to interlock in time.

As Fig. 32.16 demonstrates, most of the main notes making up the tune are in a higher register, and are played with more force than the very short notes that fall between them. Thus, there are two frequency regions divided at ≈ 950 Hz; the very first note/tone (~ 841 Hz, $A_5^{\flat}$) can be related to both the upper and the lower stream, which are divided by about an octave (tone no. 2 is at 1109.3 Hz, $D_6^{\flat}$, tone no. 3 is at 552.4 Hz, $D_5^{\flat}$, etc.).

The perception of pseudopolyphonic structures such as found in works of van Eyck and Bach depends on several parameters. One is the average interval between the upper and the lower sequence of tones, another is the tempo (measured in MM or BPM) of the performance, which determines the number of events per time unit (event density) as well as the relative duration of tones (e.g., quavers, semiquavers) to be played in a phrase. Musically trained listeners will be able to follow both the tune melody and the up-and-down motion of pitches installed between notes/tones of the upper and the lower register even if their duration can be quite short ($t \leq 200$ ms). If the tempo increases further (which can be done by digital time compression without affecting pitch) to 150% of the original version, it is more difficult to follow the pattern of up-and-down intervals. Doubling the tempo, and hence the presentation rate, hampers interval perception and leads to a percept where the tune is still present but the tones in between no longer join into kind of a *counter melody* (as is indicated by tones in the lower region of Fig. 32.16). Also the rhythmic pattern seems to have changed to a *galloping* type as has been described, for certain tone sequences, by *van Noorden* [32.255] and *Bregman* [32.229]. Of course, such a tempo would not suit any musical performance of this style of music. However, there are idioms such as the Kiganda Amadinda xylophone music of former Buganda [32.256, 257] where basically two melodic sequences are played simultaneously, in isochronous pulses, with no metric accent, at a very high speed (eighthnote $\sim$ 520–600 MM). Each sequence is of a certain length (for instance, 36 notes), and is repeated over and over. Unless one is familiar with Luganda language and the concept behind the music, it is not possible to apprehend individual sequences (which are mostly derived from songs that can be narrative in character). Rather, in particular *Western* listeners tend to perceive a number of patterns that have been explained as *inherent* in the fast tone sequences one actually hears [32.256, 258]. In this respect, such

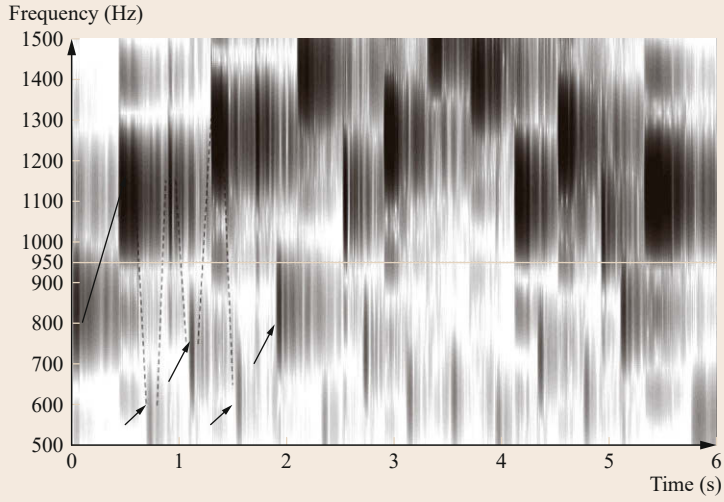

Fig. 32.16 Pseudopolyphony (after [32.254]); performance on a single recorder. The *beige line* at 950 Hz segregates two melodic streams. The tones in the lower stream (of which the first four are marked with *arrows*) are very short. The *solid line* connects the first two tones as were played and the *dashed lines* connect the tones 2, 3, 4, 5, 6, 7 in the up-and-down sequence. The decay in the tail end of the tones results from reverberation in the recording as well as from the filter response in the analysis

patterns have an objective basis. However, the Gestalt-like formations listeners perceive or imagine result from perceptual and cognitive structuring that leads to both segregation of tones within sequences into high and low pitch *streams* and to recombinations of elements into melorhythmic patterns. Since there is no objective rhythm implemented in isochronous pulse sequences produced without metric accents, the rhythmic grouping listeners realize seems to be derived from melodic patterns. The patterns listeners believe to perceive can be viewed as emerging from the very fast sequences, in an effort to group elements into coherent, musically probable formations.

The facts concerning pseudopolyphony and perception of inherent or emergent patterns briefly summarized in this section have been tested, on a much more fundamental level in a lab situation, in experiments on auditory stream segregation. An early experiment [32.259] found that, in the human hearing range up to ≈ 4 kHz, two pure tones A and B presented binaurally, each lasting 80 ms (plus 20 ms rise and decay time), appeared as a quasicontinuous up-and-down movement when their frequency difference df/f was within $\approx 15\%$ but turned into an interrupted two-tone pattern (A:B:A:B...) when the difference was larger. Seeing that the repetition rate for a pair A:B in this experiment is ≈ 5 Hz; the *trill threshold* – as the critical frequency difference was called – for 500 Hz would be close to 75 Hz, which equals 242 cent; as one might expect, this is about the width of a CB. *Bregman* and *Campbell* [32.260] reported two experiments one of which had six sine tones (2.5, 2, 1.6 kHz, 550, 430, 350 Hz) each lasting for 100 ms as stimuli. These tones were arranged in two sequences of high and low. With short duration of each tone, and high repetition rate of the sequences, subjects grouped the tones into two streams representing high and low tones. *Van Noorden* [32.255] conducted several experiments on sequential coherence of tones (as in melodies) and found that stream segregation depends on:

- The interval in pitch between two tones.
- The repetition rate. With increasing repetition rate, the interval width necessary for segregating tones at two different pitch levels into streams decreases.
- The intensity level differences between tones presented with alternating loudness, which can have an effect on perceptual grouping (termed *roll effect* by *van Noorden* [32.255]).

In addition, differences in timbre have been reported as a factor relevant in forming streams [32.261]. Finally, manipulating the phases of complexes of unresolved harmonics can lead to sequences of sounds that do not differ in power spectrum yet appear different in perception; such differences in perceptual quality may suffice for also inducing segregation [32.262].

Auditory stream segregation apparently is based on data-driven bottom-up analysis that starts at the auditory periphery. However, there are also top-down processes since segregation draws on learned schemata and on musical experience in general. It is of interest to note that quite many observations on auditory stream segregation can be viewed in regard to principles of Gestalt perception such as temporal and/or spatial *nearness* or proximity of elements, their *good continuation* as in a melody, the *common fate* partials of a harmonic complex share in FM, the *conciseness* of a certain rhythmic or tonal pattern, or its *closure*, etc. (a list of more than 100 principles of Gestalt perception was assembled by *Helson* [32.263]). A detailed discussion of experimental findings and an interpretation of many observations in terms of Gestalt perception and cognitive psychology will be found in [32.217] and [32.229]. Parallel to behavioral experiments, modeling of auditory stream segregation and development of algorithms for automated DSP-based analysis have been pursued. Though there are different approaches, many are based on peripheral auditory filtering of acoustic input and on emulating stages of neural processing [32.253, 264–267]. Separation of sources and assignment of sonic objects to *streams* or *voices* can be achieved by means of DSP algorithms operating on digitized sound files if sufficient information can be gathered from the cues named above (different onset times, different pitches and spectral patterns of concurrent sounds, identification of harmonic partials undergoing *common fate* FM as a marker of a common source, etc.). Another aspect that relates to auditory stream segregation and to auditory *scene analysis* in general is transcription of polyphonic music into conventional staff or other graphic notation [32.268–270].

Summing up this chapter on *timbre*, the term can be used to denote the spectral plus temporal features of a sound sensed by subjects as a tone quality that, however, may include dynamic changes. For example, the tone quality of a clangy metal gong sound resides largely in the modulation while the tone quality of a violin may be more dependent on spectral formant structure (and, hence, on *tone color*). In recent decades, it has been customary to address the phenomenal appearance of temporal and spectral sound features as they interrelate in sonic objects simply under the umbrella of *sound*. This is a term that has gained importance in particular in the production and perception of pop and rock music. *Sound*, in this respect, comprises various aspects having to do with the localization of sound sources in a stereo, quadraphonic or surround-sound mix as well as with the *depth* of space conveyed by the ratio of

the direct signal and (natural or artificial) reverberation. Original sound sources, in addition, can be modified by means of filters and compressors, and can be modulated in many ways. Characteristic of *sound* in pop and rock music genres is the use of special effects such as phasing, flanging, chorus, modulation of filter and spectral envelope parameters, cross-modulation between several sources, etc. applied to single or to groups of instruments (see articles by Dutilleux and Zölzer and by Evangelista in *Zölzer* [32.66], also [32.271]). Further, *sound* in pop, rock and also jazz music involves playing techniques (as is evident from rock guitar playing where one uses string bending, finger vibrato, so-called claw hammering, etc.) and also tuning of instruments. Note, for instance, the electric guitar on Pops Staples' *World in Motion* (Virgin, 1992) tuned low to C_2 instead of E_2. Moreover, the guitar apparently was played with an amp using a tremolo effect (often wrongly labeled *vibrato* in amp literature) and a 15″ loudspeaker to reinforce low frequency response and to make the sound appear *big* in volume. Further, some reverb has been put on the guitar (either in the amp or, more likely, in the mix). The *sound* resulting thus is a combination of the notes played plus the tuning of the guitar and the frequency response and other specifications of the technical devices used in the performance and recording of the song in question. *Sound*, in this respect, is a highly dynamical, time-variant construct that has objective physical and musical foundations. The actual interplay of temporal, spectral, spatial and dynamic features may undergo many changes in the course of a relatively short piece of music, which listeners may attend to; consequently, they will perceive *sound* as a dynamic process. However, one can also abstract the more recurrent and (within limits) more or less invariant features that are regarded *typical* of a certain sound (e.g., the types of distortion and of feedback in guitar sounds used in genres of hard rock productions).

33. Sensation of Sound Intensity and Perception of Loudness

Albrecht Schneider

This chapter is on sensation of sound intensity and perception of loudness. Since some of the relevant matter (on scaling concepts of loudness) has been presented in Chap. 30, and because a considerable portion of research on loudness is done outside musical contexts (namely, in industrial and environmental noise control as well as in audiology), this chapter condenses facts and models more than the previous two on pitch and timbre respectively. Section 33.1 of this chapter offers the physical and physiological basis of sound intensity sensation while Sect. 33.2 discusses features of some models of loudness sensation that have been established in psychoacoustics over the past decades. Since these models were originally designed for stationary sound signals and levels, and have been tested mostly in lab situations, they cannot adequately cover a range of real-world sound types found in natural or technical environments. In music genres such as techno presented in discos, or heavy metal performed in live music venues or at open air festivals to audiences at very high sound pressure levels, sound is heavily processed in regard to dynamics and spectral energy, which calls for appropriate measurement and assessment of sensory effects. Different from perception of pitch (where samples of subjects respond more or less in similar ways to certain types of sound signals), perception of loudness shows a high degree of variability even within groups of musically trained subjects reflecting their musical background and preferences (Sect. 33.3). Recent empirical evidence demonstrates that subjects judge loudness for various musical genres on a category scale (from very soft to very loud), however, the center (relative to loudness level and loudness scales) and the range of each category differ considerably, for individual subjects.

Finally, there is a concluding section (Sect. 33.4) in which some of the major topics and issues discussed in Chaps. 30–33 of Part D are summed up. In addition, a tentative model of the interrelationship of pitch, timbre and loudness perception is sketched.

33.1 Physical and Physiological Basis of Sound Intensity Sensation

Subjects usually have a sensation from physical sound intensity that they experience as *sound volume*, or as *loudness level*, that is, sensation grows as intensity increases. However, the exact form of such a correspondence is complex and has been the topic of a large number of studies. In addition to the descriptions and interpretations given above (Sect. 30.1.4, *Loudness Scaling* ...), some more details shall be discussed. From a psychophysical point of view, sensory magnitudes (Sect. 30.1.4) should reflect physical input parameters in some (linear or nonlinear) way. Sound intensity $\boldsymbol{I} = p\boldsymbol{v}$ as the product of sound pressure and particle velocity can be related to the sound power P like

$$I = \frac{P}{S} = cw \,,$$

where P is the sound power, S is the area (m^2), c is the wave speed in a medium and w is the sound energy density (Sect. 30.2). The sound power (acoustic power) radiated from a source is a measure of the sound energy that goes through a plane per short time unit like

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_33

$\Delta W = wSc\Delta t$. Humans and other mammals collect the sound power entering the ear channel from the pinna to the tympanon where, however, a strong divergence between the sound pressure level (SPL) measured in the free field and SPL at the tympanum can occur depending on the azimuth; the divergence is zero for 0° and increases both with angle and with frequency up to ≈ 15 dB [33.1] since, for higher frequencies, the wavelength does not permit waves to flow around the head. Moreover, a significant portion of the energy is reflected. The pressure reflectance is calculated from the complex ratio of incident pressure p_i to the reflected pressure p_r like

$$R(\omega) = \frac{p_r}{p_i} .$$

The energy reflectance then is the ratio of the reflected power P_r to the incident power P_i; the energy reflectance equals R squared

$$\Re(\omega) = |R|^2 .$$

For the human ear canal and impedance, values for the energy reflectance coefficient as dependent on frequency have been reported for adults to range from about 0.3 at 2–4 kHz up to 0.95 at 125 Hz and 0.7 or 0.8 at 8 kHz [33.2, 3]. Thus, the reflectance is significant at low and at high frequencies while much more of the incoming energy passes the tympanum into the middle ear in a frequency range from, roughly, 0.5–5 kHz. A reflection coefficient of $|R|^2 = 0.5$ means that 25% of the energy is reflected (100×0.5^2 %).

Contrary to the effect of the loss from reflection, the middle ear transfer gain increases the sound pressure up to a maximum of ≈ 23.5 dB at 1.2 kHz [33.4]. However, the power utilization ratio estimated for humans reaches about 0.4 (on a scale from 0–1) at ≈ 3 kHz (with a second peak at ≈ 8 kHz; [33.5, p. 129, Fig. 6]), and the middle ear efficiency likewise peaks at 1 kHz where efficiency is at 0.35 [33.5, p. 129, Fig. 7]. On the average, middle ear efficiency is about 0.1 from 100 Hz to ≈ 1.5 kHz and from there on diminishes rapidly. The graph of a function calculated as isopower contour [33.5, p. 131, Fig. 11] to represent the SPL (dB) in the free field needed to maintain a constant sound pressure at the cochlea for humans (threshold at 10^{-18} W) looks quite similar to the threshold curves known from psychoacoustic behavioral data [33.6], that is, the threshold is below 0 dB at ≈ 3 kHz while the slopes of the isopower contour rise quite steeply in particular toward low frequencies. In sum, of the sound power collected by the ears a considerable amount is reflected at the tympanum, and of the fraction that actually passes into the middle ear, less than half finally enters the cochlea. In this respect, the ear as a transducer is quite inefficient while its frequency characteristic response shows fair admittance for sound wave components in a range most useful for speech communication and music (≈ 500 Hz–4 kHz). The steep roll-off toward very low and very high frequencies can also be viewed as a self-protective mechanism.

In regard to inner ear excitation on the basilar membrane (BM) level, the traveling wave in the cochlea has to be considered as a combination of a compression wave in the fluid and a transversal motion of the BM (Sect. 31.3). Assuming cochleotopic frequency mapping, for simple stimuli such as pure tones a maximum of the pressure amplitude and of the local deflection can be expected at the place where a certain characteristic frequency (CF) is represented. In a passive linear system, excitation should be proportional to the pressure amplitude and to the BM transversal deflection. This, however, is not the case with the BM/outer hair cell (OHC) feedback system, which exhibits a strong compressive nonlinearity effective above 30–40 dB SPL. As has been found in animal experiments [33.7] (chinchilla), sensitivity of the BM is such that 0 dB SPL can effect a small BM displacement, while 1.6 nm were measured at 20 dB. *Russell* and *Nilsen* [33.8] (guinea pig) observed that, for a CF of 13.25 kHz, BM displacement as a function of SPL grew to ≈ 4 nm at 40 dB from where the slope flattens. At 80 dB SPL, displacement at the CF was ≈ 10 nm. In regard to gain (measured either as displacement amplitude divided by SPL, or as velocity divided by stimulus pressure), the cochlear amplifier is most effective at low SPL where gain according to *Ruggero* et al. [33.9] (chinchilla) reaches 66–76 dB relative to stapes motion for a 5–10 dB SPL input while, above ≈ 40 dB and up to ≈ 80 dB, nonlinear compression grows with level. The difference in peak gain for a low level input (5 or 10 dB) and an 80 dB SPL input was 47.9 dB [33.9]. Expressed as BM velocity (μm/s) in response to sine tone bursts, velocity was at ≈ 10^2 for a 20 dB input level and at ≈ 10^3 for 60–80 dB while BM displacement data give ≈ 4–5 nm at 20 dB and 10–15 nm in the 60–80 dB range respectively [33.9, Fig. 2 and 6].

Looking for spatial characteristics, displacement for a certain CF at low SPL (10–20 dB) was confined to a small BM section (< 1 mm), which can be viewed as a symmetric bandpass centered at CF while above 40 dB displacement is more extended [33.8, Fig. 1D]. This spread of displacement with SPL is significant in particular above 60 dB and has been incorporated as a feature into auditory models suited to calculate loudness (see below). In effect, the input/output ratio

at the BM/inner hair cell (IHC) level can be compared to an automatic gain control amplifier though its operating principle seems to be control of the local BM impedance/admittance (there are hypotheses saying that local resonance frequencies of the BM are almost invariant in regard to stimulus intensity; see [33.10]). In the range where outer hair cell (OHC) gain control seems to work best the compression ratio appears to be close to 0.2 dB/dB and reaches saturation at about 80–85 dB SPL, above which *passive* mechanical parameters (BM stiffness, fluid viscosity) seem to delimit the excitation process. The nonlinear compression carried out by the BM/OHC circuit reduces the dynamics of hearing from the ≈ 120–130 dB range at the input (defined by the lower and upper threshold [33.11, 12]) to a much smaller range effective at the cochlear transduction stage [33.13].

Intensity coding has often been viewed in regard to firing rates of neurons and fibers. In a well-known hypothesis known as *auditory nerve spike count*, the concept was that, with growing intensity of a stimulus such as a sine tone, the firing rate in auditory nerve (AN) fibers would increase accordingly so that the number of action potentials or spikes summed over the fibers activated per time interval would be in proportion to stimulus intensity. Sensation of loudness then could be directly related to the number of spikes in the AN. However, taking the compressive nonlinearity of BM motion into account, linear growth of spike rate with intensity would be unlikely. Also, the spread of excitation with input level and the shape of excitation patterns have to be considered [33.14]. Assuming the spread of excitation activates neurons in particular at frequencies above the CF corresponding to a sine tone as input, a tone high in frequency and level would not find many neurons left for such spread while a tone low in frequency could activate neurons toward higher CFs even at a moderate level. In effect, the hypothesis according to which loudness sensation can be related to AN spike activity in a simple way has been questioned [33.15]. This does not imply, though, that intensity coding would not be detectable from neural spike patterns. At least for pure tones, intensity coding for a wide dynamic range can be traced from neural spike counts such as the peristimulus compound action potential (PCAP, see [33.16]). Since the dynamic range of single AN fibers is limited to ≈ 30–60 dB depending on their rate of spontaneous activity and threshold [33.17], networks of fibers would be needed to cover broadband signals such as harmonic complexes at high input levels. Given that there are fibers with low spontaneous rates and higher thresholds as well as fibers with higher spontaneous rates and low thresholds, combinations of relatively few ($n = 50–100$) fibers would suffice to code about 100 dB of intensities [33.18]. In addition to firing rates, phase locking, lateral suppression and other effects may be involved in intensity coding. On the cortical level, an increase of activated cortex volume with rising sound level was observed in functional magnetic resonance imaging (fMRI) studies. There are some indications that the activation patterns may represent both the intensity of the stimulus and the perceived loudness [33.19].

Also memory traces have been hypothesized as a factor influencing intensity discrimination and identification processes [33.20]. Apparently, loudness levels as actually sensed enter short-term memory (STM). It has been observed that a sound with a ramped envelope was judged louder than the same sound with damped envelope [33.21]. A damped sound typically has an exponential decay, which leaves a low or vanishing level as the last *entry* into STM. The ramped version of the same sound is obtained from a simple reversal of the time series (in digitized sounds) so that the attack portion and samples with high amplitudes are the last *entry* into STM. A comparison of the sensations the two stimuli evoke can be expected to find the ramped version louder even though the energy in both stimuli is identical.

The compressive nonlinearity observed in dynamic auditory processing at one ear (i. e., in monaural stimulus presentation) apparently has some parallel in binaural loudness summation. In theory, loudness as sensed should double (ratio 2 : 1) if the input from both ears is added linearly, which could be achieved first on the level of the superior olivary complex (SOC) and at higher stations of the auditory pathway (AuP) (Fig. 31.2). In fact, it has been postulated, from behavioral experiments with pure tones (100, 400, 1000 Hz) presented at different levels (20–50 dB SPL), that binaural summation is linearly additive [33.22]. Other experiments found that binaural loudness summation gave a much lower ratio (between 1.3 : 1 and 1.7 : 1; see [33.23]) though these ratios seemed to be largely independent of level (tested for a 1 kHz tone over a wide dynamic range by *Marozeau* et al. [33.24]). In effect a ratio significantly smaller than 2 : 1 provides another hint that the power law for loudness $L = kI^{03}$ (Sect. 30.1.4, *Loudness Scaling* ...) needs correction even for elementary stimuli [33.25].

33.2 Models of Loudness Sensation

From experiments and calculations, *Harvey Fletcher* [33.26] argued that the total loudness N perceived from noise bands at higher centers of the AuP can be explained as an integral comprising partial loudnesses N_x from what he saw as 100 *patches* of auditory nerves distributed along the BM (for which he assumed a position coordinate, x), thus

$$N = \int_0^{100} N_x \mathrm{d}x \,.$$

Fletcher found a quantitative relation between a masking pattern expressed in dB and what he called agitation of nerve endings. His considerations include loudness summation across bands or *patches* as well as a correspondence between the bandwidth and frequency position of the stimulus and the *patch* (or *patches*) *of agitation*. In short, he described for loudness summation and loudness perception in general a concept later known as the critical band (CB), with a map of 20 bands covering 10 kHz stimulus frequency and 100 *patches* of nerve endings [33.26, p. 283, Fig. 8]. Later research on loudness perception [33.27–29] has drawn on the CB as the unit needed in particular for loudness summation across several bands determined apparently by the bandwidth of the auditory filter (AF). The CB unit that was developed from experiments employing a number of masking designs was called *Bark* (to honor Heinrich Barkhausen [33.30, p. 249 ff.]) The Bark scale usually comprises 24 or 25 CBs each of which is taken to correspond to 1.3 mm of the BM (Sect. 30.1.4, *Loudness Scaling* ...); the bandwidth of CB_c centered at f_c (kHz) can be calculated [33.31] like

$$CB_c/\mathrm{Hz} = 25 + 75[1 + 1.4(f_c/\mathrm{kHz})^2]^{0.69}$$

For example, the bandwidth of a CB centered at 0.5 kHz would be 117.3 Hz, for 1 kHz it is 162.2 Hz and for a band at 4 kHz it is 685.4 Hz. The problem with the Bark scale is that the bands below 500 seem too broad in bandwidth to account for perception of musical intervals in low register (Sect. 31.6.2) and particularly so in the range from $\approx 55-220$ Hz (A1 to A3). As an alternative, a revised scale known as ERB (equivalent rectangular bandwidth; [33.14, 32] and Fig. 31.9) has been established for which the bandwidth can be calculated like

$$\mathrm{ERB} = 24.7(4.37 f_c + 1) \,,$$

where f_c is the center frequency. The CB bandwidths calculated with this formula are considerably smaller than the Bark bands, and hence represent smaller sections of the BM (0.86 mm per ERB). Smaller CBs below 500 Hz than offered by the Bark(z) scale fit closer to perception of musical intervals and scales. Though both scales refer to a *rectangular* bandwidth as far as nonoverlapping, abutting CBs may be assumed, there is a technical definition of ERB in models of the AF as are central in the ERB concept of Moore and Glasberg. In research efforts of the 1940s and 1950s on audition, the CB in the range above 0.5 kHz to $\approx$ 10 kHz was already viewed as kind of a filter [33.26, 33] that could be approximated by a 1/3 octave bandpass. Behavioral data from masking experiments showed the actual bandwidth is smaller than this (1/3 octave = 400 cent) since, in the range 0.5−10 kHz, even for the Bark scale the width of the CBs is from 366 cent at maximum to 257 cent at about 2 kHz [33.34, Table 1]. Taking the CB as a bandpass filter, one can model the BM as a bank of 24 or 25 Bark filters (as in Fig. 32.13), or likewise, as a bank of 35−40 ERB filters; the absolute number of filters employed in a BM model depends on filter parameters such as the slopes of the upper and lower skirts as well as the overlap of adjacent filters. Single filters are parametrized so as to be equivalent in function and performance to the AF (or to several AFs should their characteristics not be uniform along the BM). The filter bank concept of the AF has become part of many computerized auditory models [33.35–38]. The AF according to behavioral data is asymmetric; there are several models and implementations ([33.14] and [33.39, Chap. 9]) that converge on certain features, the most important being dependency of filter shape on sound level. Without going into details of auditory filter parameters [33.14, 40, 41], it is clear that an algorithm representing the AF must vary bandwidth as measured in absolute frequencies with center frequency to account for the nearly identical bandwidth of CBs along the BM (1/3 octave bandpass filter banks with 31 ISO standardized center frequencies provide an analogy of constant-Q filtering). Further, the slope of the upper and lower skirts of the filters should adapt to changing input levels to account for the effect known as spread of excitation (see below). The so-called roex (rounded exponent) filter models the AF incorporating these characteristics; another solution (closely related in design to the roex) is the gammatone filter defined by its impulse response (cf. [33.30, Chap. 10] and [33.42], for a Mathematica™ implementation of the ear model from *Patterson* et al. [33.37]).

The following analysis might illustrate BM filter operation: pop music recordings of the so-called dance floor genre often are produced with four very strong

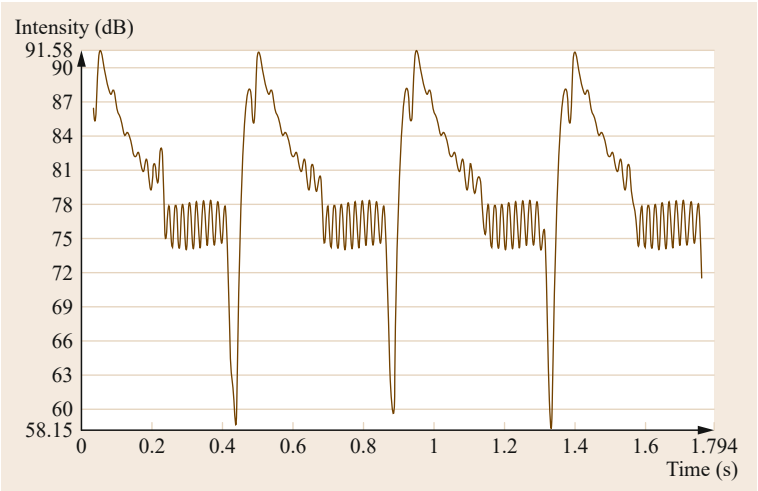

Fig. 33.1 Intensity of four beats (one measure, ≈ 1.8 s, *Fight for your right to party*)

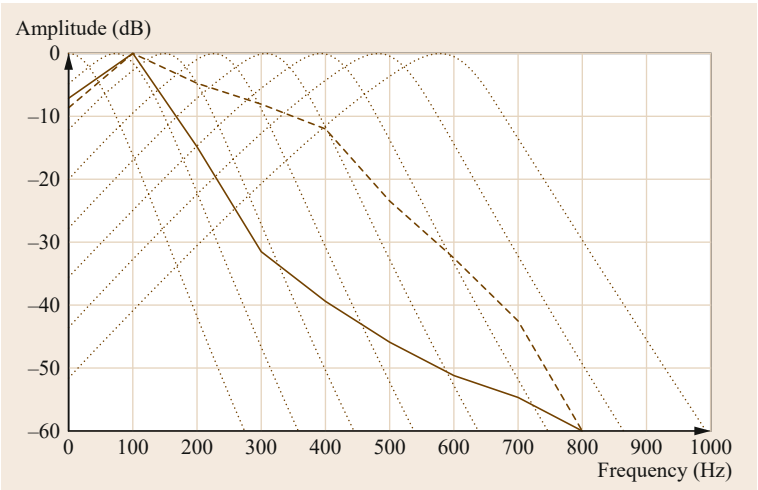

Fig. 33.2 Eight Bark filters (*dotted lines*) spaced at 0.8 Bark as applied to the analysis of a section of *Fight for your right to party* (N.Y.C.C. 1998); spectral energy at 0.1 s of the sound (*solid line*) and at 0.25 s (*dashed line*)

beats per measure marked by a (real or synthetic) bass drum sound, which can be gated (with a noise gate that opens only after a certain threshold level (dB) has been surpassed) so that the sound level rises steeply. The beats thereby become pulses as is shown in Fig. 33.1 from the CD sound file of *Fight for your right to party* in the version of N.Y.C.C., 1998, measure 1 after the intro.

As the graph demonstrates, the difference between minimum and maximum level is more than 30 dB, and the rise time from local minima to peaks is about 50 ms. Mean energy of the sound example (one measure, ≈ 1.8 s) is at 83.44 dB. Since the four beats are realized with a low bass drum sound, the energy can be expected to fall into only a few AF (or a few CBs respectively). Applying a set of gammatone filters whose center frequencies are spaced at 0.8 Bark (with the first filter centered at 0.8 Bark), and performing an analysis for the frequency range of 0–1000 Hz, the filter functions for eight filters (*dotted lines*) and the spectral energy distribution for windows of 100 ms calculated at 0.1 s (*solid line*) and 0.25 s (*dashed line*) of the time series representing the sound are shown in Fig. 33.2. Though the window size of 100 ms includes Gaussian weighting at the boundaries, it represents a reasonable integration time with respect to constants of temporal loudness integration, which have been reported to be of 80–100 ms [33.11, Chap. 11], [33.12, Chap. 8.5]. That is, loudness sensation for steady-state stimuli falling into one CB usually grows fast with stimulus duration up to ≈ 80–100 ms but only slightly for durations up to 200 ms (where the function almost saturates). From Fig. 33.2 it is obvious that particularly loud sounds from single instruments engage several adjacent AF.

Taking the AF paradigm, the energy falling into a certain filter band in a time interval t_i (ms) can be taken as a physical quantity suited to evoke an excita-

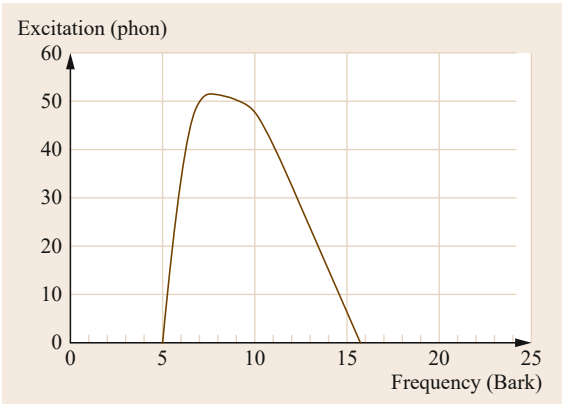

Fig. 33.3 Excitation pattern for three harmonic partials {800, 1000, 1200 Hz}; sound normalized to −24 dBfs peak level. Excitation level peaks at ≈ 50 phon

tion with a strength proportional to the the input signal. Such a view holds, in principle, if the signal is simple like a sine tone and low in input level ($L \leq 20$ dB SPL). Under such conditions, the excitation zone appears to be limited in spatial extension along the BM while transversal displacement of the BM is also small (see above). For higher levels, however, these conditions no longer apply since excitation clearly grows with level [33.14, p. 178, Fig. 7] so that even a sine tone of given frequency will bring about considerable spread of excitation at levels > 30 dB. For example, if several harmonics of a complex are used as input, even at moderate levels several AF will be engaged as is shown in Fig. 33.3 for partials nos. 4, 5, 6 of a virtual 200 Hz harmonic complex. The sound comprises three components {800, 1000, 1200 Hz} digitally normalized to −24 dBfs peak level. The three components are separated by 386 and 316 cent respectively, and should fall into separate CBs in the frequency range chosen. The resulting excitation zone, however, spans from $z = 6$ Bark centered at ≈ 700 Hz almost to $z = 16$ Bark at about 3 kHz.

Loud but undistorted sounds recorded from musical instruments are broadband signals in regard to CB/AF engagement as is shown in Fig. 33.4 for three sounds (cello, bell, crash cymbal) normalized to 0 dBfs peak level.

With increasing input level, displacement of BM segments increases in amplitude, which implies a spread of excitation along the BM. Such spread observed already at moderate levels, and massively so at high levels, means the number of inner hair cells (IHCs) activated along the BM increases with level. In particular for very high stimulus levels (120 dB) indications for multiple CP/BM resonances and corresponding neural activity have been reported [33.43]. For broadband signals such as music, energy typically falls into many AF (or CBs). In regard to perceiving the loudness of music at a certain time, it seems reasonable to assume integration of energy contributed by all the CBs that are activated within a certain period should evoke a sensation of loudness somehow proportional to the energy input and in particular to the excitation pattern corresponding to BM motion (displacement, velocity, acceleration). Taking up Fletcher's suggestion that the total loudness, N, of a sound is the integral or sum of specific loudnesses N_x contributed by each CB, one needs to measure the energy input and then find the excitation pattern needed to calculate the various N_x from which N is derived.

The model of loudness summation proposed by *Zwicker* and *Scharf* [33.29] (see also [33.44] and [33.12, Chap. 8.7]), comprises components that can be viewed as steps in a sequence of processing:

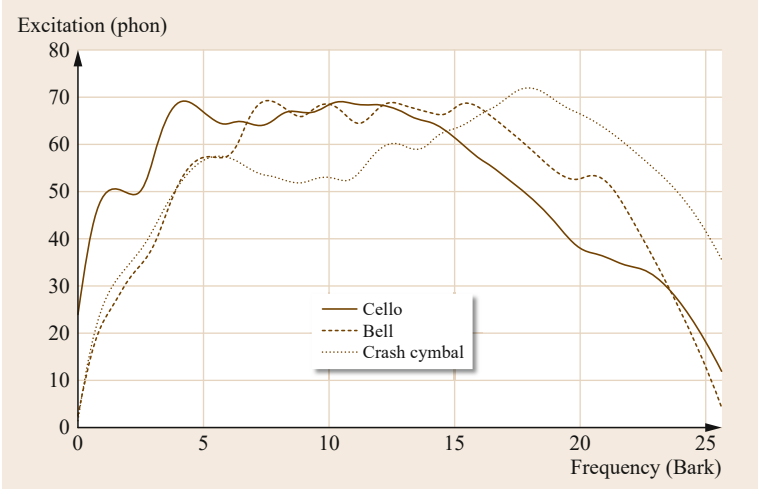

Fig. 33.4 BM excitation pattern for three loud sounds from cello (*solid line*), bell (*dashed line*), and crash cymbal (*dotted line*). Excitation peaks at ≈ 70 phon and involves all CBs

1. An input signal like a sine tone of given frequency and intensity (I, $re10^{-16}\,\mathrm{W/cm^2}$) enters the cochlea via the meatus and the middle ear ossicles (for characteristics and parameter values of the transduction, see Sect. 31.3).
2. The input signal causes a displacement on the BM at the location corresponding to the BM frequency map (Figs. 31.4–31.5).
3. The displacement then is transformed into an excitation, E.
4. From this excitation the specific loudness N' is calculated.
5. The total loudness N is summed in an integral along the Bark scale like

$$N = \int_0^{24\,\mathrm{Bark}} N' \mathrm{d}z \,.$$

The excitation level

$$L_\mathrm{E} = 10 \log \left(\frac{E}{E_0} \right) \mathrm{dB}$$

is calculated from the intensity I_G of the sound per band transformed into a critical band level,

$$L_\mathrm{G} = 10 \log \left(\frac{I}{I_0} \right) \mathrm{dB}$$

(for details, see [33.12, Chap. 6]). Assuming that the specific loudness per band approximately is

$$N' \sim \left(\frac{E}{E_0} \right)^\mathrm{k} ,$$

where E_0 is the level of excitation corresponding to the reference intensity ($I_0 = 10^{-12}\,\mathrm{W/m^2}$), the exponent needs to be determined. A value found fitting for noise bands is $k = 0.23$ [33.44, Chap. 15], [33.12, Chap. 8.7].

According to Zwicker's original model, the loudness (in sones) of a broadband sound can be calculated from the pattern of specific loudnesses if the sound is steady state over a period relevant for auditory sensation. Reasonable time constants are from 80 or 100 ms to 200 ms since the time constant is dependent on level as well as on frequency; at threshold and for tones at 500 Hz, 200 ms are more realistic while at 50 dB and 1000 Hz an integration time of 100 ms or less may apply (for empirical data obtained from tone pulses, see [33.45]). Loudness sensation for steady-state stimuli falling into one CB usually grows fast with stimulus duration up to $\approx$ 80–100 ms but only slightly for durations between 100–200 ms (where the function almost saturates). However, if stimuli are unmodulated both in bandwidth and temporal envelope, loudness adaptation to such steady-state sounds can occur if their duration exceeds a period from one to several seconds. Thereby, a reduction in loudness sensation takes place even though the amount of energy contained in the stimulus does not change. An explanation of such phenomena can be sought on the neural level where the firing rate of neurons constantly engaged might drop while the recovery time between firings grows at saturation levels.

Given that many environmental sounds are modulated rather than steady state, more recent models [33.46–48]) provide algorithms suited to cover various rates of amplitude modulation (AM) and other temporal effects such as tone bursts. These models differ in certain respects while the general design includes the ear canal transfer, an auditory filter bank and a temporal integration stage. In addition, a compressive nonlinearity has been introduced to simulate the behavior of the hearing system for higher SPL. Spectral processing (simulating AF/CB filtering) has been implemented either as short-term Fourier transform (STFT) (with several FFT processes running in parallel to cover different frequency bands, [33.46]), where the analysis window is time-shifted over the signal in small increments, or as Fourier time transformation (FTT [33.47]). Temporal integration is a special problem given the range of natural and technical signals in various environments. While a number of signals show slow fluctuations in level, many exhibit rapid ones, and some are markedly *peaky* with a more or less regular pulse structure (Fig. 33.1). Hence, the inner ear must be quick to deal with impulse-like sounds that have very short rise and decay times respectively. An obvious choice, therefore, is to provide at least two different integration constants, which in some models are accessed either in parallel or in a consecutive processing line [33.49, 50]. A low-pass filter accounts for the fact that the hearing system cannot follow temporal fluctuations in the signal beyond an upper limit frequency. The compressive nonlinearity, which relates SPL to loudness, is implemented by a weighting where a proper exponent for the power function must be chosen (common values are $0.23 < a < 0.6$). The model of *Sottek* [33.48] includes an autocorrelation analysis for the calculation of the specific loudness within each channel (to account for tonal and noise content in bandpass signals).

There have been several comparative tests [33.48, 50, 51] in order to evaluate the performance of various models relative to a range of different sounds, in particular time-varying technical sounds (most of them

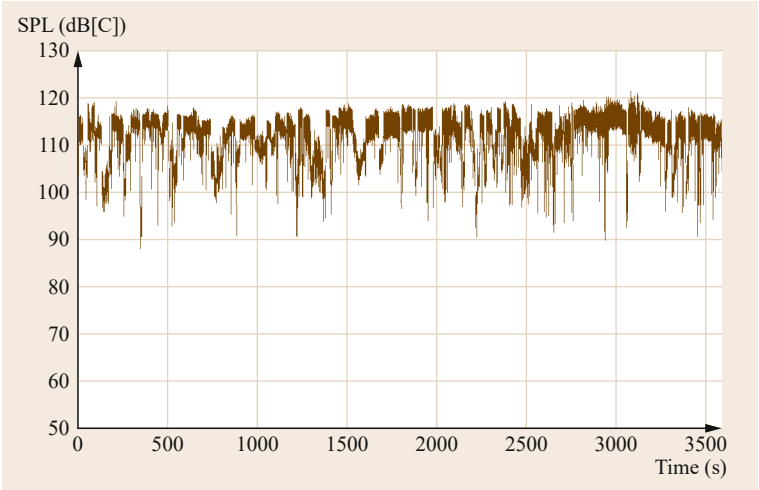

Fig. 33.5 SPL (dB[C]) over time, 1 h of hard trance music recorded in a disco (one channel)

from machines or weapons plus a snare drum). The results show that the models underestimated the loudness of certain sounds (relative to behavioral data for the same sounds taken as stimuli) while overestimating others. The deviations could be quite small in some cases (< 1.5 dB) but significant (> 10 dB) in others. However, one has to see that the behavioral data for subjective loudness usually scatter over a wide range (Sect. 30.1.4, *Loudness Scaling* ...), which poses a problem for defining reference levels as well as suited exponents for the nonlinearity. In addition to spectral and temporal loudness summation parameters, also binaural loudness must be considered in the design of models. Taking into account that binaural loudness across both ears is less than expected from linear summation, *Moore* and *Glasberg* [33.52] have modified their model assuming inhibition between outputs of both ears. The model parameters were chosen so that a signal presented diotically may appear 1.5 times as loud as the same signal presented monaurally. While previous loudness models suited to measure steady-state sound used longer integration constants, the concept of recent models adapted to time-varying sounds is to calculate short-time or even *instantaneous* loudness. With respect to sensation, in models based on FFT or FTT, window size (number of samples) can be chosen so as to yield meaningful integration constants. A software package like ArtemisS (Head Acoustics) offers a range of psychoacoustic parameters including various SPL and loudness measurements, which were used, for example, in examining loudness levels and sound characteristics in discotheques and music clubs [33.53, 54]. In one such venue where *hard trance* is the main musical genre played to the visitors, a recording of the sound did yield a SPL for one hour as displayed in Fig. 33.5. For the calculation of SPL over time (1 h = 3600 s), the integration constant *fast* (125 ms rise time, 125 ms decay) and spectral weighting according to the dB(C) filter function was applied. One can see that the average SPL is at about 112–115 dB(C), which means an average pressure of ≈ 8–11 Pa. From the same raw data recorded in this club, loudness N (sone) over time was calculated for one hour of music according to a standard method (FFT/ISO 532 B, now revised by ISO 532-1:2017). Loudness had some peaks far beyond 300 sone and reached 178.1 sone on average, corresponding to 114.76 phon. Exposure to such levels for hours can cause temporary or permanent hearing loss in subjects (see below).

A decisive aspect in algorithmic modeling of loudness seems to lie in the sequence of temporal and spectral processing stages, i. e., whether spectral analysis according to AF/CBs is performed before or after analysis of temporal envelope features. Most models carry out spectral analysis first and then look into the output of each CB filter for the envelope. It seems feasible, though, that in mammalian auditory processing temporal and spectral information is derived conjointly from BM displacement and velocity, and is coded in a parallel process rather than sequentially.

33.3 From Lab to Disco: Measurements and Perceptual Variability of Loudness

Most of the measurements on loudness sensation and perception have been carried out in lab situations where, in the tradition of psychophysics, quite often designs are employed that investigate variation in one sensory variable as a function of variation in a physical parameter, or combine a few input variables (e.g., frequency, SPL, duration) to measure their effect on sensation. In this respect, sensation of loudness as depending on the frequency and/or SPL as well as the duration of pure tones has been studied; likewise, loudness of noise bands as depending on bandwidth and/or level and/or modulation has been investigated (several of the chapters in [33.55] provide comprehensive overviews). Many of these experiments have led to understanding fundamental mechanisms of auditory processing such as masking and lateral suppression, and have also been directed to deriving basic scales of loudness (Sect. 30.1.4, *Loudness Scaling* ...). A critical aspect is that *ecological validity* might be limited as lab experiments for a number of reasons are often restricted to a small number of variables and also employ, in most cases, simple sound stimuli that are far from the complexity of environmental sounds. In this respect, there is a gap between the lab and real-life situations. However, fundamental research in psychoacoustics can provide a basis to start from for investigations that are more contextual as is necessary in regard to music perception. The study of loudness is a good case in point. While many of the lab experiments used steady SPL for sounds (pure tones, noise bands) to find quantitative relations between physical magnitudes (intensity, power) and sensations of loudness, music is intrinsically time-variant both in spectral energy distribution (Sect. 32.2.3) and in dynamics. In reality, many if not most of the tones played on natural instruments undergo some AM and FM (frequency modulation) either for physical reasons or as an effect of playing technique. Also, several tones often interact in dissonant chords or sonorities so that AM is observed in the time signal, which can cause a sensation of roughness as well as a sensation of fluctuant loudness if the modulation rate is low enough for the auditory system to follow the changes in level. The factor that influences loudness sensation apparently is not the modulation index but the difference between maximum and minimum level. For broadband noise, the level of a modulated signal (with modulation frequencies from 4 to 32 Hz) needs to be ≈ 1 dB below that of the unmodulated noise of corresponding bandwidth to be judged as equally loud [33.56]. If several or even many harmonic partials are phase locked in a sound (Fig. 31.6a), it appears louder than a complex comprising the same number of components yet in random phase [33.57]. Greater loudness of a harmonic complex with all partials locked in phase can be attributed to the absolute height of amplitude peaks as well as to the crest factor. For example, five partials from $f_1 = 100$ Hz locked in cosine phase (Fig. 30.10) yield a peak amplitude that is larger than that of a complex having the same frequency components and amplitudes but where phase angles of components are chosen at random. The crest factor apparently also plays a role in loudness sensation; noise signals were judged as equally loud as a standard when their sound level decreased while the crest factor increased [33.56], indicating that the *peakiness* of signals can add to loudness sensation. This is particularly relevant for electronic dance music and related genres where, typically, the beat is marked by sequences of strong pulses. As is evident from Fig. 33.1, the rise time of these pulses can be quite short so that the sound jumps to peak level with a steep pulse slope. Such steep pulses that reach high peak levels can be expected to cause rapid transfer of energy into the auditory system where sections of the BM and the structures it carries are accelerated accordingly. In discotheques, visitors are exposed to high sound levels of 110–125 dB(C) and to music which, typically, is based on such pulse sequences that are realized, for the most part, with sounds in the low frequency range. In effect there is massive concentration of pulsed energy in particular in low AF/CBs that can affect hearing temporarily or permanently [33.53, 54]. According to a hypothesis advanced by *Todd* [33.58, 59], the vestibular system becomes involved in hearing at very loud sounds, which can be explained in evolutionary terms (as a remnant from early vertebrate hearing systems) and might explain why young people like sound levels above the *rock 'n' roll threshold* of ≈ 110 dB(C). In a large sample of 423 grammar school pupils (age: 16–19 yr, city: Berlin) almost 72% declared that they preferred loud, very loud or even extremely loud levels in discotheques [33.60, 61]. Many of the pupils also asserted that they would listen to pop and rock music with earphones at rather loud levels. Though the intake of considerable quantities of energy into the auditory system during visits to discos or at live rock concerts as well as by using earphones (or earplugs) is dangerous with respect to hearing loss, subjects seem to respond differently to loud or even very loud sound. Apparently, musical preferences and other personal factors influence the range of SPLs that subjects can tolerate or even find appropriate for listening.

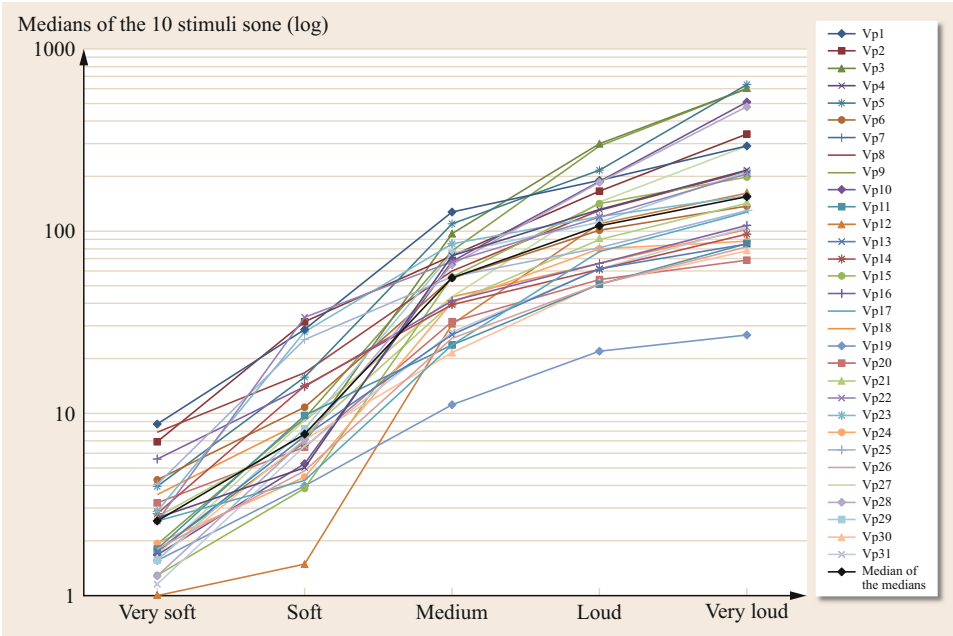

Fig. 33.6 Individual loudness functions for 31 subjects averaged over each subject's responses to ten stimuli (after [33.62], with permission from A. von Ruschkowski). The levels in sone (ordinate) are in a log scale to accommodate the wide range of levels chosen in loudness judgments. The five levels (abscissa) are *very soft*, *soft*, *medium*, *loud*, *very loud*

In an empirical study of loudness with musical stimuli covering various genres, *von Ruschkowski* [33.62] had subjects make loudness judgments by adjusting the level with a continuously variable level control according to five categories (very soft, soft, medium, loud, very loud). The signal was fed into two headsets (Sennheiser HDA 200) constructed to match the very narrow tolerances needed for audiometry, and capable of handling high input without distortion; one of the headsets was used by the 31 musically trained subjects volunteering in the experiment (all tested with audiometry for normal hearing), the other was attached to an artificial head (HSU III.2, Head Acoustics), which housed two calibrated measuring microphones (Microtech Gefell MK 250) from where the signal was continuously recorded in digital format at 24 bit/48 kHz. These data could be used to calculate SPL over time (with or without weightings) as well as loudness over time (with a choice of several methods and scales). In addition to level adjustments, four variables were included in the design (gender, age, musical preferences, current mental state and mood). The last variable was checked with a standardized psychological test (Baseler Befindlichkeits-Skala, BBS).

The results from this study [33.62] showed that responses of subjects were highly variable, resulting in broad dispersions of data and large standard deviations (SD). Though subjects in general realize a category scale from *very soft* to *very loud* as well as a monotonous loudness function, absolute values for the categories vary considerably among subjects (for instance, the range for *very loud* for 30 subjects out of 31 is from 70 sone to 600 sone; Fig. 33.6) and also with the individual stimuli. Averaged over the sample of subjects, the category *very loud* for the Adagio from Beethoven's piano sonata Nr. 14 (op. 27, no. 2, *Moonshine*) means about 100 sone (or a loudness level of $L_N = 106.44$ phon) while the same category for a thrash metal production (Slipknot, *People = shit*) means $\approx$ 227 sone ($L_N = 118.26$ phon). Besides level adjustment the variable gender did yield significant results (women prefer music at lower levels than men); further, the variable musical preferences showed a correlation with level settings.

The enormous variability in level adjustments can be partly attributed to stimulus parameters (type of music and composition, temporal and spectral structure, dynamics, production including sound effects, compression rate applied to dynamics, etc.) and partly to musical preferences and habits. Though sound pressure level (measured in mPa) certainly is the strongest factor in human loudness perception, there are evidently several personal and social factors involved as well when it comes to loudness evaluations of real music. The variability in loudness judgments, which is high when musical stimuli are presented to subjects who have different social and musical backgrounds, might indicate that loudness depends significantly on *context* (what it apparently does). However, variability in response magnitudes was observed already by Stevens and other psychophysicists in a host of lab experiments where elementary stimuli were used (Sect. 30.1.4, *Loudness*

Scaling ...). The great variability found in subjective responses to sound stimuli measured as loudness is clearly different from pitch where judgments based on sensations in general vary within much narrower limits. Though the dependence of loudness sensation on SPL or intensity is obvious, one would expect much less variability in empirical data if sound pressure and energy would condition loudness sensation in total. Rather, one needs to look into the spectral content and temporal structure of sound signals to identify features that can explain why sounds having equal energy are often perceived as different in regard to loudness. Besides sound signal characteristics, aspects discussed for intensity sensation and loudness also included the possibility of memory traces and of internal anchor points as well as decision processes mediating intensity discrimination and identification ([33.20] and a number of subsequent articles leading to [33.63]). One of the considerations was that internal *low* and *high* anchor points might narrow the dynamic range subjects actually relate to. It has in fact been observed [33.62] that some subjects, when asked to adjust sound levels so as to match five categories (from *very soft* to *very loud*, see above) do not use the full range one might expect (where *very soft* could mean ≈ 30 dB SPL and *very loud* perhaps ≈ 100 dB), but a much smaller range. Such behavior probably reflects individual experience since, for example, subjects practicing chamber music usually dislike high sound levels and may find a level of 70 or 80 dB *very loud* while subjects playing in a hard rock or metal band may regard 60 dB *very soft* and only 120 dB *very loud*. Subjective narrowing of the dynamic range hence should not be confused with the well-known bias according to which subjects tend to avoid extreme categories at both ends of rating scales. Rather, subjects seem to use loudness categories of different individual bandwidth (dB, sone) that are placed at different absolute levels (mPa, dB) probably serving as anchor points. In sum, at least musically experienced subjects distinguish between *very soft* and *soft*, or between *loud* and *very loud* sound levels, but the category centers and boundaries vary considerably along the dynamic range (0−120 dB), for individual ratings.

Another concept offered as an alternative to conventional models relating stimulus intensity to loudness was the physical correlate theory proposed by *Warren* [33.64, 65]. He pointed to the relation between perceived loudness and imagined distance of a sound source. In this respect, loudness judgments involve distance estimates since in a natural environment the loudness of a sound source can convey its distance relative to a perceiving subject that may react in his or her behavior accordingly. The physical correlate theory was proposed to explain doubling and halving of loudness (Sect. 30.1.4, *Loudness Scaling* ...) in terms of imagined distance judgments; it takes sound field characteristics into account since the proportion of direct sound to diffused (reverberant) sound changes with distance. *Warren*'s [33.64] finding that half-loudness for speech signals (−11 dB with headphones, −12 dB with loudspeakers) differed considerably from half-loudness for tone and steady-state noise signals (about −6 dB) can be taken as evidence that a single loudness scale (like the sone scale) might not be suited to represent various types of sound signals. Notwithstanding substantial evidence from both neural intensity coding studies and behavioral experiments, a full understanding of loudness sensation and perception is still an objective for research.

33.4 Summing up

This section briefly sums up some of the content as well as of the critical issues discussed in Chaps. 30–33 and concludes with a tentative model concerning relationships between pitch, timbre, and loudness.

This part of the handbook, covering fundamentals of psychophysics and psychoacoustics, opens with Chap. 30 introducing theoretical and methodological considerations in regard to sensation and perception as well as apperception. Reasons are given for an approach to sensation and perception of sound based on realism and naturalism seeking causal explanations of empirical observations. Psychophysical scaling is among the issues and problems treated in greater detail. For better understanding (and provision of some historical background for readers from areas such as musicology and music education), the development of several scale concepts has been outlined and illustrated by examples (in particular, the sone scale and the mel scale).

Subsequent sections on sensation and perception of pitch (Chap. 31) repeatedly refer to the principles of periodicity and spectral harmonicity, with special emphasis on the Wiener–Khintchine theorem. In line with findings from neurophysiological research of the past decades, pitch and also consonance are viewed as natural phenomena reflecting organization and functions of the auditory periphery and higher stations of the AuP as much as the lawful structure of sound. A basically naturalistic and empiricist perspective, which seems es-

sential for psychoacoustics, does by no means preclude regard for historical and sociocultural contexts (as was underpinned already by *von Helmholtz* [33.66]). Rather, it can be useful if not inevitable to take historical as well as ethnological and other cultural background information into account (as has been pursued in several sections of this part, for example, the sections on tone systems and scale formation, Sect. 31.8). The aim in this respect is to illustrate certain developments both in music and in research pertaining to musical acoustics and psychoacoustics or music perception. A rather critical view has been taken on some concepts of *categorical perception* based on ET12 *pitch class* constructs as applied to pitch perception and intonation practice in music. Also, some interpretations of tonal *fusion* found in the literature do not correctly represent the original concept of *Verschmelzung* as outlined by *Stumpf* [33.67–69]. Further, a general prevalence of musicians and listeners for the *stretched octave* (a commonality reiterated time and again in the literature) has been questioned on the basis of contrary evidence. In regard to so-called *auditory illusions*, the scale type constructed by *Shepard* [33.70, 71] using octave-spaced components circling under a fixed symmetric envelope (so that the sum of their amplitudes remains the same for all tones and scale steps) has been shown to realize a well-known experimental paradigm, namely keeping one parameter constant (in this case, tone height or brightness) while varying another (in this case, tone quality or *chroma*). Hence listeners perceive a circle of tone qualities presented with constant brightness. The construct becomes more of an illusion when the envelope is shifted contrary-wise to the movement of the octave-spaced components forming complex tones. Such constructs have been incorporated into works of contemporary music [33.72]. A discussion of the so-called *tritone paradox* (also based on Shepard tones, though on a version critically reduced in the number of components) has not been included into Chap. 31, for several reasons, among them being the controversial explanations the *tritone paradox* has found in regard to linguistic and other issues [33.73, 74]. Moreover, reanalyses of empirical data from earlier experiments that had led to postulating a *tritone paradox* and replications of experiments demonstrated that stimuli and conditions in previous experiments and their interpretations were not consistent or that alternative interpretations centered on sound features might be more apt [33.75, 76].

The sections on timbre and sound color (Chap. 32) perhaps differ from other accounts in that the interrelations with pitch are accentuated even though there are features distinctive of timbre that call for systematic analysis and description. The approach taken here is to discuss main concepts and issues, and to illustrate certain phenomena by sound analyses. Since timbre is a truly multifaceted area, any attempt to offer an exhaustive treatment of timbre within a single chapter would be all but impossible. In regard to music as performed and recorded, the overarching category of *sound*, which comprises aspects of sensation and perception along with factual evidence from room acoustics, studio technology, and music production, is briefly alluded to but not treated in much detail (for more background information, see [33.77–80]). Fundamentals of auditory stream segregation have been included in the sections on timbre; however, this area of research meanwhile has greatly expanded into modeling based on signal processing so that an in-depth survey of methodology and results would require an extra chapter.

The sections on intensity sensation and loudness perception (Chap. 33) were written with the goal of summing up at least part of the relevant observations and discussions while the number of publications on loudness over the past 70–80 yr is immense (comprehensive surveys are included in several chapters of [33.55]). However, a considerable portion of the literature is technical in content since studies on loudness include aspects of noise control and risks of hearing loss as well as the norms and standards of measurement. The relation of physical parameters and magnitudes to sensation apparently is even more complex for loudness than it is for the psychoacoustic domain of *pitch*. Though it is obvious that local sound pressure and sound intensity measurable in physical units are fundamental parameters for the excitation of parts in the auditory system (the mammalian ear, with some possible participation also of the vestibular system), measurement of sensation actually seems quite demanding in particular for real-life broadband sound such as music. Scales for loudness level L_N (phon) and loudness N (sone) derived from elementary stimuli in the lab probably will not cover more complex (in terms of spectral composition and temporal modulation) sound material. In addition, it seems that some of the norms of measurement even of sound level are inadequate given the actual temporal and spectral structure of musical sound. For example, it is astounding to see that an outdated weighting function such as dB(A) is still applied even in many measurements of high-level sounds where, in a techno disco or at a festival of heavy metal music, huge amounts of spectral energy is found concentrated in low frequency bands ($\approx$ 50–200 Hz). Applying dB(A) weighting to techno sound or heavy metal (or to other genres of highly amplified rock and pop) in fact means high-pass filtering where a significant portion of the energy contained in low frequency bands is suppressed. Hence, such a measurement hides the real distribution of spectral energy

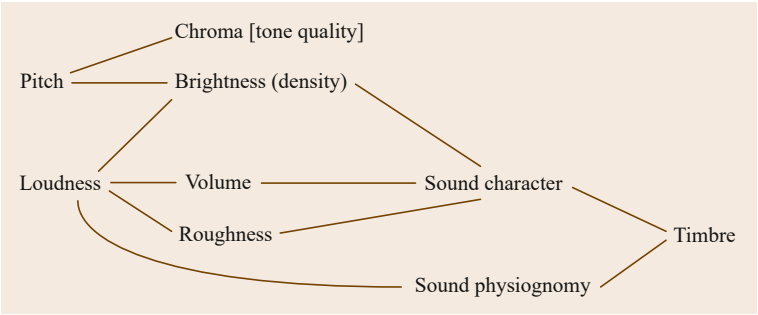

Fig. 33.7 Interrelations of pitch, loudness and timbre (after [33.81, 82])

radiated from a public address system and is unsuited for an assessment of possible risks of hearing loss. Among the temporal patterns of modern rock and pop music genres, the use of pulsed sounds is a feature that is clearly of relevance to sensation. Pulse-like sounds as are available from synthesizers as well as by *shaping* the envelope of natural sounds (by means of noise gates, filters and compressors) seem of particular interest in regard to energy transfer and BM excitation characteristics. However, in particular pulse-like sound structures are still difficult to asses with respect to effects they have on hearing since one needs to determine suitable integration constants as well as parameters covering the *peakiness* in sounds [33.83].

Finally, though research efforts in special areas such as pitch perception and loudness sensation will be continued, interrelations between pitch, timbre, and loudness should be studied as well since these are relevant for sensation and perception of music as performed and recorded. A scheme outlined already by *Hesse* [33.81] and *Thies* [33.82] from theoretical and empirical studies connects pitch, loudness, and timbre and sums up a number of attributes under the categories of *sound character* and *sound physiognomy* (Fig. 33.7, adapted from *Thies* [33.82, p. 21]).

Pitch in this scheme is largely a function of the period (f_0) of the complex envelope while *sound character* depends on the microstructure of a sound wave. *Sound physiognomy* [33.81, p. 139 f.] means the subjective experience of the sound profile in terms of the onset and the transients of a sound and the temporal envelope in general. Thus, perception of timbre can be explained as resulting from information pertaining to the interaction of the temporal and the spectral envelope, which must be understood as enclosing dynamic energy distributions that vary considerably with time in their structure. In binaural listening (e.g., to music performed in a concert hall or live music venue), spectral energy distribution and temporal envelopes can be quite different at both ears. While input is analyzed in both channels of the AuP, there are several links connecting left and right channel (Fig. 31.2), in particular SOC and inferior colliculus (IC) so that information is integrated for processing pitch, timbre, and loudness at higher stations (IC, corpus geniculatum mediale (CGM), cortical areas).

Part E

Music Em

Part E Music Embodiment

Ed. by Marc Leman

One of the main goals of systematic musicology is to understand the effects of musical (acoustical) structure on human behavior. Throughout the 20th century, this understanding was approached by considering music perception and its effect on behavior. That approach was strongly influenced by developments in the Gestalt psychology of the 1920s, the information psychology and cybernetics of the 1960s, and especially the empirical and computational approaches of the cognitive sciences since the 1980s. However, thanks to the advent of technologies that facilitated the tracking of human movement (with video cameras and sensors) it became possible to focus on new areas of music interaction as well, such as music performance and musical gesturing (while listening). These new areas of study started to emerge in the late 1990s (despite some historical antecedents in the 1920s) and they culminated in a new approach that is nowadays known as *embodied music cognition*.

Embodied music cognition puts emphasis on the human body as a contributing factor in listening, dancing and playing music. The former focus on music perception has therefore been replaced by a focus on music-related action. Understanding the effect of music on human behavior is approached from an embodied perspective. Music perception is also now reconsidered from this perspective. The rationale is that the perception of music is influenced by the way in which music is interacted with, and these interactions influence how musical structures are perceived. But these interactions depend on bodily constraints, such as physical, biomechanical, and biological possibilities and restrictions of the human body.

Embodied music cognition is in fact a natural outcome of the cognitive research paradigm that characterized the systematic musicology of the late 20th century. Its emphasis on action, and on the principles that support action (such as motor control) has broadened the concept of cognition, and this broad perspective can be considered as a major characteristic of the new approach. The rapid acceptance of this new approach by the music research community is probably due to the explanatory and predictive power of the embodiment concept; to its ability to cope with music perception as well with music performance; to its potential to generate new types of technological applications that involve both action and perception in domains such as music and wellbeing, music engineering, and neuroscience of music; and last but not least, to its influence in ethnomusicology, where studies of social interaction draw upon research results from embodied interactions with music. Embodied music cognition has rapidly evolved in the direction of a new embodied music interaction paradigm. In the near future, it is likely that the term *cognition* will disappear and be replaced by the term *interaction*. Essentially, it means that the effects of music on human behavior are based on interactive processes that involve perception *and* action.

The chapters of this section reflect the work in progress in this branch of systematic musicology. Despite its rapid acceptance by the community, embodied music cognition is still a very young research paradigm. Its epistemological and methodological foundations have barely been addressed. Its basic concept of embodiment needs further refinement in view of new findings. Its support by empirical studies requires further substantiation. Its technological basis requires a constant update with the rapid ongoing developments of technology in our society. The chapters introduce basic concepts and basic methods, and they focus on different application areas of interactions, such as music making and wellbeing.

Chapter 34 (*What Is Embodied Music Cognition*, by *Marc Leman*, *Luc Nijs*, *Pieter-Jan Maes*, *Edith Van Dyck*) explains what embodied music cognition is about. The chapter gives an overview of the major concepts behind this research paradigm of systematic musicology, including its basic ontology and epistemology, and the architecture of embodiment (involving concepts such as prediction, emergency, enactment and expression). This basis is then followed by an overview of some analytical and empirical studies, which illustrate contributions of the embodied music cognition approach to the understanding of expressive gestures, synchronization and entrainment, and the effects of action on perception.

Chapter 35 (*Sonic Object Cognition*, by *Rolf-Inge Godoy*) goes deeper into the nature of the musical material that forms the basis of human interaction with music. This material is described in terms of sonic objects. Starting from the work of Pierre Schaeffer and others, the chapter considers the nature of sonic objects in relation to human interaction behavior. A major breakthrough in our understanding of sonic objects was realized when sonic objects were associated with body motions, shape cognition and actions. This new way of understanding sonic objects offers new possibilities for sound synthesis control, and new possibilities for interaction.

Chapter 36 (*Investigating Embodied Music Cognition for Health and Wellbeing*, by *Micheline Lesaffre*) provides a framework that aims to validate musicological know-how in applications for health and wellbeing. The chapter defines the field of health and wellbeing and ongoing work in music therapy. It then explains that

the unique contribution of the embodied music cognition approach is related to user-driven and technology-driven research in which measurement and analysis of embodied interaction with music offers a path to evidence-based validation.

Chapter 37 (*A Conceptual Framework for Music-Based Interaction Systems*, by *Pieter-Jan Maes*, *Luc Nijs*, and *Marc Leman*) looks at the role of technology in music interaction. It is claimed that interactive systems can reinforce interactions with music, such that the overall experience with music is intensified, and the social, cognitive, affective, and motor skills are made stronger. The chapter introduces an overall model for music interaction based on an embodied music cognition framework that also includes the benefits of reward processing and motivation, and social interaction. Examples are given of an educational technology for learning to play a music instrument, and a technology that facilitates the synchronization of human movement to music.

Chapter 38 (*Methods for Studying Music-Related Body Motion*, by *Alexander Refsum Jensenius*) presents an overview of methods for music-related motion description. The focus is on qualitative and quantitative description methods that prepare the ground for further analysis of human-music interaction behaviour, such as methods for describing qualitative motion, or methods for describing motion features such as quantity and centroid. A distinction is made between camera-based systems and sensor-based systems. All technologies have strengths and weaknesses and the right choice depends on the research question and analysis methods.

34. What Is Embodied Music Cognition?

Marc Leman, Pieter-Jan Maes, Luc Nijs, Edith Van Dyck

Over the past decade, embodied music cognition has become an influential paradigm in music research. The paradigm holds that music cognition is strongly determined by corporeally mediated interactions with music. They determine the way in which music can be conceived in terms of goals, directions, targets, values, and reward. The chapter gives an overview of the ontological and epistemological foundations, and it introduces the core concepts that define the character of the paradigm. This is followed by an overview of some analytical and empirical studies, which illustrate contributions of the embodied music cognition approach to major topics in musical expression, timing, and prediction processing. The chapter gives a viewpoint on a music research paradigm that is in full development, both in view of the in-depth refinement of its foundations, as well as the broadening of its scope and applications.

In this chapter, we focus on the quintessence of the embodied music cognition paradigm; namely, its claim that bodily involvement is crucial in human interaction with music, and therefore, also in our understanding of that interaction. The embodied viewpoint holds that bodily involvement shapes the way we perceive, feel, experience, and comprehend music. Embodiment determines, to a large extent, why sound is experienced as music, which has a rewarding nature and provokes personal interest. But what does bodily involvement, and embodiment, really mean? What are the main assumptions, the findings, the perspectives? Are these assumptions so different from the classical viewpoint on music cognition? And what are the consequences for our understanding of music, or for future music research?

Critics could claim that nothing in the paradigm of (classical) music cognition ever claimed that perceiving music does not involve movement [34.1]. Indeed, several descriptive studies show, for example, that the expression of music is reflected in body responses (locomotion, arousal), or that expression is present in gestures that support music playing. However, the descriptive approach may fail short in adequately justifying a theory of embodied musical meaning formation. What is needed, therefore, are *more direct proofs* of the influence of embodiment on perception and on meaning formation, such as proof or evidence that music perception is determined by states of embodiment: movement states, emotional states and so on. Do such studies currently exist? Do the studies only navigate and reach beyond showing that music induces movements? Moreover, what does this imply?

What follows is an exposition of a viewpoint on the foundations of embodied music cognition, which focuses on the above questions. In the first part, we define the theoretical framework of embodied music cognition. We start with a specification of the ontolog-

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_34

ical and epistemological foundations. Then we delve deeper into some of the core concepts that define the character of the approach. In the second part, we discuss analytical and empirical studies (mainly sourced from our own laboratory) that illustrate the contribution of embodied research to topics in musical expression, timing and, especially, prediction. In the third part, we give a general appreciation of the paradigm and identify general trends and perspective for future research.

34.1 Ontological and Epistemological Foundations

The paradigm of embodied music cognition can be seen as an extension of an earlier paradigm, in which cognition was mainly considered from the viewpoint of perception. Focusing on *cognition in perception*, this paradigm treated the ability to perceive music in relation to memory, learning, and predictive processes. Music and musical processing were thereby dealt with in terms of structural features, or patterns, while emotions and movements were seen as outcomes of that kind of prediction-based pattern processing [34.1–4]. For example, the viewpoint was that a mismatch between particular perceptions and predictions would cause tensions that find their way towards bodily expression, emotion, and, ultimately, reward. Needless to say, perhaps, is that the cognitive approach to music perception has been formulated with reference to an impressive theoretical framework and viewpoint for understanding how music cognition works [34.5]. Importantly, this *cognition in perception* approach focused on predictive processes in perception, irrespective of possible bodily influences on that prediction. Recent scientific evidence, however, suggests that bodily involvement in perception cannot be ignored. For example, body movements may determine the perception of meter [34.6, 7], and bodily states may be central determinants of the musical interaction experience [34.8, 9]. Evidently, these and similar findings have serious consequences for the theoretical underpinning of music cognition research. After all, they indicate the importance of interactive processes in musical signification. Therefore, the embodied music cognition paradigm extends the *cognition in perception* approach, and replaces it with a *cognition in interaction* approach. This approach builds, to a certain extent, on achievements in previous music cognition research, but at the same time it reformulates the epistemological assumptions of music cognition. It is justifiable to say that it is traditional in its methodology, but radically different in its epistemology.

34.1.1 Assumptions About the World

Over the past decade, the concept of embodiment has become influential in music research [34.10, 11]. Embodied music cognition means that the cognitive processing of music (such as learning, memory use, prediction, etc.) is based on corporeally mediated interactions with music. Another way to approach this is to see it in terms of patterns and states, and the predictive models surrounding the connections between patterns and states [34.12–17]. Patterns are the elements that can be observed, while states are the conditions that lead to those patterns (Fig. 34.1). Predictive models of the human brain are specialized in making assumptions about those conditions, given the observed patterns. The mechanism works in fact in dual direction; namely, action and perception. First of all, humans learn that actions cause particular changes in the environment. Actions are supported by predictive models that associate motor commands for actions that have perceived sensations of the outcomes of those actions. Secondly, and parallel with the first, humans learn that particular changes in the environment can be understood in terms of actions, probably not their own action, but maybe the actions of others, or of other things. Perceptions are supported by predictive models that associate observed patterns as action outcomes in dual direction; namely, from actions to action outcomes and observed patterns, and from observed patterns to assumed conditions and actions that cause these patterns. A complication is that the owned states (such as intentional states, arousal states, energetic states, and so on) may influence the construction of these predictive models. The owned states are known through proprioceptive observations. The model of the owned state makes an assumption, therefore, about the true condition of the body, and

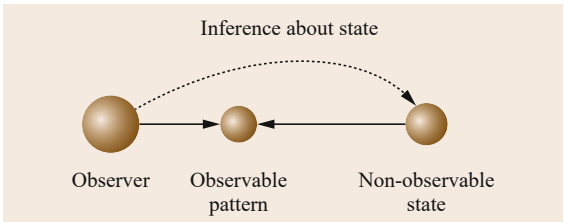

Fig. 34.1 States are conceived as causal conditions of being. Assumptions about states are based on patterns that can be observed

this assumption, or predictive model, may interfere with predictive models about the environmental conditions. In essence, the key point is that predictive models are not based on a direct line of information that informs a model about the true state of the world, nor even does it define the true state of the proper body. The true state remains unknown, and needs to be inferred based on information that its mediators provide. Stated differently, the human brain doesn't perceive the state of the world directly, but it constructs models of the state of the world using proprioceptive and exteroceptive corporeal mediators that provide the information for the models on the basis of interactions with that world.

What we call *music* can in fact be seen as the result of such a reconstruction. During the act of listening, for example, we construct models of a condition (or state) that could have generated these sonic patterns. For example, in listening to a simple tonal piece, the chord progression appears as being driven by a compelling tonal force that explains why and how the chord sequence progresses the way it does. Clearly, this assumption of force is the result of a predictive model that emerges from, at least, (i) the available sonic patterns, and their physical-acoustical arrangement, (ii) the auditory mediator and its innate way of rearranging acoustical information, and (iii) previous encounters with music that provide knowledge about the repertoire. The tonal piece, thus, rests upon a predictive model that assumes a tonal goal-directed force as the condition behind the observed patterns. Embodied music cognition draws attention to the fact that the predictive model is largely the result of the constraints of the mediators and the listener's own corporeal states [34.10]. In short, the embodied paradigm assumes that music perception is the outcome of an interaction of the perceiver's states with states of the musical environment. The construction of a predictive model of music depends on corporeal mediators and on corporeal internal states, which determine how the sonic patterns will be perceived in terms of an interactive functionality.

34.1.2 Assumptions About Our Knowledge of the World

Embodied music cognition thereby offers a way of understanding the above ontology in relation to an epistemology of interaction processing. A basic idea is that the knowledge about the world, or music in our case, becomes simple when it is related to interaction. Complex music patterns that are linked with interactions (synchronized movements, for example) acquire roles and functions that are easy to understand because the complexity of the pattern, as such, is reduced to an interaction issue that is basically dealt with at the intentional level. The embodied viewpoint holds that this process is strongly influenced by knowledge and skills (i. e., the classical music cognition viewpoint), as well as by the nature of bodily mediators (such as the auditory system and biomechanics of bodily effectors) and states of being (arousal levels, and other bodily states such as fatigue, fitness, and so on) [34.10]. The mediators impose their proper constraints by the way in which music can interact. They determine the access to the true state of the music. In addition, mediators influence the construction of predictive models about the observed musical patterns. Besides that, they offer a way of simplifying the complexity of the patterns, by helping to reduce them to an action-oriented perspective on patterns. Mediators thereby constrain the observed musical pattern in view of the proper intentional, energetic and affective states of the person involved in the interaction, but they constrain these musical patterns in such a way that they can be used for interaction. Accordingly, extremely complex musical patterns (containing dense spectral information) can be linked with gestures, or body movements that form a unit of an action, such that they appear as objects of action targets. That simplifies the concept of the patterns. Gestures thereby support the construction of an intentional state of interaction [34.18, 19]. What we claim here is that once that level of interaction is achieved the complexity of the pattern as such disappears and the pattern becomes a component of an interaction that is driven by action goals. To sum up, interaction with music is based on a coupled system of person–environment states, or a coupled system of person–music states. This system produces patterns that can be exchanged, observed, and processed, either by the person, or perhaps even by others. This allows people to generate predictive models about the patterns and about the person–environment state interaction. The predictive models reduce the complexity of the involved patterns by linking them with actions and intentions that drive the interaction. Patterns take on interaction roles. Cognition is itself an aspect of the condition for having a person–environment interaction. It is an aspect of the state of being, juxtaposed with aspects such as physical effort and emotion.

Note that the above ontology and epistemology also applies to scientific work, in particular the research in music cognition. Empirical studies thereby aim at unraveling the causality of the interaction of the person–environment states, using observations about these states as points of departure to build prediction hypotheses. The way in which a person acquires knowledge about music runs parallel with the way in which a scientist acquires knowledge about that person's acquisition of knowledge about music. Methods

and approach are different but the ontological and epistemological basis is similar.

34.1.3 A New Paradigm for Music Research?

Although the interest in embodied music cognition could be traced back to historical work on music and gymnastics [34.20, 21], and empathic moving along with music as the foundation for aesthetic experience [34.22, 23], it is only up until quite recently that embodied music cognition was explicitly proposed as a paradigm for music research [34.10], and there are several reasons for that. One is that new technologies became available that have enabled the recording of body movements. Other reasons refer to the classical debates about scientific paradigms, discussions about the restricted focus of *cognition in perception*, about anomalies in empirical studies, and ways of viewing things [34.24]. A common example is tonality perception, where the classical cognitive paradigm is said to neglect the effects of sensory processing, and where evidence is gathered about incorrect conclusions drawn from empirical facts; mainly because the world is seen from the viewpoint of a different paradigm [34.25]. Embodied music cognition can be seen as an attempt to further develop the classical cognitive paradigm. As mentioned, the empirical approach for inquiry is fundamentally the same but the main extension concerns the role of corporeal mediators and states during ongoing musical interactions, including perception. Seen in that context, the embodied music cognition paradigm has expanded its research field from *cognition in perception* to *cognition in interaction*.

Embodied music cognition research is currently characterized by two trends; namely an in-depth exploration of embodiment and a broadening of the concept of embodiment. The first trend explores in greater detail the nature of embodiment. Several studies have, indeed, introduced challenging new ideas about bodily articulations and support for expressive gesturing in relation to music [34.26–29]. These ideas currently profit from more detailed viewpoints on the sensorimotor principles and direct proof of embodied influences on perception [34.30–32]. The second trend is to broaden the perspective of embodied music cognition and to link it to research areas such as musical affect research [34.33], wellbeing [34.34], healing [34.35], music engineering [34.36], and brain studies [34.37]. This trend suggests that the power of embodiment can be put to work in a broader context, embracing sister disciplines such as music engineering, music psychology and music and brain science. Embodiment is embedded here into an overall motivational approach.

34.2 The Architecture of Embodied Music Cognition

A cognitive theory has a focus on processes that handle the anticipation, goal-satisfaction, and emergent forms (traditionally called gestalt formation) of patterns, to be understood here as musical patterns and movement patterns – in short as materiality that moves and where its movement constitutes a pattern. Patterns can be learned, and based on this acquired knowledge one can predict and estimate what happens in an interaction. The role of cognition, therefore, is to construct predictive models (through learning) and apply these models in ongoing interactions with the environment. Admittedly, this is not a new idea, as it has been a major research idea of the music cognition paradigm for decades.

34.2.1 Prediction

Prediction focuses on patterns that are expected to occur. The occurrence of those patterns would then confirm the prediction, or otherwise [34.2, 4, 5]. According to the cognitive theory of music, anticipation would typically be built up by an exposure to previous musical patterns, which is called *the context*. The patterns that define this context have inherent constraints (due to acoustical structures) that are combined with inherent constraints of human auditory physiology (the innate disposition to process sounds) and with habituations to the musical repertoire (due to learning). The combination of these constraints sets up a particular context for the prediction and the subsequent processing.

The work on tonality has been paradigmatic for this approach. Tonal sequences have a strong anticipatory character. The classical theory thereby assumes that the outcome of a prediction (whether it matches with the perceived patterns or not) may be linked with affect processing, such as relaxation, tension, and ultimately, with emotion and arousal (e.g., [34.1, 38]), and a reward (or pleasure) system that reinforces the satisfaction mechanism [34.39, 40]. Moreover, prediction can be described in terms of a pattern-processing model that functions independently from the physical carrier (the brain). The typical processing components that frame this type of cognitive processing are working memory, long-term memory,

schema construction, and schema automation. These components define a *cognitive architecture* that, together with a reward system, allows us to understand interaction with music as meaningful and motivating [34.41].

The viewpoint of embodied music cognition adds to this approach, but it stresses the bodily involvement in predictive processing. In fact, it states that bodily involvement influences the anticipation of perceptual events, in addition to perceptual events themselves. The viewpoint implies that anticipation needs to be conceived in terms of schemes that combine perception-related issues with sensorimotor-related issues. For example, embodied music cognition would stress the fact that predictions of patterns rely on innate predictive mechanisms, such as auditory mechanisms that draw upon the inherent sonic arrangements of pitches, and the temporal integration of these arrangements in short-term memory [34.42–44]. As convincingly shown in [34.25], this already forms a powerful basis for predicting the underlying tonal sense of a musical piece. Of course, it may not predict the specific musical arrangements of a particular piece. After all, the innate mechanisms do not *know* the repertoire. Learning the repertoire is a typical capability of habitual cognitive processing. Other examples can be given in relation to rhythm prediction. There we see that the predictions can be based on particular biomechanical properties of the bodily effectors, such as the propensity for 2 Hz resonances [34.45].

The embodied music cognition approach assumes that predictive schemes tap into the kinaesthetic, tactile, and haptic sensing particularities of the body. Together with the biomechanic constraints of the corporeal effectors of movement (such as legs, arms), the state of arousal, fatigue, and energy characterizes a system that filters the back and forth interaction with the environment. Accordingly, it is assumed that this system has a large impact on the prediction machinery and the prediction outcomes. Anticipation is therefore understood as the expected outcome of bodily mediated perceptions and actions, rather than the expected outcome of some type of direct line from environment to brain. The implication of this insight is far reaching, as suggested in the previous section. For example, it implies that music can no longer be seen as consisting of note-symbol arrangements, because these arrangements are lacking the inherent constraints of real musical patterns. In addition, it implies that the perceived musical structure is itself an outcome of the internal state interacting with the musical patterns. Consider the anticipation of the beat in samba music based on movement states, for instance. This is known to be difficult for Western listeners because samba has an ambiguous binary-ternary structure. *Naveda* and *Leman* [34.46] however, suggest that

> *perception of samba may be movement-based in the sense that through self-movement (of the dancer in response to music) musical patterns become rhythmically disambiguated.*

Through movement states, the perception of binary structure can be emphasized, which facilitates the prediction (see also [34.7]). Or consider the interaction with music through dancing. Based on the induced emotional state, our perception of music changes, and this perception is reflected in our dance expression [34.8, 47]. These studies show that a perception-only approach is no longer defensible. Music interaction is based on action–perception coupling, integrated within the predictive machinery, and above all, tightly integrated with the corporeal mediator constraints.

34.2.2 Emergent Pattern Building

A core aspect of the embodiment theory concerns the reconception of what musical structures are. Music cognition research thereby draws upon emergence as a basic principle of musical structure. Emergence implies processes that use structures and relationships among patterns as ingredients for new types of patterns. Emergence is a formative principle based on patterns at a lower level generating other patterns at a higher level, and this principle is fundamental to the understanding of music. For example, the Western music repertoire with its typical tonal-harmonic system of anticipation and goal-satisfaction can be seen as the result of an emergent process that is based on auditory dispositions (the way the auditory physiology works), environmental dispositions (the type of instruments used, and the fact that these instruments have a harmonic overtone structure), and previous repertoires (acquired through learning). Obviously, there are many additional factors that may mediate the formation of the repertoire, such as beliefs (e.g., the belief that music is a divine art that should display stability, or the other view, that it should display the vibrations and variability of a divine being) that foster the selection and molding of instruments and structures until they lead to a repertoire that, in turn, influences the way in which people habituate towards particular phrasings.

Embodiment draws upon the idea that this emergence is largely influenced by interactions. The focus here is on the added value of interaction in processes that leads to emergent patterns. As these patterns are often hierarchically structured, with lower-level patterns being ingredients of higher-level patterns, perception of these emergent patterns can be guided by move-

ments or actions. The role of actions is related to the attenuation (or filtering) of particular characteristics of emergent patterns, the use of action as a facilitator of particular interaction patterns (such as timing), the disambiguation of complex patterns through movement, and possibilities for motor retraining [34.30]. Emergence is a crucial aspect of the reductive process discussed above, through which complex patterns can be simplified and related to interaction roles.

34.2.3 Enactment

Enactment can be defined as the instance of acting something out. This concept embraces the idea that our corporeal involvement with music is based on acting along with the music, such as during synchronizing footsteps with music, or during the alignment of arm and hand movements along with the musical expressive flow, like in dancing, conducting, and music playing. Enactment can be seen as a musical intentionality induction mechanism. That means that it is a mechanism that turns musical patterns, as they appear to our senses, into goal-directed sonic moving forms, with value and reward. Patterns thus become endowed, and are simplified, by considering them as properties of the states built on an assumption that our predictive machinery makes about these patterns. And this assumption is largely based on the enactment, that is, on processes that ensure the synchronization and alignment of actions with those patterns. Note that enactment involves the engagement of the human action repertoire (to carry out the enactment). This action repertoire is associated with representations about the expected outcomes of these actions. Thus, when actions are carried out, they automatically become associated with representations of action outcomes (also called intentions).

Enactment may be seen as a *method* for realizing an intentional outcome. Basically this means that corporeal interactions determine prediction models for the ongoing and future interactions with music, so that music can be conceived in terms of goals, directions, targets, values, and reward. Embodiment thus provides a basis for updating the predictions of what is anticipated during the interaction with music, and this is a core element of the intentionality induction process; the way in which intentionality with music gets established; the way in which music is conceived in terms of goals, values, and reward.

34.2.4 Expression

Finally, some mention should be made of expression (the act of expressing), or expressiveness (the property of being expressive). Expression is a core feature of musical communication, and one of the key research domains of the embodied music cognition approach in today's research environment. Expression research is a challenge because it is not understood well in cognitive science. However, it is worth mentioning that a good part of the older work in continental musicology was especially focused on musical expression [34.48–52]. Interestingly, in this tradition, musical expression and expressiveness are often approached from the viewpoint of gesture. For example, *Schaeffer* [34.50] discusses sound objects and their association with the actions that might have produced these sounds. Much of the former work was embedded within a phenomenological tradition (e.g., [34.22, 53]), in which concepts such as embodiment, or motility (the capability of moving) were explored from a philosophical and music-analytical point of view. For example, according to *Broeckx* [34.52], music is expressive because music appears to humans as a material organism possessing properties and behaviors. The attribution of expressive properties to music is based on prereflective sensorimotor associations of sound properties with tactile, visual, and muscular and vascular sensations (e.g., flatness, brightness, rolling, tingling) leading to associations with feelings and moods. Moreover, it is inferred that the movement of sound properties engages a kinaesthetic process that results in associations of body movement and gestures.

This musicological tradition can, and rather interestingly, be linked with the current embodied viewpoint on music cognition. The latter thereby provides a refinement of the ontological, epistemological, and methodological framework for understanding musical expression in performance and perception. The main difference is that the current focus of study has an empirical orientation, whereas the earlier focus of study took a music-analytical philosophical orientation. The study of expression, when seen from the viewpoint of embodied music cognition, can be linked with action theories and brain theories that assume (on the basis of empirical evidence) the existence of predictive processing states related to action–perception couplings. Expressive gestures are thereby assumed to tap into innate motor expressive responses that have been integrated with predictive processing states that control expressive habits and learned expressive behaviors. The call for action science [34.15], for example, has a huge advantage because specific hypotheses about expression and aesthetics can be tested within a much larger relevant empirical framework.

34.3 Empirical Evidence for Embodied Music Cognition

We now turn to some of the empirical work that relates to the embodied music cognition paradigm. Our goal is to focus on studies that reveal evidence for embodied music cognition. However, rather than aiming at an exhaustive overview, we confine ourselves here to three core aspects of the research; namely understanding expressive gestures, understanding synchronization and entrainment, and understanding the effects of action on perception [34.54, 55].

34.3.1 Understanding Expressive Gestures

Although gesture research has a long tradition in musicology (see above) and in research on interactive music systems [34.56], it is only recently that attempts have been made to better understand gesture in relation to music [34.11, 18, 19]. The role of gesture can be understood in terms of encoding and decoding of musical expression. Encoding of expressive qualities in music happens during music performance. The gestures that support the encoding are called *expression-supporting* gestures. Decoding of expressive qualities in music happens during listening. The gestures that support the decoding are called *expression-responding* gestures. In both cases it is assumed that expression can somehow be transferred from gesture to music, of from music to gesture. This transfer implies a *mirroring* from qualities of sound patterns to qualities of movement patterns. However, rather than speaking about mirrors, it is more convenient to speak about action opportunities. Gesturing can be seen as an encoding and decoding of expressive affordances, or opportunities for action, to be put into the sound, or to be taken from the sound [34.57, 58]. This viewpoint implies that gestures are supported by actions, and that mirroring is an aspect of the gestural alignment with music. Mirroring indeed suggests a one-to-one relationship between music and gesture, but it may involve counterpoint, and an emphasis of the contrast between music and gesture. Affordances also imply that action opportunities have a goal-directed or intentional character. This means that the associated movements, or gestures, are embedded in a predictive machinery. So far, several studies have been conducted that aimed to find a better understanding of the role of gesturing in musical activities. Most studies are explorative and seek to get to grips with the complexity of the matter. This is indeed a new field in which our understanding of how gestures work in relation to expression, intentionality, and timing is still in its infancy. In what follows, we give a brief overview of some explorations in this domain.

Elementary Gestures, Articulation and Coarticulation

First consider the concept of elementary gesture, which we developed in the context of a study that addressed the playing of the guqin (the old Chinese zither) [34.59–61]. Elementary gestures can be understood as small action units, or articulations, such as moving one finger from one position on a string to another. In the context of wind instruments, an elementary gesture would be the production of one tone. These elementary gestures are needed for sound production but they also contain expressive features. For example, the movement of the finger on the string can be realized through different shades of velocity: speeding up, or slowing down, or having a straight velocity [34.59]. In wind instruments, articulation is defined by a particular tonguing technique, often denoted as *tu*, *du*, *fu*, or *ku* depending on the strength of the attack and the position of the tongue. For example, in the *ku* attack, the tongue moves backwards, rather than forwards, as in *tu*. The interesting issue here is that elementary gestures point to very basic actions that seem to be controlled by a motor impulse (see also [34.62]). Once the impulse is given, the further deployment of the action is a sort of automatism. More complex playing gestures can be understood as concatenations of an alphabet of such short actions, or movement primitives.

Note that the next stage, in which two tones are connected in coarticulation, is immediately more complex [34.63]. It involves the connection of movement primitives, often also in combination with coordinated actions, such as finger movement in the left hand, combined with string plucking in the right hand in the guqin, or a technique in combination with fingering technique in wind instruments. Articulation and coarticulation provide the expressive ingredients of larger expression arcs that define the tension of sound production during a longer term (a few seconds).

Expression Arcs and Musical Intentions

Following on, we consider expression arcs. Research shows that expression arcs are typically supported bodily gestures that accompany intentional states when realizing expressive outcomes. To facilitate that aim, performers seem to rely on a repertoire of expressive-supporting gestures (see also, e.g., [34.64, 65]). For example, in [34.66], it was possible to observe a consistent relationship between a clarinettist's musical expressive-structural analysis (indicating target notes, supporting notes, crescendo, decrescendo) and the clarinettist's gestures that support the playing of these musical pas-

sages according to the planned expressions. The study shows that intentional actions are meant to structure music according to the expressive acting. It means that expressions in music are related to particular targets that are planned ahead and it demonstrates that the musical realization is supported by bodily gestures. Expressive arcs may require accurate timing. *Maes* et al. [34.32] suggest that the accurate timing needed to carry out expressive arcs is based on embodiment. In this study, limb movements were either legato or staccato movements of the arm and hand that controlled the bow of a cello. Legato implies continuous limb movements with no pause in between the onsets of tones, while staccato implies event-based movements with a pause (a nonmovement state) in between the onsets of tones. The results show that legato playing can compensate for disrupting effects of cognitive load on timing production and expression, while staccato playing is affected by these effects, especially at slower tempi. This is probably related to the timer mechanisms involved. The continuous movements allow the outsourcing of timing to a mediator (called embodied timing), while staccato implies nonmovement duration that requires cognitive timing. Given a supplementary cognitive task in addition to playing, the timing of staccato is more affected because it taps into the same cognitive resources as the supplementary cognitive task. In contrast, the timing of legato is less affected because the timing is outsourced to a corporeal mediator that, due to its proper movement constraints and the time needed to realize the movements, provides a clock mechanism that is highly functional. The study therefore supports the idea that a mediator mechanism can provide a timer for expressive performance. Overall, this study is one of the first to show why expressive-supporting gestures are relevant in music performance. The answer the study provides is that these gestures allow the cognitive outsourcing of timing. Attention can then be devoted to other crucial aspects of the expression.

Expressive Gestural Shapes in Relation to Musical Timing

Thirdly, consider gestural shapes in relation to timing. This is of particular relevance in the context of dancing. The type of gestures considered here are generally repetitive and constrained within an overall timing framework imposed by the musical meter. The repetitive character of the gestures suggests that the movement choreography, or movement sequencing, is based on a shape (called the basic shape, or basic gesture), that reoccurs over defined time periods. The overall timing framework imposed by the music suggests that elements of the basic shape are linked with timing. In that context, we investigated two different methods of studying this link [34.28, 29, 46]. One method has a focus on the basic shape and aims at extracting this shape from the movement trajectories. A basic gesture could be defined as the average of several movement trajectories over one single period of the movement. However, due to inherent uncertainties in the neuromotor control, there may be quite some variability in the way in which these movements are timed and shaped. Due to this variability it is not possible to define the basic gesture as the average of repetitive movement trajectories. That would lead to nonrealistic irregular shapes. The best way to obtain this is by using periodicity transformations [34.46], or by building probabilistic models that allow a smooth reconstruction of the movement trajectories [34.67]. Such a model can then be linked with the timing imposed by an external musical source.

The other method has a focus on timing and aims at understanding the connection between shaping and timing by projecting features of the musical timing onto those shapes. This allows for an analysis in terms of point clouds, and spatiotemporal regions showing how the shaping is connected with the timing. Interestingly, it is also possible to plot musical features onto these basic gestures. For example, it is possible to extract the time of the beat and plot a mark of the beat on the gesture at the time that corresponds with the beat. One method is to plot these features onto the basic gesture, while another involves plotting these features onto the entire periodic trajectory. The difference is that the basic gesture provides an average of that trajectory. When musical features are plotted on the entire trajectory, one typically obtains point clouds with musical features. Accordingly, this can be done for different metrical periods (half beat, double beat, and so on). As such, one obtains a spatiotemporal plot of the musical meter onto the gesture. Such graphs show interesting differences between, for example, the Charleston and samba dances, and especially between novices and experts. When applied to different dancers, we see an interesting variability in how humans realize bodily expression in relation to music. Moreover, when dancing, it is likely that different body parts capture different periods related to the musical beat. For example, horizontal sway could occur on two beats in period, while the arms might register one beat in the period, and hands at half the beat period. As such, the human body can reflect the different frequencies present in the musical structure [34.27, 68]. The positions of the beat points may reflect *reference points*, or landmarks, that play a prominent role in the predictive control of the dance. The study on samba dance, for example, provided evidence that dancing may facilitate and disambiguate the perception of music. This is assumed to be based

on predictive mechanisms that involve the suppression of filtering of particular features that can be predicted. Moreover, the activity, as such, accords with the idea that decoding musical expressiveness is a sense-giving activity.

34.3.2 Understanding Synchronization and Entrainment

Research on sensorimotor synchronization is firmly rooted in traditions of studies that focus on the timing of finger tapping in relation to metronome ticks [34.69]. The research has recently been expanded to dancing and music, where similar issues of timing exist [34.70, 71]. Sensorimotor synchronization is deemed to be highly relevant for embodied music cognition. One of the basic ideas here is that the synchronization of movement and music is driven by predictive processes that drive error-correction mechanisms. Errors are perceived deviances between expected action outcomes and the perceived external musical stimulus. There appears to be an internal mechanism that aims at correcting these deviances so that action outcomes optimally match with the musical stimulus. For example, a particular posture in dancing should be reached at a particular timing cue. This synchronization is governed by a dynamic (called entrainment) that aims at minimizing the error between what is anticipated and what is realized.

Note that music–movement entrainment is quite a complicated timing phenomenon, involving constraints of the corporeal (and even technological) mediators in the entrainment setup [34.31, 72]. One of these constraints is related to resonance. Starting with a tapping study, *Van Noorden* and *Moelants* [34.73] found a resonance frequency (or embodied eigenfrequency) around 2 Hz. Later on, this *eigen-frequency* phenomenon was observed in several studies on walking, such as in [34.45, 74]. An interesting result has been obtained in a study that provides direct evidence for a vigor-entrainment effect [34.74]. In this study, subjects were instructed to walk in synchrony with musical excerpts that had the same tempo but different musical expression. The speed of walking is determined by two parameters; namely, the pace (step frequency) and the stride length, and the pace is fixed due to the synchronization with the music. Therefore, the only parameter that could influence the speed is the stride length, which is an effect of the muscle strength. The study showed that some music has an activating effect, stimulating subjects to walk faster, while other music has a relaxing effect, stimulating subjects to walk slower, while metronome ticks (and many other types of music) have no effect. Interestingly, the adaptation of muscle strength to music depends on the expressive characteristics of the music. These can be defined in terms of acoustical features, showing that binary and ternary arrangements in music play an important role.

Social entrainment, or the adaptation of human movement to other humans while listening and producing music, has been studied in several contexts. *Van Dyck* et al. [34.70] asked subjects to dance to music. They found a group effect for activity count and tempo entrainment when people danced in groups of five. [34.75] is based on an experiment with more than 400 children who, in groups of four, had to continue the example of an avatar that tapped along with the beat of the music. Several tempi were tested, showing that children have a 2 Hz resonance in their propensity for tapping. The results suggest that the perception and production of the pulse is related to the control of the human body, cognitive development (age), and the ability to control timing either by counting or by using outsourced embodied timer mediators. Moreover, the analysis shows a social entrainment effect in the sense that the social group, in addition to the musical stimulus, also entrains children and provokes their excitement so that they start to invent variations on their tapping rhythm. Synchronization and entrainment is a field of study that provides strong evidence in favor of the embodied music cognition paradigm.

34.3.3 Understanding Effects of Actions on Music Perception

Finally, it is of interest to consider embodiment from the viewpoint of the coupling of action and perception. Research thereby focuses on how action influences perception, as well as how perception, thanks to its close association with action, can influence action. The latter may be of relevance, for example, in motor rehabilitation where music is used to retrain maladapted motor habits. Studies that explicitly address action–perception couplings are highly relevant for the embodiment theory because they somehow provide direct proof of the role of embodiment in music perception. A crucial concept in our understanding of action–perception couplings is that of internal sensorimotor predictive models; in short, internal models. There is accumulating evidence that the sensory (e.g., auditory, visual, etc.) predictions made by these models influence the online processing of sensory information, such as music, emerging from the external environment [34.8, 76–78]. The particular influence of these predictions on the perception of music differs depending on the nature of the auditory information (when merely listening to music), or audio-visual information (when watching and listening to a music performance, for instance). *Maes* et al. [34.30] provide an overview of the recent studies

that consider the effects of actions on music perception. One of the effects of internal models is that perception becomes attenuated when the incoming sensory information matches the sensory prediction, while perception is facilitated when sensory input is incoherent with the sensory prediction. Also, when sensory input is ambiguous in nature, body movements and the related sensory predictions enable it to disambiguate incoming sensory information. Additionally, it has been shown that when moving to music, structural and affective properties inherent to the body's movements become attributed to the music. *Maes* et al. [34.30] refer to the concepts of *selective attention*, and *cue selection/identification* to explain how body movements performed to music may direct attention towards specific cues in the music. It is argued that the mechanisms described by these concepts can steer people's perception of structural features in the music (e.g., melody, beat, pitch, etc.) in a specific direction (as shown in [34.6, 7]). *Maes* and *Leman* [34.8] showed that expressive body movements can condition children's perception of musical expressiveness. In the experiment, children were conditioned with a happy or a sad choreography in response to music that had an expressively ambiguous character. Afterwards, the children's perception of musical expressiveness in terms of valence and arousal was assessed. The results suggest that the expressive qualities of the movements they learned to associate with the music had a significant impact on how children perceived musical expressiveness.

Of particular interest are studies that address the effect of emotions on music-driven movements. In [34.79], the effect of two basic emotions, happiness and sadness, on dance movement was examined. Participants were induced to feel emotional states of either happiness or sadness and then danced intuitively to an emotionally neutral piece of music, composed specifically for the experiment. The results revealed that when induced with happiness, participants moved faster, with more acceleration, and made more expanded and more impulsive movements than in the condition with sadness induced. In [34.47], it was investigated whether the induced emotion could be successfully decoded from movements (without music as extra stimulus). Observers watched a set of silent videos showing depersonalized avatars of dancers moving to an emotionally neutral musical stimulus after emotions of either sadness or happiness had been induced. Results revealed that observers were able to identify the emotional state of the dancers with a high degree of accuracy.

34.4 Embodiment and Dynamic Cognition

Based on the above selective overview, we can distinguish two important trends that mark current embodied music cognition research. The first trend is to consider musical activity as the outcome of a network of mutually interdependent sensory, motor, and affective processes [34.54]. These processes define the overall state of a person's activity involved with music. Predictive processing plays an important role in the control of these processes. In that context, perception and action are no longer seen as separate processes, but as mutually reinforcing processes that subsume predictive processing in connection with bodily states. However, the road to fully understanding the underlying mechanisms, in particular concerning the origin (innate/learned) and development (e.g., association learning, contingency, contiguity, etc.) of these associations is long. A major challenge concerns the understanding of expression in relation to this network of mutually interdependent processes. Expression can be conceived as a facilitator of the interaction among these processes but more work is needed to fully comprehend how this works. The second trend is that music cognition is being defined in terms of interactive dynamics, in which concepts such as emergence, affordance, and dispositions define states (e.g., homeostasis) and processes (e.g., error-correction mechanisms) of the dynamics. Emergence and affordance, for example, appear as interaction outcomes and interaction opportunities. They offer a new way of viewing music as the outcome of a person–environment interaction, in which particular constraints in the environment and in the mediators are controlled and adjusted in functions of particular outcomes. Accordingly, music perception should be understood as a phenomenon that emerges from the dynamic interaction of many intertwined processes evolving over time. Embodied music cognition theory draws upon a dynamical theory of music cognition in which the interaction between the various sensorimotor, affective, and cognitive systems (attention, memory, metaknowledge, etc.) and the external environment are of crucial importance.

34.5 Contributions to a Paradigm Shift in Systematic Musicology

We believe that embodied music cognition research has become an important paradigm for music research. The role of bodily involvement is no longer questioned and the empirical methodology has been expanded to quite a broad domain of musical activities. The strength of the paradigm is that it builds on a solid empirical and modeling framework. The weakness of the paradigm is that it may need further elaboration to meet historical and cultural contextualization. In recent years, the paradigm of embodied music cognition has been embraced and filtered into the following directions. Firstly, in the methodology, studies have contributed to an expansion of the existing methods. New observation devices (e.g., all kinds of sensors and camera systems) and analysis methods (e.g., multivariate, and functional data analyses) have been refined and introduced. These methods have been combined with new approaches in audio analysis, which draw upon massive feature extraction and subsequent machine learning methods [34.80]. In addition, subjective methodologies (e.g., questionnaires that probe flow or presence) have been fine-tuned and linked with performer-inspired analysis methods [34.66] and with educational technologies [34.81]. In general, the methods that are inter- and cross-disciplinary have greatly improved compared to the state-of-the-art music research of a decade ago. New user-oriented approaches have been developed in the direction of person-centered approaches in a cross-disciplinary context of collaboration with other research groups and institutions (e.g., health care institutions) [34.82]. Secondly, the ontological assumptions and the associated epistemology have been refined by expanding the traditional viewpoints (e.g., [34.83, 84]) in the direction of an enactive approach. Last but not least, the paradigm received much attention thanks to the idea that practical tools (based on interaction) contribute much to the development of the new paradigm [34.81, 85–91]. This approach may be rather new in the field of musicology, although it draws upon a certain tradition that was associated with music cognition research [34.56]. Tools offer a means by which intervention can be made into the action–perception cycle. By contributing to the theoretical development therefore, they coerce the researcher into focusing on the principles that lie behind those tools. Success in developing concrete tools can serve as a future measuring instrument used to explore the power of the paradigm of embodied music cognition. In that sense, the issue of embodied music cognition versus nonembodied music cognition is not only a matter of epistemology (and trying to discover the realities about how music interaction works) but is also a matter of practical application. Recent work clearly indicates that the embodied approach to music cognition may lead to useful knowledge about music interaction, in fields such as music education, music recreation, and even physical rehabilitation.

The paradigm of embodied music cognition has stimulated developments in cultural contextualization studies. Several recent studies (e.g., [34.92–96]) draw upon concepts and results from embodied music cognition, such as gesture analysis, analysis of entrainment in concrete musical performances, the role of music in relation to empathy, and several issues in action–perception couplings. On the one hand, these studies point to issues that may require further in-depth laboratory research. On the other hand, finding a good trade-off between laboratory findings and a profound cultural study is still a challenge. In any case, this mutual influence of cultural musicology and systematic musicology is very promising for both disciplines. More profound cultural contextualization, as well as historical contextualization, certainly injects added value into the paradigm of embodied music cognition.

34.6 Conclusion

In this chapter we provided an overall viewpoint on embodied music cognition, addressing questions related to the nature, assumptions, findings, and perspectives of the paradigm. We thereby addressed the ontological and epistemological assumptions and provided a specification of the cognitive architecture in relation to embodiment. The result is a perspective that greatly capitalizes on the framework of the (classical) music cognition research approach. However, as argued, the embodied approach is much more oriented towards pragmatism, dynamics, and interaction. The focus on *cognition in perception* has been replaced by a focus on *cognition in interaction*, of which perception research is a part. Based on an overview of recent studies, many of which are studies sourced from our own laboratory, we aimed at providing research topics and research outcomes that illustrate the development of the approach. Along that way, we identified the trend towards an in-depth exploration of the concept of embodiment in terms of sensorimotor processing and concrete proof

of the necessity for the embodied viewpoint, and the trend towards a broadening of the concept of embodiment in the direction of sister disciplines. These trends fit quite well with the accumulating evidence in favor of the embodied approach. This partners well with the exploration of novel methods for observation and analysis, adopting a pragmatic approach to music interaction, and exposing a high level of interest in the development of tools that make the theoretical views applicable in domains such as music education, sports and recreation, and rehabilitation and wellbeing. Overall, this overview provides a strong incentive for further research, especially in the direction of expressive interactions with music [34.97, 98].

35. Sonic Object Cognition

Rolf Inge Godøy

We evidently have features at different timescales in music, ranging from the sub-millisecond timescale of single vibrations to the timescale of a couple of hundred milliseconds, manifesting perceptually salient features such as pitch, loudness, timbre, and various transients. At the larger timescales of several hundred milliseconds, we have features such as the overall dynamic and timbral envelopes of sonic events, and at slightly larger timescales, also of various rhythmic, textural, melodic, and harmonic patterns. And at still larger timescales, we have phrases, sections, and whole works of music, often lasting several minutes, and in some cases, even hours.

Features at these different timescales all contribute to our experience of music, however the focus in the present chapter is on the salient features of what has been called *sonic objects*, meaning on holistically perceived chunks of musical sound in the very approximately 0.5—5 s duration range. A number of known constraints in the production and perception of musical sound as well as in human behavior and perception in general, seem to converge in designating this timescale as crucial for our experience of music.

The aim of this chapter is then to try to understand how sequentially unfolding and ephemeral sound and sound-related body motion can somehow be transformed in our minds to sonic objects.

35.1 Object Focus

The aim of this chapter is to present theories and tools for research on what we call *sonic objects*. The term *sonic object* can be defined as a fragment of musical sound, typically in the approximately 0.5—5 s duration range, a fragment perceived holistically as a coherent and somehow meaningful unit. A sonic object is arguably the most basic unit in musical experience, capable of making a rich set of perceptually salient sonic and multimodal features present in our minds.

A sonic object may encompass a single tone or chord, a short phrase of several tones and/or chords in succession, a single sound event (e.g., of hitting a tamtam, of slamming a door, of breaking a bottle), or a more composite but still holistically perceived sound event (e.g., a rapid glissando on a harp or on a washboard, a burst of marbles rolling out onto the floor, a whirl of dry leaves in the wind). The duration limits of a sonic object are determined at one end by the minimal duration necessary to perceive salient features and at the other end by a maximal duration for perceiving the object as a singular and coherent entity, i. e., as not readily divisible into smaller parts.

The term *object* here serves to emphasize the perception of a sound fragment as a coherent entity,

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_35

as something present in our minds in an instant, in a *now-point*, to borrow the expression from *Edmund Husserl* [35.1–3], although sound is something that unfolds in time. How sequentially unfolding sound is transformed into somehow more solid auditory objects in our minds seems still to be largely enigmatic [35.4], however, the point of departure in this chapter is that such *flux-to-solid* transformations evidently do take place in auditory perception and that we may indeed denote salient auditory features by way of object-related concepts and metaphors. Focusing on the *cognition* of sonic objects means trying to provide tools for exploring perceptually salient features of sonic objects in music-related research and in practical contexts for composers, musicians and producers; in short, for anyone working with musical sound.

The idea of sonic objects is generally ascribed to the seminal work of *Pierre Schaeffer* et al. in the 1950s and 1960s and as emerging from practical work in electroacoustic composition of the so-called *musique concrète* [35.5–7]. Before the advent of tape recorders, composers would record sound fragments as loops on phonograph discs, enabling the mixing of sounds by lowering and raising the pickup arm, effectively turning any sound fragment on and off in a mix. Such a loop was called *closed groove* (*sillon fermé*) and when Schaeffer et al. listened to such loops innumerable times, they discovered that their perception of these sound fragments changed, that they tended to shift their attention towards more internal and subtle features of the sound itself, away from the original and more everyday and anecdotal significations of the sound fragments. They called this shifting of attention *reduced listening* (*écoute réduite*), signifying a shift toward perceptually salient sonic features, a shift of focus that eventually lead to a very extensive theory of sonic objects in *Schaeffer*'s monumental *Traité des objets musicaux* [35.5] and related publications [35.6, 7].

This origin is remarkable in that an extensive music theory grew out of practical composition work, and notably out of a radically new way of sound-based composition, very different from traditional note-based Western composition practice. This departure from Western music tradition drove the effort to make a more general and universally applicable music theory, based on a seemingly naïve questioning of the subjective listening experience, a kind of Socratic method of trying to distinguish the various perceptually salient features in auditory experience. This approach permeates the entire project of developing a new music theory and may be termed a *top-down* approach where the point of departure is the overall shapes of any sound, what we could call its *envelopes*, with regards to loudness, pitch features and timbral features and then successively differentiating more and more subfeatures of these main features (e.g., the distribution in time and spectrum of the energy, the amplitude and rate, regularity versus irregularity, of changes in these distributions, etc.) and then, sub-subfeatures of these, etc., progressively exploring more and more details in the sonic objects. It was only at a later stage that *Schaeffer* et al. realized the affinity of this method with classical phenomenological approaches to perception (referring to Husserl and Merleau-Ponty) of taking the subjective mental images of sound as point of departure for investigations, leading *Schaeffer* to remark that they were indeed *doing phenomenology without realizing it* [35.5, p. 262].

The next step of this research program was then seen as establishing *correlations* between the subjective features and the acoustic substrates of the sound, a long-term endeavor that needed to take into account the many nonlinear relationships between the physical signals and the subjective percepts, relationships that were characterized by *anamorphosis*, or *warping*. It should be remembered that psychoacoustics as we know it today was quite different in the 1950s and 1960s when Schaeffer et al. developed their theories and that research in this area was dominated by a more *scientistic* attitude as *Michel Chion* has put it [35.7, p. 30], of regarding human auditory perception as flawed, unreliable and often distorting the *real* features of sound. The attitude of Schaeffer et al. was quite different in naming subjective perception of sound the most important tool for research, as the point of departure for extensive and systematic explorations of musical sound, and only at a later stage going on to map out the correlations between subjective perception and the acoustic signals.

The term *cognition* in the title of this chapter implies a focus on the perceptual output of any sound-producing process, be that in sound synthesis, effects processing, composition, improvisation, or any kind of instrumental or vocal performance. The idea of sonic object cognition is also linked with the method of *analysis-by-synthesis*, meaning exploring something by active creation (and/or imagining) of incrementally different variants in view of finding out what the perceptually salient features (or ingredients) of any sonic object are. Lucidly presented by *J.-C. Risset* as a strategy for exploring timbral features in digital sound synthesis [35.8], this was actually also a strategy of Schaeffer et al. in exploring the contribution of different feature dimensions to the overall subjective impressions of sonic objects (for an instructive example of this, listen to [35.6, CD 2, tracks 90–95]). In other words, the idea of sonic object cognition here denotes a two-stage process of first trying to differentiate (and give names to) what seem to be subjectively salient features of

a sonic object and then produce, or imagine, a number of variants of this sonic object where these features are somehow incrementally varied, so as to enable systematic testing of the effect of these features in subjective experience.

In short, sonic object cognition encompasses the capacity to think analytically and practically about fragments of sound in musical contexts and should aspire to combine insights from classical work (e.g., from composition and orchestration) with recent findings (e.g., from musical acoustics, music technology and music perception areas). With such a multitude of elements converging on sonic object cognition, we shall in this chapter first elaborate more on what is meant by the expression *sonic object*, try to demarcate what it is and what it is not, with some considerations of ontology: sonic objects are evidently associated with our experiences of sound, but sound is ephemeral, manifest here and now before vanishing, yet we fortunately usually have some memory trace of what we just heard. Are sonic objects then just as much mental images and in that case, what is the content of such mental images? One answer that has emerged from our own and others' research is that images of sonic objects are closely associated with images of body motion, so we shall then take a look at what is called *motor theory*, as well as associated issues of timescales and duration thresholds in musical experience. This leads to questions of how sonic objects emerge from musical experience by *chunking*, as well as how they are generated and classified. On this background, the remaining sections of this chapter shall focus on features of sonic objects as well as on how we may explore such features by the above-mentioned analysis-by-synthesis strategy, before some reflections on prospects and challenges of research on sonic object cognition.

35.2 Ontologies

Sonic objects, defined as fragments of musical sound in the approximately 0.5–5 s duration range, will in most cases have multiple significations and multiple features, i. e., be several things at once. To enhance our knowledge of sonic objects, as well as to avoid misunderstandings, we need to clarify *what-is-what*, or clarify the *ontologies*, of sonic objects. As a first step, we may take a look at Schaeffer's analysis of listening, an analysis that is the basis for the subsequent ontological differentiations of sonic objects. Briefly stated, Schaeffer distinguished four components in listening (see [35.9, pp. 129–133], for a more extensive presentation):

1. *Listen* (*écouter*), which denotes the basic capacity for discerning different sounds in our environment.
2. *Hear* (*ouïr*), i. e., the basic physiological capacity for sensing sound.
3. *Hark* (*entendre*), meaning the intentional focus on some sound(s).
4. *Understand* (*comprendre*), denoting the transition from basic listening to understanding the significations of the sounds.

In everyday situations, these four components may variably be active or not, e.g., if I hear the squeaking of a door when I am expecting a visitor, I would understand this sound as indicating the arrival of my visitor and probably not be so much interested in the sonic features of the squeak. But being sensitive to such squeaking noises, I could direct my attention towards the squeak, making a note that I should lubricate the hinges to get rid of the squeak, or I could even be intrigued by the brass instrument-like timbral features of the squeak, its pitch and dynamical envelope; in short, start to focus on the squeak as a sonic object. Shifting my attention away from the contextual and/or causal signification of the squeak to its sonic features, is typically an act of the *reduced listening* mentioned earlier.

Furthermore, that we, in the case of electroacoustic music as well as in several other listening situations, only hear the sound and don't see the source of the sound, was by Schaeffer called *acousmatic listening*, alluding to the account of Pythagoras allegedly hiding behind a screen when teaching so that his pupils should not be distract by seeing him. The principle of acousmatic experience signifies a general divide between the production and the perception of musical sound, encouraging us to focus on the actually perceived features and to disregard whatever generative scheme is behind the sounds that we hear.

This divide between production and perception could also be seen as a critique of some prominent 20th century Western music that advocated generative schemes (e.g., dodecaphony, integral serialism, various algorithmic composition schemes and also more recent sonification schemes). It could be generalized to a model consisting of a *control space* and a *morphology space* as was suggested by *morphodynamical* theory [35.9–11]. The control space is concerned with the control variables input to any generative process, e.g., the oscillator frequencies, amplitudes, envelope

shapes and modulation index in a frequency modulation (FM) synthesis model, and the morphology space is concerned with the perceptual output of any model, e.g., the timbral output of the FM synthesis model. As anyone familiar with FM synthesis probably has experienced, there may sometimes be a linear, seemingly coherent relationship between the input variables and the perceived output features, however, there may also often be a nonlinear relationship between incremental changes in control input values and perceived changes in output features, e.g., that small input value changes may result in disproportionately large and seemingly uncorrelated changes in output features.

Such discrepancies between changes in control input and perceived output may be a general risk when transferring features from one domain to another: it is not obvious that we readily perceive the relationships between any two domains, e.g., when sonifying visual or numerical information [35.12]. Such discrepancies of input and output are then a matter of mistaken ontological identity, encountered in various Western 20th century compositional schemes when an ordering scheme from one domain is uncritically transferred to another domain [35.9], and may be generalized as mistaken *mappings*. Being careful in making perceptually pertinent mappings is one of the main issues of interactive sonic design and of new instruments of musical expression [35.13], and such mappings should be based on careful analysis of the salient perceptual feature dimensions involved in sonic objects, not on more abstract numerical relationships.

Furthermore, given the acousmatic principle of disregarding the source of any sonic object, the next stage becomes an ontological analysis of the sonic object as such. First, we can list what Schaeffer indicated that the sonic object is *not* [35.7, pp. 34–35]:

- The sonic object is not the sounding body.
- The sonic object is not the physical signal.
- The sonic object is not a fragment of a recording.
- The sonic object is not a symbol notated in a score.
- The sonic object is not a state of the mind.

Furthermore, Schaeffer made an extensive differentiation of salient features that may be present in parallel in sonic objects (more on this later), noting that our intentional focus may wander from one feature or set of features to another feature or set of features, thus making it difficult or even futile to try to pin down exactly what a sonic object might be at any moment. *Schaeffer*'s conclusion after various ontological considerations and differentiations was that the sonic object is an *intentional unit*, meaning that it has several aspects, both sequentially and in parallel, that are kept together in our minds by our active mental focus [35.5, p. 263].

In the decades after the publication of Schaeffer's *Traité* in 1966, various psychoacoustic and neurocognitive research has focused on what we could broadly call *auditory object perception*. Work on so-called *auditory scene analysis* [35.14] has demonstrated a number of low-level signal features that contribute to our perceptual judgments of sonic objects, such as spectral coherence and qualitative discontinuities, documenting the effects of various gestalt principles, as well as the interaction of these low-level features with more high-level schema-based factors in our ability to discern sonic objects in listening [35.15]. Other recent neurophysiological research seems to confirm the basic gestalt-related principle of so-called *exclusive allocation* [35.16], suggesting similarities with visual domain object criteria, something that is also pursued in mapping out the different brain processes assumed to be involved here, as well as suggesting that there are cross-modal elements at work in auditory object perception [35.4]. This last point is of particular interest to our subsequent sections of multimodal features of sonic objects, in particular body motion and haptic features that clearly help us to grasp the ephemeral features of sound as more solid objects in our minds.

This research on auditory objects may be summarized as concerning the question of *coherence* in auditory perception and as also suggesting that there are both similarities and links between the different sense modalities at work here. Although there are still many unanswered questions, one candidate for such sonic object coherence is the motor schemas involved in auditory perception, an idea that has been much in focus in the so-called *motor theory of perception* and which will be an important element in the present chapter.

35.3 Motor Theory

The gist of the motor theory of perception is that we mentally (and sometimes even overtly) simulate body motion associated with whatever it is that we are perceiving, e.g., that when we hear ferocious drumming we mentally simulate energetic hand motion, or when we hear soft string music, we mentally simulate slow protracted bowing.

In our context of sonic object cognition and Schaeffer's research strategy of disregarding sources and ordinary significance, it is also clear that Schaeffer's

strategy does not exclude a motor theory approach to how we perceive and classify sonic objects [35.17]. The point of motor theory is that sensations of body motion and postures are fundamental and ubiquitous in human cognition, hence also is the basis for sonic object perception, meaning that sonic objects may be perceived in terms of body motion and body posture schemas and not only as *pure sound*.

There are several links between sound and motion in music and we have in the past decades seen a growing number of research projects and publications in this area (see Chap. 38 this volume, and [35.18] for overviews). We have in the past decades also seen a general trend in the direction of understanding body motion as essential in most areas of human cognition [35.19], such as in social contexts [35.20] and also in abstract thought [35.21]. Motor cognition may be seen as integral to several modalities, e.g., in vision with active simulated tracing of what we are seeing [35.22], or in hearing with active simulation of the sound-producing vocal apparatus motion as suggested by the motor theory in linguistics [35.23, 24]. The motor theory perspective has been progressively better supported with the arrival of so-called noninvasive brain observation methods [35.25–27]. Also various behavioral studies have clearly demonstrated the strong links between body motion and sound perception, e.g., the effects of seeing lip motion on the perceived sound in the so-called *McGurk effect* [35.28].

What is essential here is the overall energy and motion trajectory images associated with sonic objects, meaning that such images are generic and transferable from one sound source to another as long as the overall envelopes are reasonably similar. This is the deeper and more general understanding of the reduced listening: departing from the everyday and anecdotal source and signification (e.g., crashing car, breaking twig, marble tumbling down a staircase, etc.) to a more generic energy-trajectory envelope [35.17].

The basis for mental presence of the sonic object could be called *motor-mimetic cognition* [35.29–31]. The idea of motor-mimetic cognition is that any feature of sound, and of musical experience in general, can be traced as a shape. This is a strong version of motor theory and one that can be used here to explore features of sonic objects. Specifically, we see this motor-mimetic behavior in sound imitating activities, such as in onomatopoeias and in *beatboxing*, *scat singing*, but also clearly evident in so-called *air instrument performance*, where people with little or no musical training seem to be able to simulate sound-producing body motion [35.32] and in so-called *sound-tracing*, where people are asked to trace the body motion shape they believe best reflect salient features of sonic objects they are hearing [35.33].

We have various kinds of music-specific body motion, all of which may variably contribute to the motor images of sonic objects; body motion that may be categorized as follows [35.18]:

- *Sound-producing* body motion. This includes various kinds of *excitatory motion* such as hitting, stroking, bowing and blowing, as well as *modulatory motion* that modifies the sound, such as the left hand motion on string instruments, the closing and opening of mutes on brass instruments, etc. In addition, various kinds of so-called *ancillary motion* belong in this main category: motion that is not strictly sound-producing but still necessary in order to avoid fatigue or strain injury, or to help shaping the musical expression and also *communicative motion* in relation to fellow musicians or the audience.
- *Sound-accompanying* body motion. This includes dancing, walking, gesticulating, tracing, etc., often reflecting sound-producing body motion, but often more vaguely the energy and affect suggested by the musical sound.

Also, there are a number of more global, i. e., nonlocal, music-related body motion sensations, such as calm–agitated, fast–slow, smooth–rugged, regular–irregular, etc., where there are also often correlations with affective features. Hence, we should next consider some elements of timescales and duration thresholds in relation to sonic objects.

35.4 Timescales and Duration Thresholds

It is well known that we have a timescale range from approximately 20–20 000 events per second for perceiving pitch as well as stationary timbral and loudness features of sounds [35.34]. In our context of sonic objects, the sub-20 Hz region is of particular interest, as this is where we have the nuances and fluctuations of pitch, loudness and timbre, including microtextural elements such as trills and tremolos, as well as various slower elements such as envelopes of pitch, timbre and loudness of tones, and sensations of motion (gait) and rhythmical and melodic patterns.

Also in the sub-20 Hz region we have feature duration thresholds, meaning how long an excerpt we have to hear in order to get some impression of salient

features. It has been suggested that we may perceive salient features of sound in fragments as short as 350 ms [35.35], but for other musical features such as rhythmical, melodic and harmonic patterns, we have to hear longer fragments, i. e., approaching the upper limit for sonic object duration of approximately 5 s. The question then becomes that of trying to see what is *inherent* in the sound as necessary minimum duration for the recognition of salient features and what is more a matter of the peculiarities of our perceptual and cognitive processing. Hence, we should try to determine duration thresholds from two points of view:

1. That which captures most salient information, i. e., neither too short nor too long, e.g., sufficiently long for perceiving salient basic dynamic, pitch-related and timbral features, as well as more high-level features of rhythm, texture, melody, harmony, style, genre, sense of gait and affect, but not so long as to seem being redundantly repetitious.
2. That which is intrinsically in accordance with our cognitive constraints and/or predispositions. This includes what are typical human action durations, optimal durations in motor control, durations of short-term memory stores and of attention spans and timescales for awareness.

Both points of view seem to be relevant and they sometimes seem to converge with respect to duration, perhaps by adjustment of salient information timescales in human communication with ecological attention timescales, as suggested by *Ernst Pöppel* [35.36]. What seems to be clear is that we have rather different qualitative features at different timescales, and for this reason we have in our own research on sonic objects and music-related body motion applied the following main timescale categories:

- *Micro timescale*, typically in the sub-0.5 s range and including continuous and quasistationary features such as pitch, dynamics and stationary timbral features. At this timescale, we may also have some fast fluctuations in the sound such as rapid tremolos and trills, what we shall with Schaeffer call *grain*.
- *Meso timescale*, typically in the 0.5–5 s range, encompassing whole sonic objects. This timescale includes most salient musical features such as rhythmical, textural, melodic, timbral, etc. patterns, readily enabling identification of genre, style, sense of gait and affect.
- *Macro timescale*, typically in the above-5 s range, including whole phrases, sections and movements and usually consisting of concatenations of sonic objects of the meso timescale. The macro timescale is also that of narratives or dramaturgy, however, it seems not to be so well researched in terms of actual perceptual features.

One crucial feature of the meso timescale is that sequences of elements (tones, sounds) at this timescale give rise to sonic objects with qualitative new features not present at smaller timescales, e.g., a melodic contour is present at the meso timescale as a sonic object because it is *present as one extended and coherent object with a shape and not primarily as a sequence of individual tones*. Similarly, body motion at this meso timescale is also readily perceived and conceived as forming coherent motion objects with shapes, and details of such object formation are found in the topic of chunking.

35.5 Chunking

We may think of music as a continuous stream of auditory, visual, proprioceptive, haptic, etc. sensations, yet it seems that we make sense of such streams by segmenting them into somehow meaningful units, into what we call *chunks*. This process of chunking is the basis for the perception of sonic objects, hence one of the main topics in this chapter. Chunking here means not just a segmentation of a continuous stream, but also a *transformation* of otherwise sequential events or entities into qualitative new and larger units, making the formerly single events/entities totally fuse, or *disappear*, into the new chunk unit in the sense of belonging exclusively to this new unit by the so-called *exclusive allocation* principle of gestalt theory [35.14].

There are two main approaches to chunking in music, *endogenous* and *exogenous* [35.37]:

- *Endogenous chunking* is based on qualitative discontinuities in the signal such as that between sound and silence, between different pitches, timbres or levels of loudness or various repeated patterns, e.g., metrical, melodic or harmonic. Yet this may not always work, either because of insufficient discontinuities, e.g., protracted and unchanging or slowly changing sounds, or because of competing discontinuities, e.g., in a series of staccato tones alternating between sound and silence, necessitating the projection of endogenous chunking schemas onto the sounds.

- *Exogenous chunking* is based on the projection of schemas onto what we perceive, schemas based on what we have acquired in previous experience and in particular, various motor schemas acquired from experiences of sound and motion production.

In cases of exogenous chunking, i. e., when applying schemas from previous experience onto sensory input, we can see that such schemas are often constraint-based in their origin. We should thus consider some constraints at work in traditional (i. e., pre-electronic) means for sound production. This includes various features of the instrument and room acoustics (reverberation) that may shape our experience of chunks, e.g., by incomplete damping of sounds resulting in a smearing that glues otherwise distinct sonic events together in qualitative new and larger chunks. But we also have constraint-based chunking originating in our organism, both of attention [35.36], and related to motor control [35.38, 39]. Specifically, we have the following chunk-inducing constraints in musical performance:

- *Phase transition*: There are thresholds of grouping dependent on duration and rate of events [35.40], typically causing singular events to fuse into higher-level units with increase in event rate (e.g., singular impulses fuse into a tremolo with acceleration). Conversely, units may split into lower-level units with decrease in event rate (e.g., a tremolo split into a series of impulses with deceleration).
- *Coarticulation*: The contextual fusion of otherwise distinct motion and sound by the effector (finger, hand, arm, vocal apparatus) always being in a context of having just made some sound and is about to make another sound in the immediate future and that there is a corresponding contextual smearing of the resultant sound because of incomplete damping between the sound events [35.41].
- *Goal points*: That human motion control is goal directed [35.42], typically resulting in so-called *key-postures* at salient moments in time, i. e., at downbeats and other accented points in the music, resulting in chunks being centered on these goal points [35.43].

It seems that various research converges in documenting motion chunking in human behavior in general and rhythmic gestalts in particular [35.39]. As noted by *Klapp* et al. in connection with polyrhythmic patterns [35.44, p. 318]:

> *The limitation to only one motor Gestalt may be analogous to limits that arise with visual patterns such as the Necker cube. That figure can be perceived in only one of its configurations at any given instant. In either configuration, however, all of the lines of the cube are perceived simultaneously as one pattern. Thus, the Gestalt is not restricted in terms of the number of lines that can be perceived. Instead, the limit is that only one organization can be activated. Similarly, the limit in concurrent motor actions is assumed not to lie in the number of muscles that can be controlled, but, instead, the limit is that only one action pattern can be active.*

In other words, it seems that even rather complex patterns of motion may be conceived and perceived as a chunk in motor control.

In summary, we may conclude that sonic objects represent the convergence of chunking factors from the signal (constraints and qualitative discontinuities in both sound and motion), the sense of motion (internal sense of effort and proprioception, i. e., action gestalts, goal points, coarticulation, phase transitions, etc.) and attention constraints; hence, the convergence of both the exogenous and the endogenous factors of chunking in musical experience.

35.6 Sound Generation

In the beginning of the *musique concrète*, the sound fragments used were typically so-called *found objects*, meaning ready-made fragments of sound from the environment, (human, animal, mechanical, etc., but also from more conventional instrumental or vocal sources), hardly processed beyond the initial cutting before the subsequent concatenations into musical compositions. As for the boundaries (i. e., start and stop points) of these fragments, Schaeffer noted that these could be either *natural* in the sense of occurring at some qualitative discontinuity in the sound, e.g., between sound and silence, or they could be *artificial* in the sense of being cut out of a context. In the latter case, the effect of the cutting would in turn become an integral part of the sonic object, e.g., as a steep attack on an otherwise smooth, sustained sound.

Although the acousmatic attitude and the strategy of reduced listening encourages us to focus on intrinsic perceptual features of sound, we know that such fea-

tures are often the result of peculiarities of the sound source. We should then also consider some aspects of sound generation in general, including more traditional instrumental and vocal sound generation as well as sound synthesis and processing, which contribute to our perception of sonic objects. As suggested by auditory scene analysis research [35.14], we tend to perceive sounds as emanating from a source because of spectrotemporal coherence, i. e., that the spectral components tend to fuse into one sonic object because of low-level gestalt principles such as synchrony of onsets and motion of partials. Yet also, there are cases when schemas from past experience come into play in identifying sound sources, i. e., where there is great spectral variation over the entire pitch range and different playing modes of an instrument (e.g., the full range of a piano), yet where the instrument is usually perceived as *the same* in spite of such significant differences.

Also, we should remember that motor theory suggests that production schemas are projected onto what we hear, largely independent of the source and it may be argued that this also applies to acousmatic listening [35.17]. The point is that motor theory in general applies to any perceptual feature by its relation to body motion kinematics, haptics, proprioception and effort, something that was in fact suggested also by Schaeffer in the three basic dynamic envelopes of sonic objects, regardless of source:

1. *Sustained*: Continuous transfer of energy from the body to the instrument such as in bowing or blowing, resulting in a more or less stable and continuous sound.
2. *Impulsive* A spike or sudden peak of effort such as in hitting or kicking, resulting in a sudden attack in the sound followed by a longer or shorter decay.
3. *Iterative*: A rapid back and forth motion as in a tremolo or a trill, resulting in fast ripple-like features in the sound.

These main categories of sound-producing motion and the corresponding resultant sounds are subject to phase transitions dependent on rate and duration of the events: shortening a sustained motion turns it into a impulsive motion, and conversely, lengthening an impulsive motion turns it into a sustained motion, and slowing down an iterative motion turns it into a series of impulsive motions, etc.

Additionally, there are also body postures projected onto the sound by way of past knowledge of sound-producing motion, e.g., narrow positioning of hands versus spread positioning of hands on a keyboard, or vocal tract shapes of open, closed, pointed, etc. The motor theory perspective suggests that in general, there is a projection of assumed body motion onto whatever it is that we are hearing and that this in particular goes for overall sense of effort, including sense of velocity, acceleration and jerk in the music; in short, that music has what could be called rich gestural affordances [35.45], and that all these sensations of body motion evoked by the sound contributes to our perception and subsequent *objectification* of the music.

In summary: Schemas of sound production may reflect basic body motion schemas, regardless of the sound source in question, meaning that sonic object cognition is largely determined by body motion shapes, in turn based on a number of constraints. In the case of very long and stationary or slowly evolving sounds, the energy envelopes may tend to be perceived as *non-human* in that there are no rests in effort and also that the duration may be above the usual thresholds of attention, c.f. *Pöppel*'s suggestions of the perceptual present and the tendency to shift attention in experiences lasting significantly longer than approximately 3 s [35.36].

35.7 Constraints and Idioms

Needless to say, the scope of musical expression is vast, if not infinite, but there are also a number of constraints in musical sound production. The physics of musical instruments and the ergonomics of sound production together make up a number of constraints on music making, constraints that in turn also influence our perceptions of sonic objects.

The basic scheme of sound production is that of energy transfer from the human body to the instrument by way of hitting, stroking, plucking, bowing, blowing, etc. and the response of the musical instrument to any such excitatory body motion. The energy dissipation of an instrument is then a shaping factor of sonic objects, providing its overall envelopes of pitch, timbre and loudness, as well as a number of transients and fluctuations in the course of the sonic object. Additionally, the room acoustics, e.g., the reverberation and other resonant features, contribute to the features of the sonic object. The patterns of excitation and subsequent energy dissipation are highly characteristic of different instruments and people seem to possess quite extensive knowledge about these patterns [35.46].

The combined physical and ergonomic constraints of any instrument typically result in what is commonly

called *idioms*. Idioms are sound-producing motions, on any instrument or the human voice, that are considered particularly well-sounding and also comfortable or easy to perform, hence based on successful combinations of instrument physics and ergonomics. Idioms may variably so contribute to images of sonic objects and are of particular importance in the more composite sonic objects we find in orchestration (more on this later).

The most basic constraint of music performance is that *all sonic events are embedded in action trajectories* and that there is no immediate transition from one sound-producing event to another, i. e., that all effector motion (by fingers, hands, arms, lips, tongue, feet) takes time and that all effector motion (regardless of speed) makes for continuous trajectories. In sum, we have the following constraints of sound-producing body motion contributing to sonic object cognition:

- *Effort constraints*, i. e., there are limits to endurance and musicians need to take rests when performing to avoid fatigue and strain injury.
- *Speed constraints*, related to the previous constraint, but partly also a matter of motor control.
- *Phase transitions*, i. e., the transitions based on rate, speed and duration of basic motion-sound categories mentioned earlier.
- *Coarticulation*, based on the fact that human motion cannot be instantaneous and that there always is a transition from one effector position to another effector position, hence there always are both so-called *spillover effects* and *anticipatory effects* in performance, leading to a contextual smearing of both motion and sound.
- *Goal points*, meaning that performance motion is organized hierarchically and that these hierarchies are also (variably so) reflected in the shaping of the sonic objects.

In summary, there are a number of constraints on traditional sound production in music, constraints that can be summarized as concerning envelopes of energy and as forming schemas that also seem to extend to electronic music.

35.8 Sound Synthesis

Although available technologies for sound synthesis and sound processing present great possibilities for generating a large variety of sonic objects, they also present substantial challenges of how to control the parameters involved in this generation (see Chap. 38 for more on this). The main point in our context is then how to access perceptually salient sonic object features in sound synthesis and processing. (The division between *synthesis* and *processing* may not always be so clear cut, e.g., convolving two signals may be a case of cross-synthesis or source-filter synthesis, but may also be a case of effects processing, e.g., adding reverb to a sound or simulating various other room acoustic coloring of sound.)

This is initially much dependent on the type of synthesis model being used. The main classification into so-called *signal models* and *physical models* may be useful here: physical models shall in principle incorporate some element of energy input (excitation) and energy dissipation (resonance), albeit often in a highly simplified form. On the other hand, the signal models are inherently more abstract in the sense that there is really no simulation of real-world excitation and resonance except for what we may put into the control parameters, e.g., by designating envelopes that approximate expected behavior of real-world sonic events such as of plucking strings, hitting membranes, or stroking metal plates.

Compared with traditional musical instruments and the human voice, there are then no transfers of energy, no motion constraints and and no idioms, involved in sound synthesis (although for the expert listener there may be detectable peculiarities of the synthesis models being used, in a sense resembling *idioms*, e.g., of the often-heard FM and granular synthesis models). This does not preclude that we may project various schemas from past musical experiences onto new kinds of sonic objects (so-called *anthropomorphic projection*), or that the composition is organized more in accordance with traditional score arrangements of sounds (as is sometimes the case in multitrack music production). What seems to be an inherent tendency in our perception is then that of grouping sounds into events and sources as if they were originating from real-world sources and that we project various motor schemas onto sonic objects that have really no body motion element in their origins.

However, the desire to introduce more nuances and expressiveness into the domain of sound synthesis and processing has in the past couple of decades lead to much effort in developing new means for real-time control, including new interfaces of various kinds (e.g., New Interfaces for Musical Expression (NIME) conferences), as well as extending traditional musical instruments with new control possibilities. The latter development has the advantage of exploiting musicians'

already acquired skills, as well as to explore the sonic territory stretching from that of traditional instruments into new sounds.

Besides the ergonomics, one main issue here is that of mapping, i. e., of how body motion is assigned to the control parameters of whatever sound synthesis or processing model is being used. Different schemes of mapping have been explored [35.13], however one crucial question here is actually that of trying to determine what are the perceptually salient feature dimensions of sonic objects and how these may be correlated with body motion features.

35.9 Feature Taxonomy

Schaeffer's work suggests that any sound whatsoever, natural or synthesized, may be considered a sonic object provided it fulfills the criteria of having a suitable duration and capable of being perceived as a holistic and coherent entity. The challenge then becomes that of developing some kind of conceptual apparatus that enables us to diagnose salient perceptual features of sonic objects, i. e., to differentiate these features and compare their relative variable values (e.g., degree of dynamic fluctuation, degree of stability of perceived pitch, etc.).

The project of developing a feature taxonomy becomes a multistage process of firstly discerning and naming some feature that we believe is salient in our subjective image of a sonic object, and secondly to distinguish further what may be subfeatures of this main feature and sub-subfeatures of these features, etc., as far as we see useful for our analytic and/or practical purpose at any time. This means applying a number of metaphorical labels and try to define what they refer to in the sonic object (e.g., the fast dynamic fluctuation as the *grain* of the sonic object). The next step will then be to see these metaphor-labeled features as dimensions in a multidimensional feature space, where each dimension may have a minimum and a maximum value (e.g., between minimum and maximum amplitude of the grain fluctuations) and where any sonic object may be positioned in such a multidimensional feature space.

Such a scheme is very general, applicable to any sonic object and in no way limited to our traditional Western music theory. It is not constrained by a symbolic notation system and all features may be taken into consideration. In this sense, Schaeffer's feature taxonomy is concerned with *concrete* and not with *abstract*, features [35.7, p. 39] and [35.9, p. 216]. There are of course categories at work here, e.g., for pitch and for timbre, but the point is that the feature space of sonic objects is much more extensive than that afforded by traditional Western music theory and its associated categories. As we know, e.g., Western categories of pitch are not universal and other musical cultures (e.g., in India) have more nuanced concepts for pitch. In this sense, the symbolic versus subsymbolic divide is bypassed by Schaeffer's taxonomy and we could add also the symbolic versus suprasymbolic divide as well, in the sense that several fused tone events (or sound events in the case of nonpitched sounds) may very well form a new and larger sonic object with its own overall salient features. In other words, this may include features beyond those of mainstream analysis (including music information retrieval (MIR) and its so-called chroma vectors (i. e., pitch extraction) and other pattern retrieval schemes), features that so far are not well captured by symbolic queries but which are highly significant in musical experiences, e.g., phrase shapes and other meso level emergent features.

In the decades since the publication of Schaeffer's *Traité* in 1966, there has been significant progress in detecting and representing a large number of previously unnamed features in psychoacoustics [35.47, p. 326]. Also software development, e.g., like the *MIRtoolbox* and the *Timbre Toolbox* and *Praat*, has made it much easier now to work directly with sonic object features such as spectral shapes, spectral centroid, spectral flux, formantic shapes, etc.

However, as argued earlier, sonic object cognition will not only include acoustic features, but also corresponding motion features, i. e., trajectories, contours, postures, etc.; that is, various perceptually salient features that may be correlated with acoustic features, as was the long-term goal of Schaeffer's research program.

The main principle of Schaeffer's feature taxonomy is that any feature whatsoever may be given a shape-related metaphor labeling. This gives us a very general and systematic conceptual apparatus for dealing with features in a lucid manner, as well as bridging the gap towards quantitative data of sound and motion.

35.10 Shape Cognition

Sound, as well as associated sensations of body motion, are ephemeral, yet may evidently also result in more solid mental images in our memory. That we now have the technologies for capturing, replaying and making various representations of the ephemeral is indeed one of the most significant developments of our times, as it was, albeit to a much more modest extent, in the late 1940s with the beginning of the *musique concrète*. However, these possibilities of freezing sound and motion also raises new questions of what kind of knowledge we may represent by these various technology-based schemes, and what are the fundamental knowledge goals of our research, questions that point to *shape cognition* as a very basic epistemological and also quite pragmatic paradigm for representing sonic object features.

The term *shape cognition* designates our capacity for thinking and representing sound and motion features visually, as geometric objects in two or more dimensions and as distinct from symbolic representations. As for the symbolic representations, ranging from common-practice Western notation to more recent schemes such as MIDI (musical instrument digital interface) and MusicXML (music extensible markup language), one major challenge is to overcome the discrete bias that prevents us from having good notions of sonic objects, i. e., we need representations that highlight the actual continuous sonic unfolding and make the individual Western pitches and durations fused into coarticulated, coherent sonic objects, as well as to represent the many significant nuances of musical sound. We have in the course of recent decades seen some interesting attempts to more closely represent the holistic features of sonic objects as shapes:

- Enhanced spectral representations of actual musical sound, from the pioneering work of *Robert Cogan* several decades ago [35.48] to the presently readily available software, e.g., the earlier mentioned toolboxes.
- Animations of various kinds that represent the unfolding of sonic objects, be that based on spectral images, on MIDI data, or conventional notation.
- Subjective sketches (also with a signal basis e.g., in the *Acousmographe* software) and various graphical scores [35.49].
- Various body-motion-based shape renderings of sonic objects, including the mentioned *sound tracings* [35.33] and *air instrument performances* [35.32], as well as possibilities for extracting shape information from music-related video and motion capture material of musical performances and other music-related body motion [35.50].

The overall rationale here is that any feature may in principle be traced as a shape, hence making even the most ephemeral sensation *solidly* present for scrutiny and further differentiation. Morphodynamical theory has given us an extensive and well-reflected basis for shape cognition [35.9–11, 51]. In the words of *René Thom* [35.51, p. 6]:

> [...] *the first objective is to characterize a phenomenon as shape, as a spatial shape. To understand means first of all to geometrise.*

In sum, shape cognition offers a top-down approach to sonic object design in that we start with the overall shapes for loudness, pitch- and timbre-related features, something that we following Schaeffer may call the *typology* of sonic objects, then going on to subfeatures and sub-subfeatures of these shapes and into the more internal features, what we may call the *morphology* of the sonic object.

However, shape cognition and shape representation is a long-term project where we have substantial challenges of developing schemes for graphics, animations, feature choice, etc. But for now, whenever confronted with some feature(s) of sonic objects we want to study, we can start by drawing them subjectively, with pencil on paper or just mentally and then successively formalize such sketches into graphs and animations.

35.11 Typology and Morphology of Sonic Objects

A good point of departure for more systematic shape cognition of sonic objects could be the typological and morphological classification scheme of Schaeffer. The *typology* can be summarized as denoting the overall shape, or envelope, of any sonic object, with regards to its dynamic (loudness), and timbre- and pitch-related content. The *morphology* is on the other hand primarily concerned with that which goes on within these overall shapes. Schaeffer's typology and morphology scheme implements a kind of *form-content* distinction, with the advantage of being a general, flexible, top-down differentiation scheme applicable to any sonic object, regardless of origin.

The typology can be seen as a first sorting of sonic objects in that the perceptually most prominent features are taken into account. The typology starts with the three general dynamic envelope categories we have presented earlier and that correspond clearly with body motion categories:

- *Sustained*
- *Impulsive*
- *Iterative*.

This overall dynamic envelope classification is followed by a similarly coarse classification with regards to pitch:

- *Tonic stable*, meaning having a clearly perceivable pitch and that the pitch is relatively stable during the course of the sonic object.
- *Tonic varying*, meaning having a clearly perceivable pitch, but that this changes during the course of the sonic object, e.g., has an upward glissando.
- *Nontonic*, meaning inharmonic or noise-based sounds without any clearly perceivable pitch.

This results in a 3×3 typological matrix, a first and rather coarse but still useful classification of sonic objects. It should also be mentioned that prior to this typology, some other criteria of selection have been applied, i. e., first of all of length and of variability, criteria that are summarized in the notion of the *suitable object* [35.17].

Moving on to the more *internal* features of the sonic object, these are classified according to the principles of the morphology of Schaeffer's theory, here with two main dimensions of the morphology:

- *Gait*: Slower fluctuations in the sound, e.g., as made by a series of slower repeated tone onsets on an instrument, by slower opening–closing of mutes on brass instruments, by slow up and down glissandi on string instruments – in short, any motion in the sound slower than that which is typically perceived as tremolos or trills.
- *Grain*: Fast fluctuations in the sound.

All kinds of grain fluctuations within the sonic objects can be differentiated with our own terms:

- Tremolo, active shake, e.g., as on a violin with rapid back-and-forth bow motion or with *flatterzunge* on a brass instrument.
- Tremolo, passive response, e.g., washboard, maracas, or the grainy sound of a deep double bass or deep bassoon tone.
- Vibrato and/or trills, possible on several instruments.
- Spectral flux by active modulation made e.g., by rapid opening–closing of mutes on brass instruments.
- Spectral flux as passive response to excitation on various instruments, e.g., by scraping a tam-tam with a metal rod.

Note that different terminologies are possible and that the main point is thinking about objects holistically and qualifying their feature dimensions top-down, from the overall to the microlevel. This also goes for Schaeffer's concept of *mass*, i. e., spectral content of sonic objects, and this may be related to psychoacoustic elements, such as the following:

- Spectral shape of any kind, both quasistationary and changing in the course of the sonic object
- Spectral centroid, or the *focus* of the mass
- Correlating body posture shapes with spectral shapes, both of the vocal apparatus and other effectors.

There are a number of categories, subcategories, sub-subcategories, etc., here, but the important thing to keep in mind is that this is all in view of being a practical tool for sonic diagnosis, i. e., it should be considered a *questionnaire* and not a *balance sheet* [35.7, pp. 92–93].

35.12 Singular, Composed, Composite and Concatenated Objects

Although one of the key features of a sonic object is that it should be perceived and conceived holistically as a unit, it is also possible to consider variants of sonic objects not only along feature dimensions (as in the preceding section on the typology and morphology), but also by adding and/or expanding sonic objects. For this reason, it could be useful to make distinctions between singular and more complex sonic objects, distinctions that are in fact often encountered in orchestration and multitrack music production:

- Sonic objects may be *singular*, i. e., one basic and *simple* sound, e.g., of a tone from a piano, a flute, or a plucked string. As we know, such sonic events may in themselves contain several components, typically attack transients in the beginning of the sound, various fluctuations in the course of the sound and in the decay parts.
- Singular sonic objects may also be expanded by superposition, typically by adding other sonic objects to the attack point, resulting in what Schaeffer called *composed*, sonic objects. This is often found in both instrumental and electroacoustic composition, e.g., as in the example from Lutoslawski's *Jeux Venitiens* in Fig. 35.1a, where there is a loud percussive attack object added to the soft attack of the sustained string instrument chord.
- Sonic objects may be extended in the temporal direction, i. e., temporally smeared by adding prefixes and/or suffixes, what Schaeffer called *composite* sonic objects, frequently encountered as various ornaments and other figures in different kinds of music and also associated with coarticulation, i. e., the fusion of rapid tone events and sound-producing motion into higher-level sonic objects [35.41]. In Fig. 35.1b, we see an example of this from Messian's *Regard de la Vierge* where a rush of demisemiquavers and the final quavers fuse together to one single composite sonic object.
- Sonic objects may of course be *concatenated* to form longer stretches of music, as is evident in various kinds of collage-type composition, not only in electroacoustic music and disc jockey scratching music, but just as much in more traditional instrumental music (e.g., Schnitke, Maxwell-Davies, etc., or it may be more homogeneous, e.g., as in works by Messiaen, Stravinsky, etc.). This is what happens at what we above defined as the macro timescale and this is also an area that is not well researched in the field of music perception, but it would not be unreasonable to assume that there are new emergent contextual effects at the macro timescale not present at the meso and micro timescales.

In general, questions about what happens in long stretches of music are not addressed by classical sonic object research. From the cognitive science research referred to above, we could guess that attention is not constant, that it may tend to fluctuate, similar to gestalt flips when looking at the Necker cube, as suggested by *Ernst Pöppel* [35.36]. What does seem to be both quite clear and also feasible to document in sound- and body motion-based research, are the overall global features of longer stretches as done by MIR software (e.g., global indicators of loudness, harmonicity, roughness, spectral flux, etc.) and in body motion software (quantity of motion, mean square jerk, etc.), features that probably are quite good indicators of overall subjective sensations of effort and affect in musical experience.

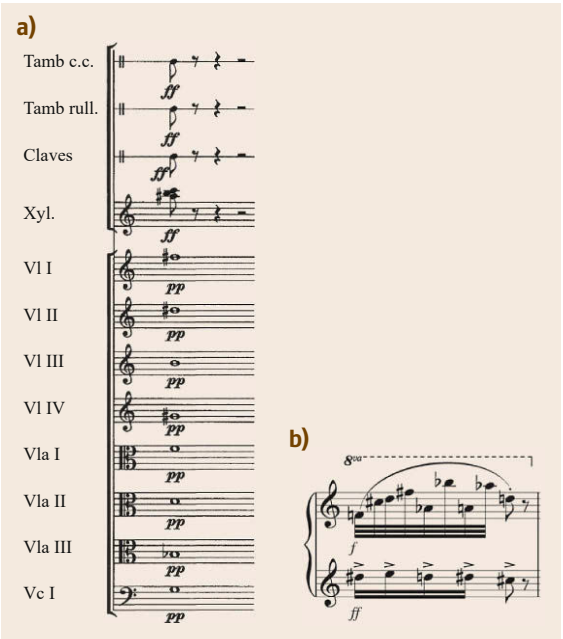

Fig. 35.1 **(a)** A *composed* sonic object from the first movement of Lutoslawski's *Jeux Venitiennes* consisting of a sustained and soft string chord with an added loud percussion attack. **(b)** A composite sonic object from Messian's *Regard de la Vierge* where there is a coarticulated prefix with a rush of demisemiquavers towards the final quavers (reproduced with permission from [35.31])

35.13 Textures, Hierarchies, Roles and Translations

The term *texture* can here be defined as the distribution of sound components within any sonic object. All sonic objects have internal textures, but notably, these textures may vary between totally stationary sounds (e.g., perfectly harmonic sounds) and complex, inharmonic, noise-dominated, or *chaotic* sounds, with most sonic objects found somewhere between these extremes. This is a wider definition of texture than usually encountered in more traditional music analysis, however, the traditional textural categories of homophony, polyphony, heterophony and monody, may be included in this definition as subcategories. This wide definition of texture, besides being in line with the morphological principles of Schaeffer, also reflects the theories and aesthetics of *Xenakis* of various statistical distributions of sound grains [35.52], and also reflects the textural focus in other late-20th century compositions e.g., by Ligeti and Lutoslawski.

The point with the wide definition of texture is to accommodate textural features of any sonic object and also to see that textures may sometimes be explicitly made (e.g., as in a tremolo on a piano) or may sometimes be emergent features of a singular sound, e.g., as in the case of the tremolo-like grain sound of a deep double bass tone. This view of texture is again very much in line with the acousmatic principle of Schaeffer's theory of disregarding the source and focusing on the perceived sonic object features.

Texture encompasses patterns in the sub-20 Hz region and may in speed range from very rapid tremolos and trills (i. e., close to the approximately 20 Hz continuous sound threshold) of *grain*, to the very slow, tentatively down to 30 BPM [35.53], and even slower of *gait*, ultimately also to completely stationary sounds.

In addition to the mentioned categories of grain and gait, there are various subcategories and dimensions, mainly specifying various kinds of spectral distributions and patterns of change. We could think of texture as situated in a multidimensional feature space with each dimension extending from some minimum to some maximum value, e.g., as in the following:

- Dense–spread
- Thick–thin
- Synchronous onsets–asynchronous onsets
- Short tones–long tones
- Many sustained tones–few or no sustained tones
- Wet–dry
- Little or no melodic movement–much melodic movement
- Small intervals in melodic lines–large intervals in melodic lines etc.

A division between foreground melody and background accompaniment is needless to say a very common texture in Western music. Added to this is the phenomenon of simultaneous different speeds in many musical textures, i. e., that the foreground is moving faster than the background, however, there are also deviations from this ordering. What is necessary then is to make an analysis of what could be called *role hierarchies* in sonic objects (and in longer musical excerpts as well). Such an analysis may typically reveal:

- Foreground, i. e., that which is the focus of attention at any moment.
- Background, i. e., that which is more in the periphery of attention.
- Role groups, meaning that complex sonic textures may often be composed of a smaller number of main roles (e.g., foreground + background), but that these main roles in turn are divided into subroles, as in the example in Fig. 35.2 below.
- In some cases, also totally fused, e.g., *Ligeti's Atmosphères* with the entire ensemble dedicated to one

Fig. 35.2 An excerpt from Nikolai Rimsky-Korsakov's *Golden Cockerel Suite* containing different textural roles. See main text for details

singular sonic object, where the role of each instrument is more like that of being a partial in a complex spectrum.

Roles differentiated into subroles, sub-subroles, etc., are in cases of what may be considered successful orchestration, matched with suitable instrumental idioms. As an example, consider the fragment from the opening of Nikolai Rimsky-Korsakov's *Golden Cockerel Suite* in Fig. 35.2. Here we can observe a clear role organization:

- The foreground is made up by the English horn, transferred to the oboe in the third measure, doubled in the harp, the harp changing to harmonics in the second measure. This foreground may be regarded as a series of *impulsive* sounds and at that, *composite* with the attacks in the English horn doubled with the plucked attacks in the harp.
- Against this ascending foreground, we have a descending chromatic line in the flute, celesta and violin I and II, a line of basically sustained sounds that are in fact also a series of *composite* sonic objects with the sustained flute sounds as the core, with the celesta as attacks coloring and with the tremolos in the violins adding a *grain* texture to this.
- The *pp* in the strings enhances the white noise nature of string sound, making the *pp* tremolo on the cymbal, also with a soft white noise cloud, melt into this hushed background of the strings. Together, strings and cymbal clearly have the role of sustained sound, equivalent to adding a *wet* reverb signal to the sound.

In summary, we have in this excerpt three main roles and these main roles have in turn subroles, each of which matches the instrumental idioms well and, on the other hand, results in a rich and colorful orchestral sound as a whole.

To further study textural elements in music, we should also consider transfers of a musical idea/intention from one setting to another, as is done in orchestration and arrangements and which may be collectively called *musical translation*. But what is a musical idea and what is the gist of that which is translated? Besides a practical matter of making and evaluating different arrangements or orchestration versions of tunes or other musical compositions, translating sonic objects from one setting to another is also an encouragement to make us reflect on textural features and role functions in music, including on the role of idioms in music. As we know, it is usually more difficult to translate highly idiomatic expressions from one language to another and attempts at making a more literary translation, as close as possible word-by-word to the original, will often lead to quite strange, or even ridiculous, results. A translation that renders the more general meaning will usually be considered more useful as well as more true to the intentions of the original expression. Similar considerations apply in music, meaning that a task of translation could proceed as follows:

1. An analysis of textural elements
2. Assignments of textural elements to roles, including voice leading
3. Assignments of roles to instruments according to optimal match with idioms
4. Combinations of roles into textures, also taking optimal acoustic (spectral) distribution into account.

In sum, sonic object cognition may enhance our capacity to think analytically about orchestration or instrumentation from a combined perceptual-generative (including motor perspective) point of view, combining the best from the classics, e.g., the main principles of Rimskij-Korsakoff of idiom use, of spectral distribution, fusion, voice-leading, etc., with present schemes for sonic object feature analysis and synthesis, as well as more systematic research on similarity in music.

35.14 Analysis-by-Synthesis

Analysis-by-synthesis can be defined as the systematic exploration of features at all timescales, micro, meso, and macro, by producing and perceptually evaluating a series of sonic objects with incrementally different features. With a foundation in *J.-C. Risset*'s ideas [35.8], we may expand the idea of analysis-by-synthesis to include any activity where people are somehow engaged in producing a number of variant versions of a sonic object and evaluating these variant sonic objects in view of finding the most appropriate, suitable, pleasing, well-sounding, etc. sonic objects for the occasion or task at hand. This will then mean that most musical practice, rehearsal, studio production and composition work has some element of analysis-by-synthesis in that there is a trial-and-error, incremental tweaking of parameters going on. Analysis-by-synthesis is then de facto a familiar phenomenon in musical practice, however, this may have eluded much of music theory and analysis.

The strategy of analysis-by-synthesis applied to sonic objects is then a process with the following steps:

1. Determining some feature dimension(s)
2. Incrementally varying the value(s) of this feature's dimensions
3. Evaluating the subjective perceptual results of these variations.

It may turn out that incremental value changes are perceived as just that, as a gradual change in some hue, but it may also turn out that an incremental change suddenly results in a very distinct qualitative change. Examples of this are encountered in sound synthesis, e.g., the bowed-plucked transition with a gradual decrease in the attack time duration, or a significant change in timbre with FM synthesis.

In summary, the working strategy here is to explore categories, categorical thresholds, intercategorical and intracategorical variation of sonic objects through such analysis-by-synthesis, thus progressively building up our knowledge of sonic objects.

35.15 Summary

The focus on sonic objects, both in the works of Pierre Schaeffer and various later research [35.46, 54], is motivated by the belief that the sonic object is a highly significant element of musical experience, that it has a privileged status in our understanding of music and as a tool for music creation as well. The point is that in spite of significant advances in musical acoustics, psychoacoustics, music cognition, music technology and music information retrieval during the last couple of decades, there are still many unnamed salient features in musical sound and we definitely still need the top-down approach as was presented by Schaeffer et al. half a century ago. In other words, the concept of *object* has great potential as the core of now fast growing insights from a number of music-related research areas.

Needless to say, there are serious challenges of representation, however there is work going on that progressively gives us better signal-based representations, i. e., more selective and focused visual representations that enable in-depth, systematic explorations of sonic object features as shapes. In particular, various graphical and animation representations of combined sonic and body motion features are promising in offering us insights into how rich aesthetic sensations emerge from the ephemeral.

36. Investigating Embodied Music Cognition for Health and Well-Being

Micheline Lesaffre

The aim of this chapter is to highlight challenges involved in the successful deployment of the rather young paradigm of embodied music cognition in the comprehensive domain of health and well-being. Both our current society and systematic musicology are experiencing transitions that have given rise to cross-disciplinary research collaboration between researchers in musicology, the sciences, and a variety of stakeholders in health and well-being. It has been shown that the interdisciplinary, empirical approach that typifies embodied music cognition research has the potential to bring new perspectives to therapeutic approaches for well-being. However, to bring this potential to fruition, researchers have to face the many challenges that arise from the difficulties of using new methods and technologies, especially when working in unfamiliar domains and contexts. In this chapter a framework is presented that provides support to the prominent question of how know-how from the paradigm of embodied music cognition can be efficiently transferred to the sectors of health, rehabilitation, and well-being.

36.1 Transitions in Musicology and Society

There are several transitions occurring both in systematic musicology and in society that provide a challenging basis for *cross-disciplinary* research studies between musicology, the sciences, and practitioners in healthcare. Here cross-disciplinary research refers to cooperation of a group of persons, academics and non-academics, trained in disciplines with different concepts, methods and data, organized into a common effort on a problem. Such teamwork is fundamental to the achievement of investigating goals, but to make sense of the issues of importance one has to face the strong challenges of dealing with the diversity of theoretical and practical perspectives of each partner in a team.

The link between music and health is a perennial knowledge that has been understood and practiced in varied ways across history. However, it was only recently that interdisciplinary scholarship began to research and theorize the richness of music, health and well-being, and made attempts to bridge gaps between scholarly and professional territories [36.1–5]. The renewed attention directed at using the power of music for health and well-being is associated with one of the major transitions that research in systematic musicology is currently experiencing. Because of the development of the *embodied music cognition* research paradigm [36.6], the way music is understood is changing completely, in the sense that it is replac-

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_36

ing the traditional theory for music that focused more on the mind rather than on the body. This approach offers a challenging framework, for example for thinking and setting up experiments on the mechanisms behind corporeal musical interaction and gestural communication [36.7]. Therefore, among scholars in systematic musicology, there is a shift of attention from the mind as a receiver of auditory stimuli to the human body and to the perception–action loops that are mediated by the body.

Furthermore, in our Western culture there are several societal issues, where novel paradigms in music research could make a difference. Typical problems that require attention are for instance the continuous growth in numbers of overweight persons and in young people with anxiety disorders. But, most striking is the ever-increasing phenomenon of an ageing population, which is affecting most countries around the world. Population aging has profound implications for many facets of human life that go beyond the elderly. The global share of older people (aged 60 years or over) increased from 9.2% in 1990 to 11.7% in 2013 and will continue to grow as a proportion of the world population, reaching 21.1% by 2050 [36.8]. Because chronic and neurodegenerative diseases are more common at older ages, there is an augmented prevalence of disorders such as memory loss and depression. Increasing life expectancy therefore raises the question of whether longer life spans result in more years of life in good health, or whether it is associated with increased morbidity and more years spent in prolonged disability and dependency.

Taking the above-mentioned transitions in musicology and society as a starting point, and given the extent of literature on the use of music in everyday life, in this chapter musical interaction is rather conceptualized as a therapeutic intervention as opposed to an everyday activity. Even within this constraint, the cross-disciplinary embodied music cognition approach has given rise to such a broad range of concepts that may be associated with music interventions for health and well-being, that it is hardly possible to define a unique framework. Throughout this chapter examples will be restricted to review papers on music therapeutic interventions and to specific studies that use music and movement to deal with problems of neurodegenerative diseases and physical or mental impairment. The emphasis will be on individual rather than social approaches to health and well-being.

Using music for therapeutic goals dates back a long time. In *Horden* [36.9] and *Bunt* and *Stige* [36.10] the history of music therapy is discussed from different perspectives, including ecological and anthropological viewpoints. *Antonietti* [36.11] provides an overview of ways of employing music for therapeutic purposes in *rehabilitation*. Here the field of *music therapy* is approached from a psychological viewpoint, as a tool of the mind, using cognition and emotion as the avenue towards accomplishing goals for rehabilitation. The advantage of using music in therapeutic programs for the elderly and beyond is that it has the benefit of being painless, nonintrusive, easily accessible, and cost-effective. For the elderly, music therapy may be an enjoyable means for the maintenance and improvement of cognitive, physical, and social functioning. In that perspective *Hays* [36.12] examines the importance of music in facilitating well-being for older people who have special needs and discusses how music can contribute to their *quality of life*. *Clair* and *Memmott* [36.13] detail the benefits of music therapy for aging populations. Their work addresses caregivers who use music to enhance the quality of life of older adults. An important remark that has to be made is that, although there are very many initiatives on the topic of *music for the elderly*, especially around musical activities with persons with *neurodegenerative diseases*, they are usually not supported by *evidence-based* theories.

Today, the challenges of using the power of music for the benefit of people's health and well-being are becoming the focus of extensive scientific discussions in disciplines beyond music therapy. A cross-disciplinary scientific approach to understanding the fundamentals of the benefits people can get from music has developed only recently. Unfortunately, there is practically no literature connecting music therapy with the fundamentals of *embodied music cognition*. Because of its emphasis on the tight relationship between perception and action, the young paradigm of musical embodiment offers a novel tool for the exploration of specific forms of *nonverbal communication*. Through physical behavior in response to music a person may for example reveal clues to unspoken intention or emotion. This is particularly the case for target populations, such as people with *dementia*, who tend to put bodily sensations immediately into action. One important and challenging characteristic shared by researchers who intend to apply embodied music cognition theory, is that embodiment in music experience and behavior is foremost investigated on an *empirical* basis using advanced technologies and tools to measure the effects that music can have on the human body. As a consequence, the evolution in systematic musicology toward the embodied music cognition approach goes along with two strongly connected shifts. Firstly, the focus of interest has moved toward the role that *tools and technologies* can have as *mediators* between experience and environment. Secondly, *user-centered research* involving a broad range of stakeholders in the research process has become an important topic in music research.

To summarize, the societal and musicological transitions mentioned above suggest that bringing the fundamental concepts of musical embodiment into practice, for the benefit of health and well-being, is not straightforward because:

- Challenges of cross-disciplinary research in the field have not been identified yet.
- The impact of new tools and technologies on research methods and strategies still remains underexplored.
- Involvement of a broad range of stakeholders throughout the research process is still not common in music and movement research.
- Current programs using music and movement are not sufficiently supported by evidence-based theories and practice.

So, the question is not to consider *whether* to engage with scientifically validated music applications for health and well-being, but *how* to engage with them.

This chapter has two major parts. The first part provides an understanding of how the field of health and well-being is defined and how the determinants thereof may be connected to current models in music research. The second part deals with the underpinnings of the embodied music cognition framework. It is subdivided into one section considering the theoretical perspectives of musical embodiment and another one discussing the use of tools and technology and user-related strategies involved in current empirical music research. The aim is to provide a framework that supports the deployment of the embodied music cognition paradigm in the field of health and well-being.

36.2 Models of Music, Health and Well-Being

Before exploiting the conceptual framework of embodied music cognition for the benefit of *health* and *well-being*, it is important first to have an understanding of how the field is defined and second what the existing models of music, health and well-being are.

36.2.1 Dimensions of Health and Well-Being

The most commonly accepted and straightforward definition of health was set out in the preamble to the Constitution of the *World Health Organization* (WHO) in 1946. WHO defines health as *a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity* [36.14]. These three dimensions of health are defined as follows:

- *Physical well-being* is concerned with the efficient functioning of the organs and the system.
- *Mental well-being* is the ability to cope successfully with the normal problems and stresses of life.
- *Social well-being* relates to people's roles within society as a whole.

However, the WHO definition has been subject to criticism and several other definitions have been put forward. For an overview see, for example, *Üstün* and *Jakob* [36.15]. And, although the WHO moved the focus beyond individual physical abilities or dysfunction, it is still often ignored in favor of a biomechanical focus on the physical health of individuals only. Over the last decades, the acquired knowledge that mind and body are not as separate as previously thought gave birth to new conceptualizations, such as the *psychobiological* model [36.16] which explores interactions between social, psychological and biological factors, and the *holistic* model [36.17] which includes a fourth dimension, the spiritual. According to *Chatterji* et al. [36.18], who approach the subject from a medical perspective, health must be understood as being inextricably tied to states of the human body and mind and as such distinct from extrinsic environmental features. In this discussion paper, health is not assigned to environments or behaviors, but to the health states or conditions that environments or behaviors produce in individuals. Interestingly, Chatterji et al. elaborate a conceptual framework in which *health states* are described in terms of levels of dimensions such as mobility, pain, hearing, and seeing.

But, how does health relate to well-being and vice versa? Health has been recognized as an important element of well-being because physical, mental, and social health have a direct impact on quality of life (QoL), especially for older people. Therefore, in the majority of models well-being is regarded as a concept related to, but separate from, the concept of QoL. Moreover, the term QoL is used differently in health literature than in sociological literature. In health literature, many QoL instruments have been developed. These generally contain items that relate to symptoms of impairment, functional status, and emotional states and affect. In sociological literature, quality of life refers to the feeling of how good, desirable, and enjoyable life as a whole is. From that perspective well-being

has been viewed variously as happiness, satisfaction, enjoyment, contentment, engagement, and fulfillment or a combination of these and other, hedonic and eudaimonic factors. *Kahneman* et al. [36.19] propose five conceptual levels as relevant for research on well-being. These are:

1. External (objective) conditions (e.g., income, neighborhood, housing)
2. Subjective well-being (e.g., self-reports of satisfaction/dissatisfaction)
3. Persistent mood level (e.g., optimism/pessimism)
4. Immediate pleasures/pains, transient emotional states (e.g., joy, anger)
5. Biochemical, neural bases of behavior.

Hjelm [36.20] distinguishes between and discusses the characteristics of five dimensions of health:

1. Physical
2. Social
3. Emotional
4. Intellectual
5. Spiritual.

Cutler and *Landrum* [36.21] characterize the multifaceted health of the elderly and aim at understanding how health along multiple dimensions has changed over time. They combine 19 measures of health into 3 broad categories representing:

1. Severe physical and social incapacity
2. Less severe difficulty
3. Vision and hearing impairment.

Notwithstanding the variety of approaches, it is possible to observe a general agreement concerning the main conditions shaping health and well-being. Researchers differentiate between well-being that incorporates objective measurable conditions and subjective well-being, which is well-being as defined, or assessed, by individuals themselves and which may include subjective response to objective conditions. The distinction between *objective* and *subjective well-being* is conceptual as well as methodological. External conditions can for example be assessed by self-report (subjective) as well as by independent (objective) observation.

The intertwined concepts of health and well-being are widely used in very many disciplines, but with little consistency. One important reason, that is not so often mentioned, why health and well-being research cannot easily be classified consistently is that its *dimensions* impact one another. For example, people with physical disability may also have problems with respect to mental health, such as feeling depressed or being anxious, or may be excluded from social life. The connectedness between the dimensions of health and well-being provides an imperative challenge for researchers who often restrict their studies to one single dimension without examining its relationship with the others. However, a person's health and well-being results from a complex interplay of the multiple dimensions of health. The knowledge that these dimensions are not unique and differ between target groups makes it even more complex.

36.2.2 Linking Music and Health and Well-Being

In recent years, there has been considerable interest in exploring and understanding the positive effects that music can have on health and well-being in diverse populations and settings. The majority of studies that connect music with health and well-being investigate indicators of social and emotional factors contributing to the overall quality of life of individuals. This approach is supported by the fact that healthcare services are evolving from a disease and symptom model into one of prevention and wellness that emphasizes quality of life and lifestyle in addition to pharmacological treatment. Music therapy is becoming more and more part of lifestyle-enhancing programmes that promote strategies for coping with stress and increasing pleasure in life. From that perspective, *Hanser* [36.22] gives a comprehensive overview of music therapy approaches that document how music experiences can promote and facilitate health and well-being. The author reports on the effects of music on stress, pain, immune and neurological functions, and devotes special attention to conditions of childbirth, depression, coronary heart disease, and cancer.

In the last decade, serious efforts have been made to map the practical and theoretical field of music and health and to determine the relationship between music and health and well-being. Authors have analyzed the field from different approaches, research contexts and methods, for instance health musicking, music in everyday life, and qualitative research. The availability of distinct models that have different types of interventions associated with them shows the complexity of the field. The following examples of studies provide an account of this difficulty. *Bonde* [36.23] starts from the concept of *health musicking*, which is any form of participation in musical activities and the influence thereof [36.24]. The notion of health musicking draws attention to human action and the performance of relationships. Bonde presents a theoretical quadrant model showing how health musicking relates to four major purposes. Here health musicking is understood as the common core of any use of music experiences to regulate emotional or relational states, or to promote

well-being, be it therapeutic or not, professionally assisted or self-made. The four goals of this model are:

1. The development of communities and values through musicking
2. The shaping and sharing of musical environments
3. Professional use of music(ing) and sound(ing) to help individuals
4. Formation and development of identity through musicking.

In Bonde's model health musicking is described as an interdisciplinary field of theory and practice including specific disciplines like music therapy, music medicine, community music (therapy), and professionals with many different backgrounds and qualifications.

In her book on well-being through music in everyday life, *DeNora* [36.25] develops an interdisciplinary framework for music, health and well-being. Considering health and illness both in medical contexts and in the realm of everyday life, DeNora argues that these identities are by no means mutually exclusive. It is suggested that the promotion of health and more specifically, mental health, involves a great deal more than a concern with medication, genetic predispositions, clinical and neuroscientific procedures. Interestingly, in DeNora's approach music is not adjunct to medicine but an equal partner in the performance of well-being.

In a special issue on music, health and well-being, *MacDonald* [36.4] maps the current field of research, introducing five areas that encompass a perspective on music and health. They are the following:

1. Music therapy
2. Community music
3. Music education
4. Everyday uses of music
5. Music medicine.

MacDonald places the emphasis on the benefits of *qualitative research methods*, because this approach facilitates the exploration of the subjective and phenomenological aspects of musical experience. Indeed, musicological research often goes together with a growth of qualitative research performance within healthcare contexts. However, besides relying on qualitative research methods, unraveling the relationship between music health and well-being also depends on the study of quantitatively measurable processes.

Lesaffre [36.5] presents a model as a *contextual* framework conceived from the viewpoint of music and movement applications for health and well-being. In that model, the three basic dimensions of health (i. e., physical, mental, and social well-being) are connected to contexts that can shape health. Activities in the domain of physical and mental well-being encompass musical interventions for the body and the mind. They mainly pertain to what is known as music therapy, movement therapy, and dance therapy. Social well-being is related to lifestyle and quality of life and more specifically to the extent to which music and movement activities can contribute to this.

A review of the literature has shown that studies that provide a framework for music, health and well-being have so far been short on accounting for the mechanisms that underlie the power of music to support health and well-being. Notwithstanding, scientific evidence of strong connections between mind and body and the study of action–perception coupling processes have opened new perspectives for musical therapeutic interventions. Supported by innovative theories in cognitive sciences and musicology, such as the embodied music cognition paradigm, new ways of exploring the extraordinary relationship between man and music are being uncovered. Especially, as more sophisticated technology facilitates the understanding of human functioning in both the body and the brain, there are more means to support the great impact of music.

36.3 From Theory to Therapeutic Approaches

A future key challenge of implementing the embodied music cognition paradigm will be to demonstrate what unique contributions its framework can make to the domain of health and well-being. This challenge can only be met if a broad range of *stakeholders* are involved through all stages of the process of developing evidence-based foundations for future programs and interventions. Stakeholders can be individuals (including scientists, therapists, developers, testers, sponsors, patients, and anyone impacted by a project) or organizations (e.g., caregiving centers, hospitals, sports clubs) that have an interest in a particular project and ideally are involved in the project from the very beginning. However, including a variety of stakeholders introduces music researchers to unfamiliar research approaches pertaining to unfamiliar disciplines. Therefore, it is essential to integrate the theoretical perspectives of embodied music cognition into the empirical framework in a way that enables stakeholders to make sense of the complexities of concepts and methods applied. An

additional challenge is the development and testing of technologies, methodologies, and associated tools in accordance with user approaches that are rather novel to the domain of music research. The concepts and ideas pertaining to these issues are discussed in the next subsections.

36.3.1 Theoretical Perspectives of Musical Embodiment

A significant feature of the embodied cognition research approach is that it views the body as being central to the way the world is experienced. This means that it is assumed that cognitive processes are ruled by sensorimotor capacities and their interactions with the environment. Because embodied cognition already is the product of various research fields including psychology, movement science and neuroscience, *Shapiro* [36.26] refers to it as a research program rather than a theory. *Gallagher* [36.27] provides an overview of the variety of theorists that have attempted to outline different approaches and meanings related to the concept of embodied cognition. Although there are various approaches to embodied cognition, its central claim can be summarized in the idea that there is a representational equivalence between perception and action [36.28].

With his theory of embodied music cognition, *Leman* [36.6] introduces the concept of embodiment in systematic musicology. He argues for the understanding of the human body as the most natural mediator between musical subjects and their musical environment. Leman's framework distinguishes between four fundamental components of musical embodiment, namely:

1. The body as mediator
2. The action-oriented ontology
3. Action–perception coupling
4. Embodied musical communication or expression.

These components provide the conceptual scaffolding for cross-disciplinary research between embodied music cognition, the sciences, and health and well-being. In the next paragraphs a brief description of the meaning of these fundamentals is given, together with references to studies and applications in the domain of music, health and well-being. For a more extensive explanation of these fundamentals, see *Leman* [36.6, 29, 30].

In embodied music cognition the idea of the *body as mediator* implies that the human body is conceived as a mediator intervening between a person's physical environment (i. e., the music) and a person's subjective experience of that environment. The physical environment can be described in an objective way (e.g., the waveform), whereas experience can only be described in a subjective way. Similarly, musical gestures can be described in an objective way as movement of body parts, but they have an important experiential component that is related to intentions, goals, and expressions. Starting from the concept of the body as mediator, *De Bruyn* [36.31] has, for example, developed an empirical methodology that uses motor tasks to assess music perception skills. A music application was developed that provides therapists with a methodology for music perception training, for example in auditory rehabilitation of persons with a cochlear implant. The application called *Sound Caterpillar* is conceived as a musical game that uses motor tasks to assess music perception skills.

The second component, the *action-oriented ontology* or action–gesture repertoire, consists of a set of gestures and related expressions that a person has built up over years. The effect music might have on a person is strongly dependent on the experiences that people have accumulated during their gestural interactions with music. As corporeal articulations and actions are carried out in space and time, it seems natural to conceive of the action repertoire as a container of spatial–temporal patterns. In current studies these *spatial–temporal* patterns have been examined through aspects of gesture [36.7] and *entrainment* [36.30, 32]. Entrainment is the process of synchronizing endogenous sensations of beat with an external rhythm of movement. These studies open new perspectives for understanding the relationship between entrainment and expressiveness. In a review paper, *Nombela* et al. [36.33] address the underlying mechanisms of musical entrainment and its effect on improvements in gait and motor improvements in people with Parkinson's disease. Especially neuroimaging studies provide valuable insights for developing potential movement therapies.

The *action–perception coupling system* is a complex mechanism that controls the interaction between environment and subjective experience. It is responsible for predicting the outcome of corporeal actions and musical intentions. Understanding the components and dynamics of the action–perception coupling system holds promising potential for motor rehabilitation. *Wolpert* et al. [36.34] review recent research in human motor learning with an emphasis on the computational mechanisms that are involved. In *Maes* et al. [36.35] the action–perception coupling mechanism is approached from the embodied music cognition perspective. Maes presents a theoretical framework that captures the ways in which the human motor system and its actions can reciprocally influence the perception of music. Such a framework offers a foundation for research that investigates the effect of musical activities, for example in people with motor disorders.

The fourth component, *embodied musical communication*, is based on the processes of encoding and decoding *expressiveness*. Traditionally, body movements have not been considered a parameter of *musical expression*. However, the work of *Davidson* [36.36] has shown, that body movement is in fact one of the most salient features when communicating expressive intentions. The idea that music may establish an intentional layer of communication between listener and performer, links the component *musical communication* to the concept of *musical intentionality*. Musical intentionality is based on an action–perception coupling system that uses actions as causes of perceived patterns. The system turns perceived sound patterns into action patterns that could have caused the perceived sounds. *Davidson* and *Emberly* [36.37], for example, provide a cross-cultural analysis that allows for the examination of distinct notions of embodied musical communication whilst building on developments that support the idea of musicality and its role in enhancing quality of life and feelings of well-being.

36.3.2 Tools, Technologies, and Their Users

Over the last decade, the omnipresence of music interaction tools has formed the basis for a shift in systematic musicology toward *technology-driven research*. In embodied music cognition, such research is of key importance, because it makes it possible to complement the subjective approach with objective studies of the phenomenon of musical empowerment, for example, by investigating body movement in music-related activities or studying the characteristics of the action–perception coupling system. This means that researchers in musicology not only enter the rather unfamiliar domain of tool use and tool design, they also have to take into account the specificities and needs of the various groups and subgroups in the domain of health and well-being they are targeting. The next paragraphs consider the challenges of working with novel *measurement tools*, *technologies*, and *user-related strategies* involved in current empirical music research.

Tools for Measurement and Analysis

Many aspects of music's role in relation to health and illness have been subject to measurement. Apart from *qualitative methods* such as interviews and focus groups, a range of *quantitative measurement* instruments in the form of *self-assessment* tools or *observer-rated* tools and clinical tests is typically employed. Prominent examples are the mini-mental state examination MMSE [36.38] for testing cognitive impairment and quality of life (QoL) surveys, such as the widely used short form health questionnaire SF-36 [36.39] for measuring self-reported physical and mental health status and the QUALIDEM scale [36.40] that was designed for persons with dementia.

These and many other measurement instruments have been subject to critique, for example concerning their *ecological validity* [36.25]. Indeed, the traditional situation of testing often involves responding to a survey guided by a trained assessor and is limited to a lab setting and thus outside the context of everyday life. Therefore, critical thinking about tool use is required in order to produce ecologically valid accounts of how music may promote health and well-being. Furthermore, such surveys offer retrospective perspectives and are therefore subjected to distortion. Moreover, in humanities, too many researchers studying the response to music solely rely on self-report and questionnaires as evidence and in some cases questions are used that were not validated. In any case, such information does not capture the complexity of feelings, intentions, and thoughts a person may have. Also, the accompanying concepts do not have an unambiguous meaning because most behaviors are the result of more than one condition. Therefore, this subjective *top-down* approach needs to be supported by additional objective *bottom-up* information like measurements of parameters related to body movement or brain activity.

Embodied music cognition research particularly concentrates on the empirical use of a variety of tools for measurement and on tool development. But, working with a combined set of tools and technologies produces *high-dimensional data* which require advanced skills to handle. It is for example very likely that apart from using surveys, an experimental design using optical motion capture will include measurements for several subjects of several body parts (e.g., hands, legs, heads, trunk). In addition it may include measurement of other information indirectly related to movement such as biometric data (e.g., heart rate, inhalation and expiration volume, and cerebral blood flow measured by techniques like fMRI (functional magnetic resonance imaging)). All these measurements result in huge multivariate datasets causing challenges not only for *data collection* and *storage* but also for methods of analysis and visualization. The *integrated analysis* of top-down and bottom-up measurements of human physical and/or mental movements in a musical context is a real challenge in cross-disciplinary science today. *Multimodal modeling* is an important goal in order to provide a combined representation and analysis of the collected data. In a study on monitoring and analyzing the effect of live music performances on people with dementia, *Lesaffre* et al. [36.41] combine the use of various questionnaires, the MMSE test, measurement of quantity of movement, and audio and video record-

ing of participants and performers. For this multimodal dataset, an analysis tool was developed that combines the bottom-up and top-down approach for comparative analysis. In this way it was possible to show that live music invites people with dementia to move more to the music than listening to music from loudspeakers and that there is a significant effect of the degree of cognitive impairment on their motor response.

Technology-Driven Research for Music, Health and Well-Being

Technology-driven research groups aim at developing health and well-being by means of technological applications rather than care itself. In many cases the main activities are service design and follow-up and evaluation methodology development. In embodied music cognition research the technology-driven approach is rather young. Its emphasis is more on using technologies to investigate the fundamentals of action–perception processes and on developing tools for monitoring or retraining purposes, for example of people who have had a stroke.

The elaboration of tools and technologies has introduced the concept of *mediation technology* in systematic musicology. It is based on the idea that technology mediates human perception and action. Mediation technology is the equipment by which the human body and consequently also the human mind, can be given an extension in the digital musical domain thereby enabling the performer/user to explore the domain of sound and music. From the embodied music cognition perspective the focus is on the acting body as the center of the mediation process that makes it possible to behave in resonance with music. During musical interaction, a musical instrument or an electronic device typically extends the human body. These body extensions allow mediation between subjective experience and physical (i. e., musical) reality. In regard to that process a musical instrument is considered to be the most natural corporeal–technological mediator [36.42]. But, we do not yet fully understand the way in which technology mediates perception and action, neither how mediation tools are dealt with. It is even more challenging when entering the domain of health and well-being, where users of mediation tools are foremost nonmusicians. Moreover, when designing tools for older people, one is likely to be challenged by difficulties of adaptability and openness to new experiences involving new devices.

Interaction with mediation technology for musical activities also confronts researchers with the challenge of building and testing of paradigms. So far there has been little research looking at benefits of musical interaction by means of body-extending devices for health and well-being. In a study that investigates musical interaction between normal-hearing people and hearing-impaired individuals with cochlear implants, *Lesaffre* et al. [36.43] present an experimental framework to test the user's sense of embodiment in sound identification and creation. Here attention is paid to the possibilities of coupling the well-known psychological concepts of *flow* and *presence* as a valuable top-down strategy for the design of embodied music interaction tools. It was shown that these states of mind are important factors in the experience of having fun or immersion in a shared environment and therefore are valuable concepts for exploring future applications.

Apart from the problems encountered by working with existing technologies, developing new tools or applications that expand the natural link between music and movement is even more thought provoking. For instance, *Moens* et al. [36.44] developed an interactive music player called D-Jogger that analyzes body movement in order to dynamically select music and adapt its tempo to the user's pace. This smart music player can use a wide range of sensors such as 3-D accelerometers, gyroscopes and pressure sensors, capable of measuring the users' movements. D-Jogger was used to explore how music can entrain human walkers to synchronize to the musical beat without being instructed to do so [36.45]. This study has shown that entrainment is controlled by brain mechanisms that work on time-differences between movement and music. Moreover, it was shown that perfect synchronization with the beat of the music has an enormous impact on the motivation to move. These insights show potential for performance enhancement in those who suffer from movement difficulties (e.g., patients with Parkinson's disease) or those who seek a movement boost (e.g., for sports performance).

However, to use such applications in a rehabilitation program it has to be demonstrated that these devices are effective through clinical trials. At this point in time, the barriers they are confronted with often discourage researchers. We report on a selection of barriers in the following. Time constraints mean that clinicians and therapists are not keen on adapting their program to the testing of new tools. They would rather hang on to a number of different therapeutic technologies that are available for use in clinics. But, the value of these technologies to the treatment program is not well defined. The use of technology in health and well-being is highly dependent on the application or therapy program for which it will be used. Besides, its effectiveness will also be determined by the user's receptiveness, attitude, and motivation. Furthermore, new and unfamiliar technologies can generate ethical concerns. Therefore, trust and confidence issues must be addressed.

User-Centered Research in MH and W/User Involvement

User-centered studies are more and more seen as the cornerstones of working with music mediation technology [36.46]. This transition implies an expansion of methodologies for addressing relevant features of musical action, musical tool use, and user-based tool development. The benefits of user-centered research methodologies in general are well documented in the literature [36.47]. However, apart from some investigations in the domain of *music information retrieval* (for an overview see [36.48]), using the principles of user-centered design is still underexplored in music research. Thus, along with the increased concentration on tools and mediation technologies goes the challenge of involving a broad range of stakeholders throughout the process of tool development, system design, and empirical studies.

The process of *user involvement* is a joint activity of a cross-disciplinary team of stakeholders that cooperate throughout the whole research procedure. However, it is not straightforward to involve users in empirical music research activities, especially with regard to health and rehabilitation. User involvement still faces many barriers, some of which are not easy to pass. A not exhaustive list of important reasons includes the following:

- In a caregiving context, users are time and time again approached as a patient, i. e., in terms of their illness or impairment. Being approached as a patient is an obstacle that discourages many people from being involved in empirical research.
- Ethical constraints force people with an impairment or disease to come to a hospital to test newly developed tools and programmes. Their personal experiences associated with illness, injury, and contact with doctors may hinder their participation.
- Professionals in healthcare are not always supportive of user involvement, for example because effective teamwork may require a restructuring of therapy programmes.
- Problems due to limited budgets are likely to be encountered, including time costs for the professionals and users themselves.
- Many of the products that are available on the market, such as smart phone applications for physical activities, have not been scientifically validated by user research.
- Involving users requires that designers cope with the huge variability among people's abilities and demands. There is a need for new testing paradigms that can cope with differences in personality and levels of impairment.
- Involving users with different ability levels, needs, and backgrounds requires tools to be developed and therapy programs to be conceived at an individual level.

Teamwork of stakeholders, including users, can be characterized as a multistage problem-solving process. It not only requires that researchers analyze and foresee how users in the field of health and well-being are likely to interact with a music interaction tool, the validity of the assumptions should be tested as well. Although this problem-solving activity is a simple reiterative process, given the schedule pressures of many research projects, in reality it is not widely implemented and therefore requires more attention. A supportive framework is presented that breaks the user-involvement process into five phases that are:

1. Defining user requirements
2. Outlining user strategies
3. Designing tools and experiments
4. Investigating user experience
5. Building a user interface (Fig. 36.1).

User requirements are identified early on in a research project. The process of defining user requirements starts from theoretical models as a foundation for case studies. Ideally, all researchers, experts, and beneficiary parties in the field of health and well-being (e.g., nursing, physiotherapy, gerontology, and ethics) that develop user strategies, user-experience designs, and/or user interfaces for a music interaction system

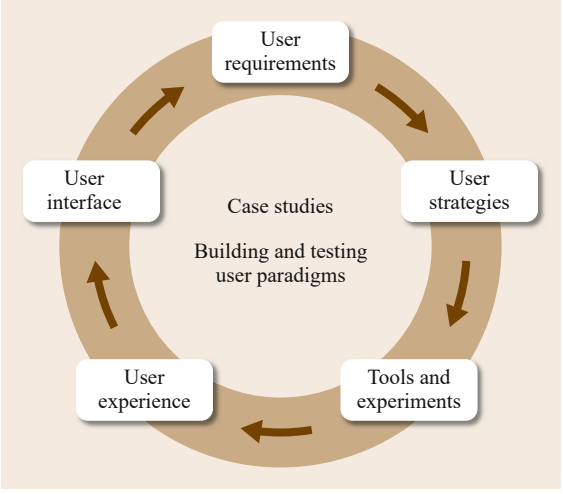

Fig. 36.1 Framework for the multistage problem-solving process of user involvement representing the reiterative procedure of defining user requirements, outlining user strategies, designing tools and experiments, investigating user experience, and building a user interface

will participate directly in gathering and defining the necessities of a specific target group. Although many researchers acknowledge the importance of identifying user requirements and their input into the process of designing tools and experiments, they often have no real plan as to how to achieve this. User requirement activities targeting the elderly may for example address questions concerning what kind of music devices they generally use, what kind of approach has the potential to add value to the daily lives of persons with impaired motor skills, or what musical preferences people with dementia have.

User strategy basically refers to the outlining of a clearly specified plan that flows from knowledge of user requirements of specific target groups and is initially created from the ideal user experience perspective. Typically, user strategy is embedded in *use cases* wherein certain assumptions are made, for example about features of action–perception coupling. Currently, user-oriented strategies have been developed in the direction of person-centered approaches where successful identification and interpretation of individual characteristics is at the focus of attention. Especially healthcare is becoming more and more individualized. The shift to practices where a patient becomes an active subject rather than a mere object of care is rooted in humanistic psychology and the person-centered therapy advocated by *Rogers* [36.49]. This type of therapy encompasses a nondirective, empathic approach that empowers and motivates a person in the therapeutic process. From that perspective the motivational power of music, for example to move our body, is still underexploited. *Van Noorden* [36.50] explains in his work the systemic principles of why music motivates movement.

Ideally, the process of *designing* (*music interaction*) *tools and experiments* for music applications for health and well-being is guided by the principles of *participatory design* and person-centered approaches. Participatory design [36.51] represents part of the cross-disciplinary collaborative work and implies that stakeholders with different expertise and knowledge have a deciding vote in the design process. However, inclusion of patients in tool design remains a challenge, especially when their characterization is atypical, as is the case with disabled persons who do not have the capabilities of persons with normal motor skills. The person-centered approach implies that music interaction and analysis tools need to be flexible enough to customize in situations where a paradigm for each different user type is required. In view of adapting the design process to disabled users, *Veytizou* et al. [36.52] for example propose a method that integrates parameters such as motor specificities and progression over time in the design process. *Holone* and *Herstad* [36.53] use the strategy of participatory design and *design for all* in a project that aims at improving health and quality of life for persons with severe disabilities by means of *co-creation* between children, their families, and caregivers.

User experiences deal with both experience related to the *usability of tools* and experience of embodied interaction with music. The study of effectiveness of tools and programs looks into users' corporeal articulations, behaviors, attitudes, and emotions about a particular system or tool. Experiences of musical interaction involve ways in which aspects of embodied experiences lived by means of music may support physical, mental, and social well-being. User experiences, more than anything else will determine *user satisfaction*. Interaction with embodied mediation technology for musical activities requires building and testing of paradigms of user experience. A study probing users' sense of embodiment in sound identification and creation has, for example, confirmed the importance of an approach that is concerned with embodied interdependency between the user and music mediation technology [36.43]. One problem that could be tackled through cross-disciplinary cooperation is the alignment of the functionality of technologies with the agency of the user. Designers often treat users as secondary to their tools or do not have sufficient time to follow the whole process. For example, when it comes to the development of musical applications for people with neurodegenerative diseases the design process requires analysis of user actions and experiences of the specific target population in order to move beyond merely addressing its functionality.

The *user interface* is the space where human–machine interactions occur. It may consist of visual, auditory, and/or other components through which users may interact directly or indirectly with the system. *User interaction* is facilitated through a musical user interface, which can be personalized to meet user's preferences and deliver the necessary cues. For example, *Lesaffre* et al. [36.41] (submitted) developed a musical balance board that is a musical user interface for retraining of balance in stroke patients. The system provides real-time sonification of weight distribution together with the motivational effect of music to retrain maintenance of equilibrium.

A last question to be asked is who the *potential users* for musical applications for health and well-being are. They are numerous, being everyone, disabled and not disabled, that can benefit from communicating, experimenting, playing, and training with music. Music tools may for example address sportsmen looking for new training possibilities that support prevention of injuries or individuals with specific impairments such as

the retraining of balance in hemiplegic patients. However, apart from finding and prioritizing the *right* user needs it is also important to address the scope of users from which to draw insights. From the perspective of the embodied music cognition paradigm, the scope of potential users (in therapeutic interventions and beyond) could be narrowed down to persons who comply with some or all of the following characteristics:

- Like, enjoy, or have an interest in music
- Being sensitive to musical reward experiences
- Have a positive attitude towards (new) technology
- Are willing to experiment and perform musical activities
- Have adequate motor skills
- Are willing to perform within a group (co-creation)
- Are able to hear sound (or at least feel it).

36.4 Conclusion

Starting from transitions in society and musicology, in this chapter a framework is provided that is meant as a support for providing an answer to the question of how to engage with scientifically validated music applications for health and well-being. The presented framework is stimulated by the belief that the scientific expertise to be gained from using the embodied music cognition approach in promoting music and movement interaction for health and well-being holds promise for future achievements. This chapter has discussed models of music, health and well-being. It was shown that the growing prominence of new tools, technology-driven research, and user approaches indicate key developments toward achieving demands of bringing the embodied music cognition approach into the practice of musical interventions and therapeutic programs for health and well-being. To conclude, this final summary brings together the key challenges that were explained in this chapter.

With respect to theory:

- Cross-disciplinary research in the context of the embodied music cognition framework requires the integration of theoretical principles into the empirical framework in a way that enables all stakeholders to make sense of the complexities of concepts and methods applied.
- The connectedness of the multiple dimensions of health requires the study of the relationships between these dimensions rather than focusing on one dimension alone.
- The development of musical interventions and musical therapeutic programs should be grounded in evidence-based theories.

With respect to technology:

- The shift to technology-driven research requires the development of new tools that expand the natural link between music and movement.
- Testing of technologies, methods, and associated tools needs to be done in accordance with predefined user requirements and strategies.

With respect to users:

- The multistage problem-solving process of user-centered research requires involvement of all stakeholders throughout the process.
- User-centered strategies need to be expanded to account for person-centered approaches.
- Ecological approaches are required that recognize the interconnectedness of individuals and their personal context.

With respect to modeling and analysis:

- A multimodal modeling approach is a prerequisite for allowing integrated representation and analysis of high-dimensional data.
- The analysis framework should be developed in such a way that the subjective top-down and the objective bottom-up approach become tightly connected to each other.

37. A Conceptual Framework for Music-Based Interaction Systems

Pieter-Jan Maes, Luc Nijs, Marc Leman

Music affords a wide range of interactive behaviors involving social, cognitive, emotional, and motor skills. In this chapter, we consider the role of technologies in relation to these interactions afforded by music. A general conceptual model is introduced that forms a basis to frame and understand a vast number of music-based interactive systems. In this model, we consider the necessity of coupled action–perception processes, in combination with human reward, prediction and social interaction processes. In addition, we discuss three perspectives on how music-based interaction systems may involve users' actions (monitoring, motivation, and alteration). To conclude, we discuss two case studies of technologies to illustrate the most innovative aspects of the presented model.

A distinct characteristic of music is that it stimulates active behavior, individually and collectively. For instance, music performance brings people together to actively play an instrument in coordination with others. Also, listening to music spurs people to move along with the beat and other musical features. Accordingly, music can be considered an excellent medium that affords and reinforces sensorimotor interactions between humans, and their sensory environment. The impact of music is far-reaching and may have a bearing upon general skills that are conducive to the general development of human beings. For instance, both performing and listening to music have been shown to promote interpersonal entrainment, or *joint action*, which engenders social skills, such as imitation, collaboration, the nonverbal understanding and sharing of intentions, hierarchy formation, empathy, etc. [37.1, 2]. Also, music performance and music listening enable people to explore, experience, and develop human affective engagement with expanded complexity and phenomenal character [37.3]. In addition, it has been suggested that people's engagement with music calls on temporal processing systems, which in turn may develop domain-general cognitive abilities such as sequential learning, temporal integration, and serial recall [37.4, 5]. Finally, music may facilitate auditory cueing, motivation, and/or diversion, which may contribute to movement performance in sports and motor rehabilitation [37.6–8]. In short, music affords a wide range of interactive behaviors involving social, cognitive, emotional, and motor abilities.

In this chapter, we consider the role of technologies in relation to these interactions afforded by music. We claim that music-based interactive systems can reinforce interactions that contribute to a heightened experience of music, and to the improvement of domain-general social, cognitive, affective, and motor skills. Technologies are thereby considered extensions of the human body. Acoustic musical instruments are a basic example of technologies that extend the human body: endowed with its sensorimotor capabilities, into the external (musical) environment [37.9]. However, since the 1990s advances in electronic and digital technology development have drastically changed the landscape of music production; the emergence of sensors, motion-capture technology and digital sound

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_37

processing modules have expanded the possibilities for interaction. Moreover, this has not been limited to only sound production. For instance, many technologies are developed specifically to enrich people's experience of listening to music; think of the mobile phone, wearable digital media players, or sophisticated music streaming-on-demand services. Also, new music technology has created an immense potential for assisting and optimizing teaching methods in a music educational context [37.10–12], or for enhancing social interaction [37.13].

However, despite the possible benefits of using new electronic and digital technologies, they have also introduced new problems and challenges with regard to musical interaction and communication. For example, a fundamental problem inherent in digital music production is the fact that the mediation between the different modalities (basically from movement to sound) has an arbitrary component, which is due to the fact that the energies of the modalities are transformed into electronic signals. This is not the case with traditional instruments, where energetic modalities are mechanically mediated and where the user gets a natural feeling of the causality of the multimodal interface. Therefore, in the domain of electronic and digital music production, there is a need for more *transparent* mediation technologies that create a feeling of nonmediation; as if the mediation technology *disappears* when it is used [37.14]. Similar issues exist in other music-based interaction technologies. Researchers therefore believe that music-based technology development must be informed by knowledge on the cognitive, sensorimotor, and social dispositions and capabilities of human beings. This requires the integration of fundamental research in order to fully exploit the potential of electronic and digital music technologies.

This chapter introduces a general conceptual model that forms a basis to frame and understand a vast number of music-based interaction systems. The model is intended to serve as a guideline for practical developments in the future. Its focus is on music-based technologies that enable action and interaction (human–music interaction, and human–human interaction). These technologies are mediation technologies in the sense that they offer ways to extend the coupled action–perception mechanisms and sensorimotor integration processes that are *naturally* involved in people's engagement with music. The model expands the concept of action–perception couplings so as to incorporate the concept of the human reward system and social interaction processes. We then go on to discuss three perspectives on how music-based interaction systems may involve users' actions (monitoring, motivation, and alteration). To conclude, we discuss two case studies of technologies to illustrate the most innovative aspects of the presented model.

37.1 A Conceptual Model of Music-Based Interaction Systems

The classical, *information processing* approach in cognitive science considered behavior and perception as separate peripheral processes outside central cognition [37.15]. By now, this model has been further developed in favor of embodied accounts that emphasize the central role of sensorimotor interaction with the external environment in human behavior and perceptual-cognitive processes [37.16]. This interaction requires the integration (coupling) of action and perception processes. Acting in and onto the environment guides perceptual-cognitive processes, which reciprocally influence motor control and behavior. Moreover, this interaction process is driven by subjective aspects, such as intentionality, reward and affect, and is situated within a specific context (cultural, social, etc.).

Our conceptual model of music-based interaction systems considers technologies from the perspective of this action–perception loop and its role in human–environment interactions. We consider the aim of technology development to intervene the natural coupled action–perception processes, in order to extend the cognitive, sensory, sensorimotor and social capabilities, and to reinforce a human's interaction with the external environment (Fig. 37.1). Such *mediation* technologies enable an engagement into new realms and an opening up of exciting possibilities, such as those in the domain of electronic and digital music processing [37.14]. This approach to technology development is closely related to the theories of the *extended mind*, where humans use technology to connect with the musical environment [37.17], and *situated cognition* where the goal is to find a way of interacting with the environment such that meaning emerges from it [37.18].

Mediation technologies that intervene in the action–perception loop in support of sensorimotor interactions contain two components. First, systems must be allowed to capture actions and to align them with sensory outcomes. Typically, this is what traditional musical instruments do. However, the ability to extend actions into the electronic and digital domain, drastically increases the possibilities for sound production. Unlike traditional instrument teaching where the input–output

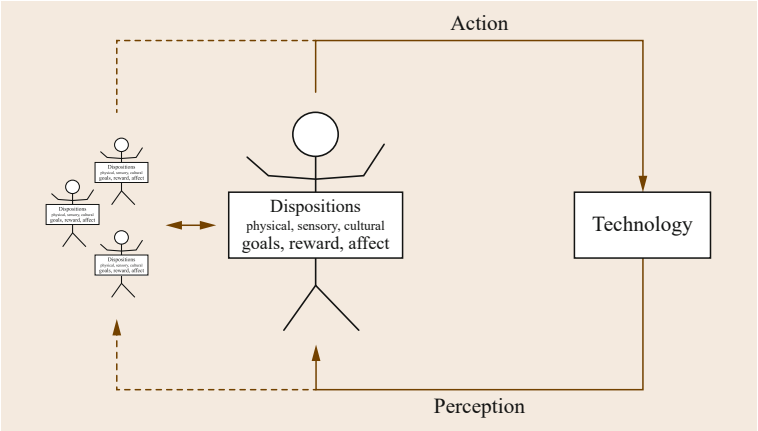

Fig. 37.1 Schematic overview of the conceptual model of music-based interaction systems

is determined, the use of electronic and digital devices allow for a complete rethink on the familiar relationships between physical input and sound output and to incorporate aspects of instrumental design related to sound design and interaction modes [37.19]. For example, obvious relationships can be reversed (e.g., small actions produce loud sounds, short notes trigger extended sounds). The possibility of rethinking the input–output model provokes musical exploration and development of novel emotional experiences [37.3]. Additionally, in transferring actions into sensory outcomes, systems could contribute to the multisensory monitoring of one's action and develop awareness of an individual's movement performance [37.20]. The availability of monitor movement performance could be exploited in various domains of research and practice, such as dance, sports and motor rehabilitation.

Second, mediation technologies may focus on the alignment of actions (i. e., movement responses) to specific musical and/or multisensory feedback or stimuli [37.21]. The applications are numerous. Movement responses to music have been shown to improve the perception of structural and expressive musical structures [37.22]. Additionally, music's ability to guide movement responses to specific goals may be used for sports and rehabilitation purposes, or it may facilitate social interaction and entrainment. Although musical mediation systems may capitalize on one or the other of the components just discussed, *real* interaction exists only when the two components are operating in combination. In that regard, actions are transferred to appropriate sensory outcomes and, in turn, these sensory outcomes are generated such that they support or adapt actions towards specific expressive, motor, or social goals.

In Sects. 37.2 and 37.3, we discuss in more detail how coupled action–perception processes can be further linked to the physiological processes related to reward, and to social interaction [37.23]. More importantly, we discuss these processes in light of our conceptual model, and how music-based interaction technologies can tap into the processes underlying reward and social interaction in order to reinforce musical experiences, as well as enhancing various skills (Fig. 37.1).

37.2 The Human Reward System

A somewhat disregarded aspect of interactive music systems is the role of the human reward system, and related subjective phenomena such as motivation, intentionality, affect, etc. However, a closer look at the role of reward in the design of interactive music systems shows that it is a fundamental component of the interaction dynamics. Current thinking on the reward system understands the process as a collection of neural structures that contain dopamine-secreting neurons in the midbrain with pathways to other brain structures such as the nuclei accumbens and prefrontal cortex [37.24, 25]. In general, reward serves as a *reinforcer*, motivating and regulating voluntary behavior control by inducing feelings of pleasure and happiness.

In the following, we provide arguments to support our claim that the reward system and reward values play an essential role in many aspects of electronic and digital music systems. First, we discuss the importance of reward values in learning processes that are required in many of the interactive music systems. Secondly, we discuss how reward, and musical pleasure during music listening relates to the ability to anticipate and predict

forthcoming events. Moving on the argument, we extend this idea to the coupled action–perception loop involved in music performance, and in (synchronized) movement responses to music.

Research suggests that dopaminergic projections to prefrontal cortices underpin executive functions related to attention, memory, and learning [37.26–30]. Of major importance are the findings that the close intertwining of the reward and cognitive systems in learning processes is modulated by prediction mechanisms. Traditional learning theories emphasize the role of temporal *contiguity* in associative learning processes. That is, whenever two events or phenomena occur quasiconcurrently, such as a stimulus and a reward, they become associated. However, current learning theories suggest that learning processes are grounded in the discrepancies that occur (errors) between what is expected/predicted and what actually happens [37.28, 30–32]. In these studies, it is shown that dopamine neurons encode reward learning prediction errors; a positive response of dopamine neurons occurs when a reward is given unexpectedly, while this response gradually decreases as that reward becomes increasingly predictable. Importantly, it has been demonstrated that high stimulus-reward predictability, and a corresponding decrease of dopaminergic activity, prevents the concurrent (behavioral and neuronal) learning of other stimuli–reward relationships (cf. blocking paradigm; [37.30]). These findings stress the necessity to integrate issues such as surprise and novelty into the design of music mediation technologies that almost always involve some degree of learning.

In a recent study, *Zatorre* and *Salimpoor* [37.33] investigated the neural bases of the feeling of pleasure during music listening. It was found that temporal expectancies, and their associated predictions again play a key role. When listening to music, incoming auditory information is processed by auditory cortices and, in interaction with frontal cortices, fit into *templates*, or a *musical lexicon* [37.34]. Based on these templates, representations of structural regularities in the music can be generated, which in turn facilitate the generation of expectancies and associated predictions. Emotional responses and the sense of reward then result from the degree of confirmation or violation of predictions. An important remark made by *Zatorre* and *Salimpoor* [37.33] is that the *templates* used to fit incoming auditory information, and eventually generate predictions and musical pleasure, are developed through prior musical experiences within a specific context. Accordingly, the authors suggest that these mechanisms could possibly explain the variation and diversity in peoples' musical choices.

The ability to anticipate or predict forthcoming events has been identified as a major source of reward in musical activities that involve sensorimotor coordination and synchronization [37.35, 36]. This can relate to the production of sound (as in music performance), as well as to (synchronized) movement responses to music (as in dance, or walking/running to music). Much like playing a *traditional* musical instrument, learning to play an electronic and/or digital instrument for gesture-based musical expression (e.g., http://www.nime.org/archive/) requires sensory-motor association learning in which action and perception become intricately interwoven. Playing such an instrument can be considered a goal-directed, intentional act, with the production of sounds being a primary goal. Reaching that goal requires obtaining knowledge about the relationship between the actions afforded by the instrument, and the auditory consequences of these actions. This knowledge is gradually acquired by exploring and manipulating the possibilities afforded by the instrument using (at first) arbitrary actions that lead to (at first) unexpected auditory events [37.37]. In that process of exploration and interaction, one systematically and repeatedly associates performed actions with heard sounds. At that point, playing an instrument may become a goal-directed act, in the sense that performers have the ability to exert control over the auditory outcome of performed actions. Similarly, body movement responses to music are often (spontaneously) performed in synchrony with particular musical structures, most often the musical beat. Auditory–motor synchronization, or *entrainment*, requires finely-tuned sensorimotor coordination to align spatiotemporal motor patterns with musical features. A successful alignment requires prediction mechanisms to anticipate forthcoming events. Accordingly, the successful prediction of how musical passages unfold may arouse feelings of reward, and even an imaginary sense of control, or *agency*; as if one produces the music oneself (e.g., air guitar).

To conclude, the proposed model incorporates aspects of reward, motivation, and affect into the design of music-based interaction technologies. Taking into account this motivational aspect in relation to the cognitive aspect (e.g., learning, prediction), an important challenge lies ahead. We have shown that the reward system capitalizes on prediction mechanisms that relate to music listening as well as to the (implicit or explicit) knowledge of how specific actions lead to specific sensory outcomes. Up until quite recently, it has been argued that reward outcomes are dependent on successes as well as on failures in prediction, or in other words, on confirmed as well as violated expectations [37.35]. However, it is of valid interest

to consider the roles of sensorimotor control (when sensorimotor expectancies are confirmed and thus provide a sense of control), and of surprise and novelty (when sensory outcomes do not match the expected outcomes) [37.36]. Additionally, it is important to note that prior experiences define, to a large extent, the reward values and outcomes of specific interactions. Therefore, music-based interaction technologies should ideally be capable of taking into account user-related backgrounds.

The focus on the human reward system extends our model, which views mediation technologies as tools to intervene and augment the action–perception loop involved in music-based interactions. In a sense, technologies may be considered tools that *grant access* to the human reward, and by extension the physiological response system. Sensorimotor interaction processes could arouse feelings of reward and pleasure, and in reverse feelings of reward and pleasure may evenly facilitate sensorimotor (learning) processes.

37.3 Social Interaction

Music-based interaction systems often function within a social context. Music is indeed a particularly powerful medium that brings people together, as it invites people to dance or to produce music together. Accordingly, music provides an excellent platform to express, share, and understand other people's emotions in a direct, nonverbal way. Research suggests that understanding the feelings and emotions of others (i. e., *empathy*) is, at least partly, an action-based process modulated by the human mirror neuron (HMN) system [37.38]. The main idea is that the mere observation of another person's behavior activates (simulates) corresponding motor representations in the brain of the observer, which facilitates psychological inference about the other person's mental state, and subsequently the person enters in an empathic relationship. Another characteristic of many social interactions, apart from empathy, is *joint action*, a concept referring to situations where actions are coordinated in conjunction with others in order to reach a shared goal. These two concepts, empathy and joint action share a common denominator in that they both promote prosocial behavior and, by extension, may positively contribute to people's happiness, well-being, and health. Multiuser social music systems are perfectly suited to stimulate communication and interaction in socially situated activities [37.39, 40]. For instance, listening to music solicits people to move in synchrony with each other, which may reinforce empathic relationships. Also, producing music engages and challenges people to jointly coordinate their actions in order to realize a particular musical (expressive) outcome [37.41–43]. Thereby, new technologies offer a wide range of opportunities to reinforce these interactions. For instance, motion capture technologies enable a transfer of body movements into multisensory representations, which may help people to align rhythmical body movements (visual, auditory, tactile, etc.). Digital audio signal processing technologies and (online) music databases also offer opportunities for people to experience a wide range of appealing auditory stimuli (for listening and production purposes). Additionally, online new media applications enable people to connect worldwide in their shared interests. Our main point here is to emphasize the idea that technologies serve not only to reinforce coupled action–perception processes and emotion-regulating processes in individuals, but also the interactions of these processes in social contexts.

37.4 Monitoring, Motivation, and Alteration

The above model suggests that engagement with music, in its broadest form, impels interactions between a wide range of brain functions involving cognitive, sensory, motor, and reward/emotion-related systems. The central point of this chapter is to consider the role new technologies take in reinforcing and extending these interactions, enriching people's engagement with music, and developing domain-general cognitive, social, and affective skills. In the following, building on the standpoint of recent overviews of embodied theories on perception, cognition and behavior [37.44], we consider the motor functions to be of central importance. Related to the design of music-based interaction technologies, motor functions can be approached from different perspectives. In the model that we introduce here, we consider three main perspectives; namely, how music-based interaction technologies can facilitate the monitoring, motivation, and alteration of actions and behavior [37.22].

Monitor Actions: Just as with any other type of human behavior, the active engagement with music

(e.g., dancing, performing) relies on an internal feedback mechanism that continuously monitors on-going behavior and provides the basis for a self-reflective psychological judgement about the appropriateness of one's musical behavior [37.45]. The feedback is generated in different sensory modalities (auditory, visual, tactile, kinaesthetic, and vestibular) and informs the degree to which musical intentions are successfully realized. This relies on the prereflexive control of actions, which is based on the combination of forward and inverse models: they enable a nonconscious comparison for the prediction of an action with the perceptual inputs [37.46]. When the coupling between actions and perception is experienced as matching, that is, when the outcome of an action satisfies the anticipated results, it generates a sense of being in control and of being the cause of altered inputs [37.47, 48]. Mediation technologies enable quantifying and displaying aspects of motor behavior. By externalizing internal feedback mechanisms, i. e., translating actions into various sensory information streams, they increase the perceptual experience of one's own body (*body image*) and stimulate the awareness of self-generated movements. As such, attention might be directed to previously nonconscious operations of the body (*body schema*) making it possible to affect these operations [37.49]. This is particularly interesting as the body tends to efface itself from conscious experience in most behavior. Therefore, motor aspects of behavior (e.g., performance) might disappear under the radar of bodily awareness, including aspects that might hinder or even prevent an intended result (e.g., a technically smooth and expressive performance). Augmenting the natural monitoring mechanism with technologies that enable the objective measurement of motor behavior and the translation of the measurement into different kinds of feedback might optimize the fine-tuning of action–perception couplings, the unconscious monitoring of the body (body schema) and, subsequently, the general movement performance quality and efficiency. The use of sound and music in sonification or auditory display systems has been shown to be of particular relevance to improve various forms of movement behavior (for reviews, see [37.50, 51]).

Motivate to (inter)act: Music is known for its motivational qualities in exercise and sports [37.6, 7]. The motivational qualities of music have been attributed to four hierarchically related factors: rhythm, musicality, cultural impact, and association [37.7]. This aspect of motivation is closely related to the concept of reward as discussed earlier.

Alter actions: In many music-based interaction systems, one tries to guide movement behavior towards specific goals. Here, we introduce two strategies that may be applied to realize this goal. Both are informed by fundamental knowledge of sensorimotor control processes. These two strategies, based on synchronization and prediction mechanisms, can be applied in a wide range of domains where the goal is to have an impact on people's movement behavior (e.g., sports, musical instrument practice, motor rehabilitation, motor retraining, interactive sonification, social interaction, etc.).

37.4.1 Spontaneous Synchronization

Humans have a natural tendency to synchronize their movements with external rhythmical stimuli or with the rhythmical movements of others. Research suggests that spontaneous synchronization is a dynamical, self-organizing principle that strives towards finding stability (e.g., phase-locking) between people and their external environment [37.52–54]. This spontaneous drive towards synchronization can be used in the design of music-based interaction systems to steer the users' movement behavior towards specific goals by means of a specific presentation and/or manipulation of musical stimuli and/or auditory feedback [37.55, 56].

37.4.2 Spontaneous Motor Adaptation

The mechanism of motor adaptation offers another strategy on which music-based interaction systems can capitalize. This adaptation mechanism relies on learned sound–movement relationships, typically named *internal models*. Once internal models are developed, they enable a prediction of the auditory outcome of planned actions [37.22]. When a mismatch occurs between the expected and the actual outcome of performed actions, these actions will be altered in order to reduce prediction errors [37.57–63]. Sensorimotor adaptation is exactly that: a process in which motor commands are updated in response to altered environmental conditions. Accordingly, one can take advantage of this adaptation mechanism to guide people's movement behavior, first by developing sound–gesture relationships (through associative learning processes), and second by a deliberate manipulation of the self-generated auditory feedback.

37.5 The Evaluation of Music-Based Interactive Systems

The above-described perspectives emphasize the possible benefits of music-based interaction systems. Indeed, from a theoretical point of view, they hold promising potential. Also, a growing number of empirical studies suggest that the realization of this potential is feasible. However, careful consideration and adopting a critical stance towards their design, development and implementation are needed. Each of the presented perspectives conceals, equally, a potential disadvantage to the development of the proposed aspects (e.g., learning and reward) of technology-based musical interactions. For example, interactive systems that focus on monitoring may increase cognitive load, create dependency or stimulate an internal focus [37.64]. Interactive systems that focus on motivating behavior may succeed in providing experiences that are fun at first glance, but fail to generate the desired long-term effects. By acknowledging these potential pitfalls, we believe that introducing empirical testing and evaluating music-based interactive systems is of vital importance. Indeed, there are currently several approaches at our disposal. For example, one of the emerging approaches for testing and evaluating interactive music systems is to borrow tools and techniques from human–computer interaction (HCI), often focusing on the usability of controllers and interfaces [37.65–67]. Another approach focuses on measuring (video observation, questionnaires) the quality of the subjective experience while engaging with an interactive music system (e.g., [37.68, 69]).

However, empirical studies are scarce and often encounter problems of methodological robustness. For example, with regard to sonification, *Dubus* and *Bresin* [37.50] state that a proper evaluation of mappings is performed only in a marginal proportion of publications. *Collins* and *d'Escrivan* [37.70] observed that the evaluation of IMSs has often been inadequately covered in reports. With regard to educational interactive systems, *Nijs* and *Leman* [37.64] argue that studies are often based on one-time experiences, a limited number of participants and a lack of statistical analysis to support the findings.

In our view, the presented conceptual model provides a framework for the development of adequate evaluation methods and robust experimental designs based on qualitative and quantitative measurement. Our work suggests that the development of interactive music systems needs to appeal to the cognitive architecture encompassing the basic mechanisms (e.g., reward, prediction) that underlie musical interaction. As such, the evaluation of interactive music systems can probe the degree to which aspects of the system (e.g., feedback, controller) intervene with these basic mechanisms. For example, concerning the use of visual feedback, evaluative methods can be developed in order to determine how different kinds of visual feedback (e.g., concurrent versus terminal, actual versus modified, static versus dynamic) affect prediction mechanisms and, consequently, the reward system. Concerning the use of different movement sensing controllers, evaluation methods can be developed that probe qualitative changes in the use of the body while performing.

Evidently, the development of technology evaluation methods work in tandem with the development of methods used to evaluate aspects of musical interaction such as musical understanding (e.g., structure, harmonic progression) and creativeness.

To conclude, the empirical testing and evaluation of interactive systems is in need of an elaborated framework that would form the basis upon which the construction of robust empirical designs can be set. We believe the presented model illustrated here serves as the basis for such a framework.

37.6 Some Case Studies of Applications and Supporting Research

The following provides two examples of music-based interaction applications to illustrate some of the key assets of the introduced conceptual model.

37.6.1 Music Paint Machine

The Music Paint Machine (MPM) is an educational technology that allows a musician to create a digital *painting* by playing music while making various movements on a colored pressure-sensitive mat [37.69, 71] (Fig. 37.2).

The overall objective of the MPM is to support instrumental music learning and teaching by assisting the development of (1) musical creativity, (2) an embodied understanding of music, and (3) an optimal relationship between musician and musical instrument [37.72]. Interaction with the MPM is based on the real-time monitoring of a player's music and movement, and on translating extracted sound and movement parameters into a clear, visual representation. In this way, the MPM intervenes in the player's action–perception loop by complementing the *natural* multisensory monitoring

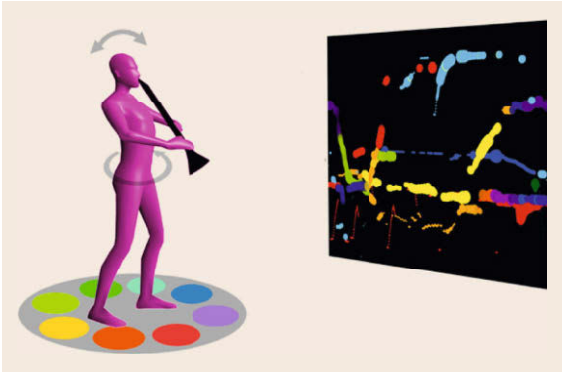

Fig. 37.2 The Music Paint Machine

of one's music playing with immediate (real-time) and unambiguous (based on objective measurement) visual feedback. Through the repeated multimodal experiences in which the visualization provides concurrent feedback on sound and movement, the sensorimotor couplings that occur during the initial trial and error experiences are gradually refined and consolidated into the mental schemas that realize the tight action perception couplings that underlie the interaction with the system (and the musical instrument). These mental schemas are composed of forward and inverse models [37.73]. Due to the tailor-made composition of the MPM's software (e.g., mapping, backgrounds), different activities can be designed in order to shape the development of these internal models [37.64]. For example, to train an inverse model, the system can provide learners with a target painting (e.g., a straight line that increases in stroke size). The learner then *copies* this while playing the instrument. Learners are then challenged to imagine the musical goal (play a long note with crescendo) and this would be shown in the model painting. To generate the appropriate motor command (e.g., blow harder) would be realized in the associated sensory outcome that would imitate the model. To train forward models, learners can be asked to perform specific tasks (e.g., play one note louder, increasing in volume), and the painting would provide information on the sound produced. Here the actual outcome (e.g., a somewhat curved line with increasing stroke size) might not concur with the expected outcome (e.g., a straight line with increasing stroke size), which will thus urge the player to adjust their motor commands (e.g., better breath support) in the next trial. Gradually, the learner will be able to predict the sensory outcome that follows a certain motor command with greater ease. Moreover, placing a visual representation of the desired and the actual outcome side by side on the screen can facilitate the interaction between the partnership of teacher and learner. Importantly, the MPM's visualization of music and movement goes beyond the mere provision of visual feedback. It invites users to creatively use music and movement in order to obtain a personalized outcome: namely, the digital *painting*. Accordingly, it allows a musician to reach out and engage with a new realm of experience, constituted by the combination of music, movement and visuals, and to discover novel ways of music making. It allows players to deliberately manipulate the self-generated visual feedback and, reinforced by straightforward mapping, stimulates implicit learning (because the focus is on the *painting* of auditory–motor couplings). Therefore, besides appealing to the motor adaptation mechanism to consciously guide music playing, the MPM may also enable a more accurate spontaneous motor adaptation of pre-established goals and artistic intentions. Furthermore, engaging with the system appeals to the human reward system. Next to supporting prediction mechanisms (based on the real-time visual feedback), the system could possibly facilitate the occurrence of an optimally pleasurable experience (flow experience, feeling of presence [37.69, 71]). Flow experience, which is a highly intrinsically rewarding state [37.74], has previously been related (mainly from a theoretical point of view) to the release of dopamine in the brain [37.75]. The MPM facilitates a broad range of activities (e.g., challenging games, creative painting) that foster surprise (*Hé, did you see that, I painted a . . .*) and injects added novelty into playing music, while at the same time, error prediction mechanisms are activated due to the system's mapping strategies. To conclude, the MPM has the potential to monitor, to motivate and to alter musicians' actions while playing a musical instrument. We believe this approach positively contributes to the development of genuine musicianship.

37.6.2 D-Jogger

D-Jogger is a technology that facilitates the synchronization of human movement to music [37.55, 56]. It is an example of a system that interrupts the human action–perception cycle (Fig. 37.3). It functions by spontaneously changing human activity at a subliminal (nonconscious) level. The technology has been developed primarily for walking and running applications, but it can also be coupled with biological rhythms, such as breathing and heart rate.

The overall objective of D-Jogger is to manipulate the tempo and phase of music such that it becomes possible to walk or run in synchrony with the beat of the music. D-Jogger can be understood as a technology that aligns two coupled rhythms: a musical rhythm with a movement rhythm (or a gait pattern). This alignment

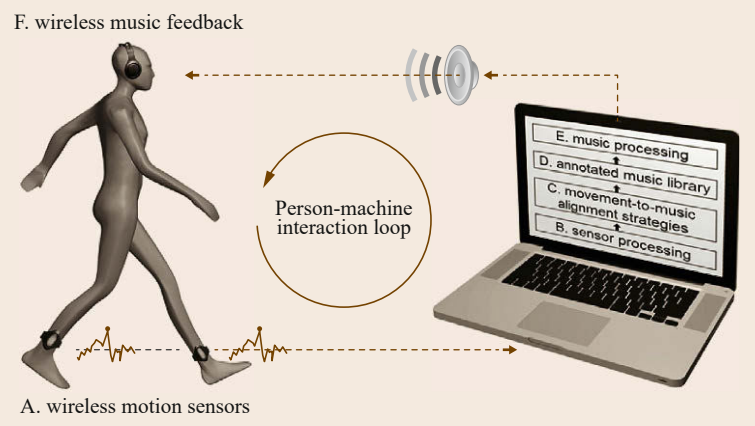

Fig. 37.3 Smart music player: person–machine interaction loop and the main components involved

is based on the timing of two salient moments of these rhythms: the musical beat and the footfall (i. e., the moment when the foot hits the ground). D-Jogger does this by monitoring the movement rhythm, using sensors (such as accelerometers or gyroscopes) that measure the timing of the gait pattern. Once the tempo is found, it looks for music which comes as close as possible to the tempo. Then it adapts the music tempo (by a stretching technique known as phase-vocoder) altering the music to match the gait tempo. The next step is then an adjustment of the phase such that beat and footfall can be precisely predicted.

D-Jogger intervenes in the human action–perception system, in particular with the internal models that predict the (perceptual) arrival of the musical beat, and thus the proper gait patterns are activated to allow for a match of the footfall with the beat. D-Jogger offers several options to control this match. One of the options is to ensure that the song starts in the same tempo as the tempo of the gait pattern, irrespective of whether the beat starts at the same moment of the footfall. For example, the music can have the same tempo of the gait, but the beat may not match the footfall. In that case it is likely that the human movement rhythm will be entrained and automatically adjust itself to match the beat. Apparently, internal forward models adjust the phase of the human movement rhythm at a subliminal level, which is an example of spontaneous motor adaptation. Interaction with D-Jogger has a strong rewarding effect because it facilitates synchronization. Being able to synchronize gives a feeling of control and satisfaction that is energizing and empowering.

37.7 Conclusion

Music is ubiquitous in people's daily lives. The accessibility of music and music services has grown exponentially in the past few years, and makes up an important part of a popular lifestyle. Music is a powerful medium because interaction with music taps into various cognitive, sensory, motor, and emotion regulation processes, and can lead to social interactions. In this chapter, we discussed the role that new electronic and digital technologies could play in reinforcing music-based interactions. In so doing, we have introduced a conceptual model that provides a framework upon which a vast number of music-based applications have already been developed, as well as offering a guide for future developments in this domain. The crux of the model is the idea that technologies function as extensions of the natural cognitive, perceptual, physical, physiological, and social dispositions and capabilities of human beings. Thus, technologies profoundly change and enrich people's experiences and interactions with their sensory and social environment, and help to develop people's social, cognitive, motor, and affective skills. The central mechanism in which music technologies can intervene is the coupled action–perception loop that is central to how people engage in a manifold of musical activities, such as music performance, music listening, and dance. In all of these activities, motor control and behavior, and sensory information processing become reciprocally linked. Further, we have discussed how this action–perception loop, and in particular the role of music-based interaction systems therein, further links to physiological processes related to reward, and to social communication and interaction. Following embodied theories on perception, cognition and behavior, we emphasized the role of the human body, and its actions, in

the design of music-based interaction systems. In that context, we have outlined three important perspectives that music-based systems may consider; monitoring actions, motivating actions, and altering actions. The last perspective is especially innovative, and it would be interesting to further explore this perspective in, for example, the context of interactive sonification systems.

This chapter was not intended as an overview of existing music-based technologies. Given the colossal number of realizations, this would be an impossible endeavor. Rather, we wanted to introduce a theoretical and conceptual perspective on the design of music-based interaction systems. Thus, we discussed some key concepts that could frame previous realizations, but more importantly, we hope that they can guide future developments in the field. Our discussion made clear that the design of music-based interaction systems is a highly complex task, as it incorporates knowledge and draws on expertise from several fields of practice and research. Alongside the engineering aspect, the design of music-based interaction systems must be informed by fundamental research on psychological, physiological, and social mechanisms, and incorporate viable educational methods. Therefore, the development of music technologies should ideally be realized in close collaboration with the sciences, the arts, and educational practices.

38. Methods for Studying Music-Related Body Motion

Alexander Refsum Jensenius

This chapter presents an overview of some methodological approaches and technologies that can be used in the study of music-related body motion. The aim is not to cover all possible approaches, but rather to highlight some of the ones that are more relevant from a musicological point of view. This includes methods for video-based and sensor-based motion analyses, both qualitative and quantitative. It also includes discussions of the strengths and weaknesses of the different methods, and reflections on how the methods can be used in connection to other data in question, such as physiological or neurological data, symbolic notation, sound recordings and contextual data.

38.1 Some Key Challenges

The last decades have seen a rapid growth of interest in studying *music-related body motion*, that is, all types of human motion that appear in a musical context [38.1–4]. This includes the motion carried out by *performers*, such as musicians, conductors and dancers, and the motion of *perceivers*, such as that of audience members during concerts, people dancing at clubs, or people's spontaneous motion to music in everyday life. As such, music-related motion is a functionally diverse category, ranging from describing purely instrumental motion (such as hitting a piano key with a finger) to purely communicative motion (such as gesticulating in the air with the arms). Furthermore, music-related motion may occur in any type of location, for example in a concert hall, at home, or in the street.

The challenge for musicologists interested in studying motion as part of their empirical material is to choose methods that allow for studying such motion in a systematic manner. However, before deciding on a methodological approach, it is important to properly evaluate the content and context in which the motion is to be studied. Some questions to consider are:

- Aim: why is music-related motion interesting in this study? What kind of interaction is planned (sound–human, human–sound, human–human)?
- Subjects: how many subjects will be studied? What is their demography (gender, age, music/motor abilities) and personal context (familiar/unfamiliar with the task)? Will they move individually or in groups? What is the social context of the study?
- Motion: what type of motion is expected, and in which parts of the body? Are they large or small? Are they slow or fast? Will the subjects be stationary, or will they move about? Is it necessary to find the absolute position in space, or is relative motion information (such as acceleration) sufficient?
- Environment: will the study be carried out in a *controlled* environment (such as a lab) or in an *eco-*

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_38

logical setting (such as a concert hall)? Is power available? How much time is there to set up equipment? What are the lighting conditions?
- Artifacts: will there be any instruments, tools or other types of technologies used in the setup, and how will they be captured and synchronized?
- Audio: what type of sound recording is needed? How many channels? What sampling frequency and bit rate? What is the necessary level of synchronization between motion and sound data?
- Video: what type of video recording is needed? How many cameras? What resolution and frame rate?
- Data handling: how will the different types of data be synchronized? What software and data formats will be used? What type of storage, backup, and sharing solutions are planned?
- Analysis: what type of analysis is planned? What types of visualizations are needed? What types of features will be extracted?

When it comes to the latter – analysis – there are numerous approaches to choose from, but they can be broadly categorized into two main categories:

- Descriptive analysis: the motion is described through *kinematics* (such as velocity or acceleration), *spatial features* (such as size and position in the room) or *temporal features* (such as frequency).
- Functional analysis: the motion is described through functional properties, such as whether the actions are sound-producing or sound-accompanying (see [38.5] for an overview of functional categories).

The former may often be associated with quantitative analysis approaches, such as using statistical methods on numerical data, while the latter may be based on qualitative analysis approaches. In most cases, however, one would typically need to carry out both descriptive and functional analyses, and utilize both qualitative and quantitative methods. As such, the methods should be seen as complimentary rather than competing.

This chapter will not focus on the analytical methods per se, but rather on methods that prepare the ground for such analyses to be carried out. We will begin by presenting a few methods for qualitative motion analysis, before moving to some quantitative approaches.

38.2 Qualitative Motion Analysis

There exist numerous systems for systematic notation, analysis and exploration of body motion from a qualitative and observational point of view, including the Alexander technique [38.6], Rolfing [38.7], expressive motion [38.8], Dalcroze [38.9] and Benesh [38.10]. Several of these systems were developed in parallel to, or influenced by, the work of Rudolf Laban (1879–1954). Here we will look more closely at two of Laban's methods: *Labanotation* and *Laban Movement Analysis* (LMA).

38.2.1 Labanotation

Rudolf Laban worked as a dancer and choreographer before he became interested in the description and analysis of human motion at large, with the aim of developing a universal system for motion analysis. For that reason he spent time studying all sorts of human motion, including that of factory workers. In 1928 he presented a system called *Schrifttanz* [38.11], a method for the notation of motion as symbols along a vertical axis. This system was later to become *Labanotation*.

When writing a motion score through Labanotation, it is common to start with a description of *motifs*. These motifs are reduced versions of a full score, and they provide a rapid approach to writing down the main elements of a motion sequence. This first sketch is later used to write a more detailed Labanotation based on a structured set of symbols allowing for the notation of any type of motion of any body part. Figure 38.1 shows examples of Labanotation, with time running vertically, from bottom to top. The vertical line in the center of each notation system marks the center of the body, and

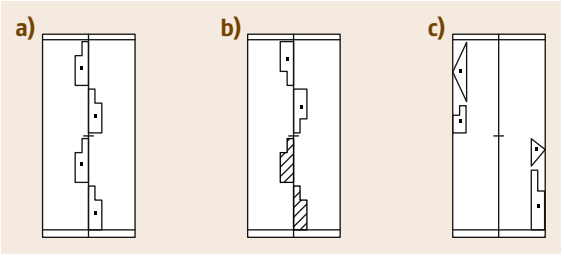

Fig. 38.1a–c Three short motion sequences written in Labanotation, with time running vertically from bottom to top: **(a)** normal walking forwards with right and left feet; **(b)** right and left feet moving forwards on their toes, followed by walking backwards; **(c)** right side of the body moves forwards and then to the right, followed by the left side of the body leaning forwards and then to the left

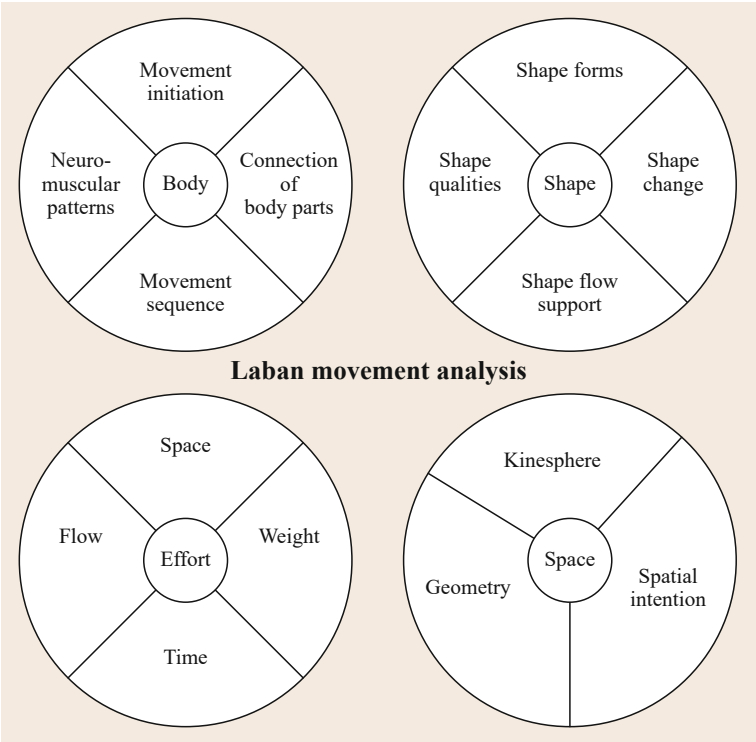

Fig. 38.2 Overview of all the categories in Laban Movement Analysis (LMA)

motion is notated through symbols on the left and right sides of the center line. Each of the body parts has their own symbol, and the duration of motion and position are given through different types of symbols inside the shapes of the body parts.

Although not very widespread, Labanotation is still in active use today, particularly in larger ballet and dance companies. There are also examples of the scholarly use of Labanotation, with an increasing interest from researchers within human–computer interaction and machine-assisted motion analysis [38.12]. However, the complexity of the system means that very few people really master Labanotation at a level with which they can read and write scores fluently. So, as opposed to music notation, which one can easily assume that most musicians and music researchers master well, it is hard to find people that can comfortably read and write Labanotation outside specialized circles.

38.2.2 Laban Movement Analysis

The theoretical basis for the Labanotation system was developed within a framework that has later been called *Laban Movement Analysis* (LMA). Even though Labanotation and LMA coexist, they can be used independently of each other. In fact, the LMA has received more widespread usage than Labanotation, also within the study of music.

As opposed to Labanotation's focus on writing motion structures in time, the LMA system is based on describing motion qualities. Fundamental to using the LMA is that the analysis should always start from the observer's point of view, and by asking the question *how does this motion feel from my own body?* [38.13]. As such, the LMA is by default subjective, even though it aims at being a general method for the observation of motion.

The LMA system is based on four main categories: *body*, *space*, *shape* and *effort*, each of which are subdivided into categories describing different motion qualities, such as outlined in Fig. 38.2. In this context we will mainly focus on one of the four main categories, the *effort* element [38.14], which has proven to be particularly relevant for musicological studies.

The effort category can be further divided into four subcategories, each with a descriptive axis:

- Space (direct–indirect). Space describes how one moves through the physical space, and how one relates to the body's *kinesphere*, the maximal volume we can reach around our body when standing fixed on the floor.

- Time (quick–sustained). Time is used to describe the rhythmic character of motion. Laban was concerned that time and rhythm should not be split. We experience rhythmical patterns all the time, and we have our own bodily rhythms defined by our pulse and breathing.
- Weight (strong–light). Weight is related to gravity, and the fact that we need to use muscular activity to work against gravity when moving upwards. We also use gravity to help us when moving downwards, and it is this constant interplay between our body and the Earth's gravitational pull that help shape our motion.
- Flow (bound–free). Flow describes how motion unfolds in time and space. Free-flow motion is both relaxed and continuous at the same time, while bound flow is when the motion is hindered.

Even though the four effort parameters are but one small part of the full LMA system, they have been used separately in several musicological studies, including sound–motion correlations in free dance to music [38.15], the phrasing motion of clarinetists [38.16], and relationships between music, emotion and dance [38.17].

38.3 Video-Based Analyses

If thinking about an axis from purely qualitative methods to purely quantitative, video-based analyses can be argued to cover quite a large part of the axis. For example, having a video recording that can be played back multiple times, and at various speeds, is very useful for carrying out LMA analysis. And, as we shall see in the next section, even a regular video recording can be used to extract meaningful quantitative motion data. Furthermore, it is also common to use video recordings as a reference when recording motion with sensor-based motion tracking technologies. In such cases, the video recording can be used to help the qualitative interpretation of numerical results.

For many applications, a regular video recording is often the easiest, fastest and cheapest solution to start working systematically with the study of music-related motion. Nowadays, everyone has access to high quality video cameras even in their mobile phones, and the cost of professional-quality video cameras is also within the reach for many. The main challenge for musicologists, then, is to record the video in a manner suitable for later analysis.

38.3.1 Recording Video for Analysis

One thing to bear in mind is that a video recording meant for analytical purposes is quite different from a video recording shot for documentary or artistic purposes. The latter type of video is usually based on the idea of creating an aesthetically pleasing result, which often includes continuous variation in the shots through changes in the lighting, background, zooming, panning, etc. A video recording for analysis, on the other hand, is quite the opposite: it is best to record it in a controlled studio or lab setting with as few camera changes as possible. This is to ensure that it is the *content* of the recording, that is, the human motion, which is in focus, not the motion of the camera or the environment.

Even though a controlled recording environment may be the best choice from a purely scientific point of view, it is possible to obtain useful recordings for analytical purposes also out in the field. This, however, requires some planning and attention to detail. Here are a few things to consider:

- Foreground/background: place the subject in front of a background that is as plain as possible, so it is possible to easily discern between the important and nonimportant elements in the image. For computer vision recordings it is particularly important to avoid backgrounds with moving objects, since these may influence the analysis.
- Lighting: avoid changing lights, as they will influence the final video. In dark locations, or if the lights are changing rapidly (such as in a disco or club concert), it may be worth recording with an infrared camera. Some consumer cameras come with a *night mode* that serves the same purpose. Even though the visual result of such recordings may be aesthetically unsatisfactory, they can still work well for computer-based motion analysis.
- Camera placement: place the camera on a tripod, and avoid moving the camera while recording. Both panning and zooming makes it more difficult to analyze the content of the recordings later. If both overview images and close-ups are needed, it is better to use two (or more) cameras to capture different parts of the scene in question.
- Image quality: it is always best to record at the highest possible spatial (number of pixels), temporal (frames per second) and compression (format and ratio) settings the camera allows for. However, the

Fig. 38.3 A *motion image* is created by subtracting subsequent frames in a video file (Frame (2) minus Frame (1))

Fig. 38.4 Individual motion history images of 14 separate percussion strokes allow for studying stroke heights and patterns. The images have been made by adding a motion history image on top of a picture of the scene, thus showing both motion features and the contextual information

most important is to find a balance between image quality, file size and processing time.

As mentioned earlier, a video recording can be used as the starting point for both qualitative and quantitative analysis. We will here look at a couple of different possibilities, moving from more qualitative visualization methods to advanced motion capture techniques.

38.3.2 Video Visualization

Videos can be watched as they are, but they can also be used to develop new visualizations to be used for analysis. The aim of creating such alternate displays from video recordings is to uncover features, structures and similarities within the material itself, and in relation to, for example, score material. Three useful visualization techniques here are *motion images*, *motion history images* and *motiongrams*.

Motion Images

One of the most common techniques when working with motion analysis from video files is to create a *motion image* by calculating the absolute pixel difference between subsequent frames in the video file (Fig. 38.3). The end result is an image where only the pixels that have changed between the frames are displayed. This can be interesting in itself, but motion images are also the starting point for many other video visualization and analysis techniques.

Motion History Images

Motion images only display the motion happening between two frames in a video file, but often it is desirable to visualize motion over a period of time, say a few seconds. This can be done through *motion history images* that display the temporal development of a motion sequence. There are numerous ways of creating such displays [38.18], but many of the most common techniques are based on adding several motion image frames together. The usefulness of motion history images depends on carefully selecting a time window that fits the content of the motion, as can be seen in the examples of percussion strokes in Fig. 38.4.

Motion history images have been used in various types of music analysis, such as in the study of music and dance [38.19], and are also often to be seen in visual arts and creative practice.

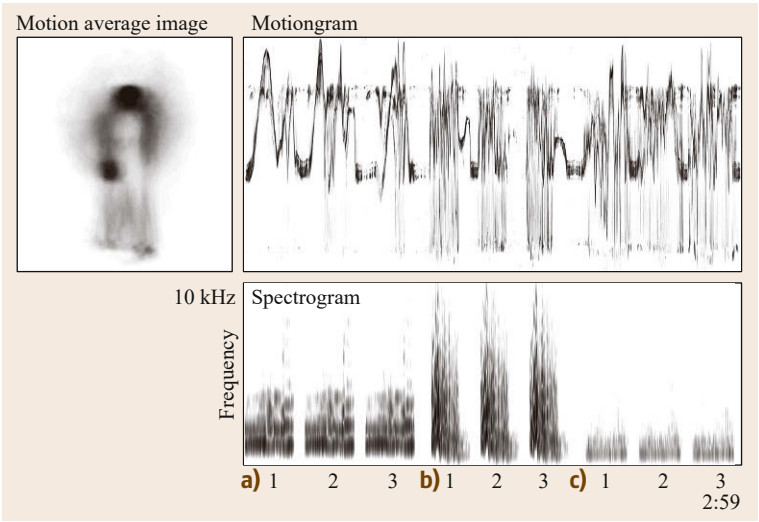

Fig. 38.5 A motion average image and a motiongram of a three-minute free-dance sequence to music make it possible to study both spatial and temporal features of a performance in connection to the spectrogram of the audio

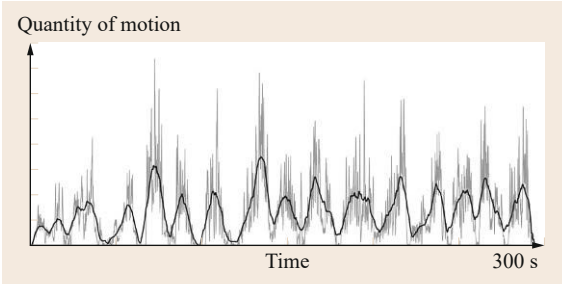

Fig. 38.6 A plot of the quantity of motion for a five-minute long dance sequence. The gray line is a plot of the tracked data, and the black line is a filtered version of the same dataset

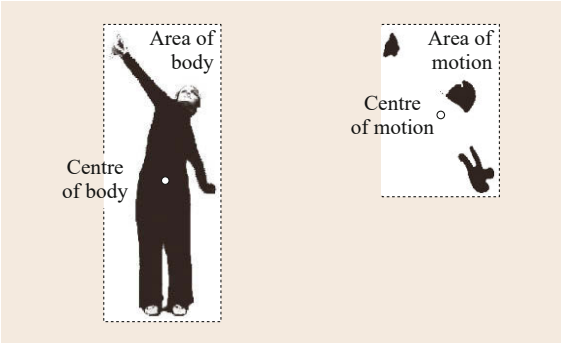

Fig. 38.7 Illustrations of the area and centroid of body and motion

Motiongrams

While a motion history image may reveal information about the spatial aspects of a motion sequence over a fairly short period of time, it is possible to use a *motiongram* to display longer sequences [38.20]. Figure 38.5 shows a motiongram created from a dance improvisation recording, and this display is created by plotting the normalized mean values of the rows of a series of motion images. The motiongram makes it possible to see both the location and quantity of motion of a video sequence over time, and is thus an efficient way of visualizing longer motion sequences.

A motiongram is only a reduced display of a series of motion images, with no analysis being done. It might help to think of the motiongram as a display of a collapsed series of pictures, or *stripes*, where each *stripe* summaries the content of a whole motion image.

Depending on the frame rate of the video file, motiongrams can be created from recordings as short as a few seconds to several hours. For short recordings it is possible to follow detailed parts of a body, particularly if there are relevant colors in the image, while motiongrams of longer recordings will mainly reveal larger sections of motion. Motiongrams work well together with audio spectrograms and other types of temporal displays such as graphs of motion or sound features.

38.3.3 Computer Vision

The broad field of *computer vision* (CV) is concerned with extracting useful information from video recordings. There is a lot of progress in the field, as summarized in [38.21–23], and we will here only look at a few possible methods.

Some basic motion features that are commonly used in music research are derived directly from the motion image. Since the motion image only shows pixels that have changed between the two last frames in a video sequence, the sum of the values of all these individual pixels will give an estimate of the *quantity of motion*

(QoM). Calculating the QoM for each frame will give a numeric series that can be plotted and used as an indicator of the activity, such as illustrated in the graph of a dance sequence in Fig. 38.6. Here it is possible to see where the dancer moved or stood still.

The *centroid of motion* (CoM) and *area of motion* (AoM) are other basic features that can easily be extracted from a motion image, and the differences between them are illustrated in Fig. 38.7. The CoM and AoM features can be used to illustrate *where* in an image the motion occurs as well as the spatial displacement of motion over time.

The field of computer vision has diverged into a number of different directions over the years. Most notably, there are now numerous methods available for tracking bodies and body parts in space, many of which are also being used in music interaction and analysis through tools such as EyesWeb [38.24], GEM for PureData [38.25] and Jitter for Max [38.26]. In addition to using regular video cameras for such analyses, there are several different types of specialized cameras that are made particularly for computer vision methods, including:

- Infrared cameras capturing only light in the infrared (nonvisible) range. Such cameras can be very useful in musical applications, since they work well also in dark spaces (such as a concert hall) or in locations with changing lights (for example club or stage lights).
- Time-of-flight cameras emitting a modulated acoustic signal and receiving the reflected signal from which it is possible to measure the time it took for the signal to return to the camera.
- Stereo cameras employing the same strategy as human vision, using two cameras next to each other (like our eyes), and then using the differences between the two images to estimate motion and rotation.

There are also examples of the combination of these three capturing methods, as well as the use of multiple cameras around the capture space. By combining multiple cameras distributed in space it is possible to create true three-dimensional recordings. This can now be done without markers on the body [38.27], but still the state-of-the-art when it comes to camera-based motion tracking are the marker-based systems using infrared cameras.

38.3.4 Infrared, Marker-Based Motion Capture

What many people refer to as *motion capture*, can more precisely be described as optical, infrared, marker-based systems. Such systems usually consist of at least six cameras positioned around the capture space (Fig. 38.8). Each of the cameras contains a ring of infrared light sources, and this infrared light is reflected on small markers and captured by the cameras. The system then calculates the exact position in space based on triangulating all the marker positions from each individual camera. The end result is a three-dimensional tracking of the markers in space, often captured at high speeds (more than 100 Hz) and at a high spatial resolution (in the range of millimeters). The captured points can be visualized directly or used as the basis for further analysis.

Fig. 38.8 Setup for motion capture of pianist Christina Kobb. In addition to the cameras placed in front, there are also cameras placed behind the pianist to capture the motion in three dimensions

An advantage of marker-based motion capture systems is that they allow for reliable tracking of the position (and sometimes orientation) of individual body joints. Furthermore, together with force plates and physiological sensors such motion capture systems may provide very precise and accurate data about the kinematics and kinetics of human motion.

There are, however, also some drawbacks of infrared, marker-based motion capture systems. The price tag is one, although such systems have become more affordable in recent years. More problematic from a user's perspective are the constraints enforced by the need of a controlled recording environment. Also, even though the markers used in such systems are small and lightweight, a recording session necessarily feels somewhat unnatural for the subjects. So when deciding on

whether to use such a system for a study, it is important to weigh the benefits of a high-quality motion recording against the obvious limitations of such an unecological setup.

38.4 Sensor-Based Motion Capture

Sensor-based systems are very different technologically to the camera-based solutions mentioned above. One main difference is that sensor systems are often modular, allowing for more flexibility when it comes to the types and numbers of *sensors* being connected to a sensor *interface*.

38.4.1 Sensor Interfaces

The sensor interface is the unit that digitizes the electrical signals coming from the sensors through an analog-to-digital converter (ADC), and which also contains the electronics needed for recording and/or connecting to a computer. Many sensors are analog and therefore have a theoretically infinite resolution, so the sensor interface is often the limiting factor of a digital sensor-based system. It is therefore important to choose a suitable sensor interface for the task [38.28], and some elements to consider are:

- Sampling rate: the speed at which the sensors are read, often ranging from a few to several thousands of samples per second.
- Bit rate: the resolution of each recorded sample, often ranging from 7-bit (like MIDI) to 10-bit or even higher.
- Connectivity: whether the interface is cabled or wireless, and the types of wired (USB, ethernet, etc.) or wireless (Wi-Fi, Bluetooth, etc.) connection being used.
- Power: whether the system needs external power or can run on batteries.
- Expandability: how many sensors that can be connected at the same time, and with what types of connectors.
- Size: anything from the smallest imaginable to fairly large-scale devices, typically dependent on all of the above together with the price.

Fortunately, sensor interfaces are constantly becoming smaller, faster, cheaper and more reliable, so there are numerous solutions to choose from, both ready-made and modular systems [38.28].

When it comes to the sensors themselves, there are many ways of classifying and evaluating these [38.29–32]. The presentation below follows the classification of tracking technologies used by *Bishop* et al. [38.33], in which the different systems are sorted according to the physical medium of the technology: *acoustic*, *mechanical*, *magnetic*, *inertial* and *electrical*.

38.4.2 Acoustic Tracking

Motion capture systems based on acoustic sensing use the principle of time-of-flight mentioned above, which measures the round-trip an acoustic signal takes from being transmitted, reflected on an object and received back at the sensor. In the same way as for infrared, marker-based systems, it is necessary to have multiple transmitter/receiver pairs to be able to estimate the three-dimensional position of an object through triangulation of the individual points.

Acoustic sensor systems usually work in the ultrasonic range, and can therefore be used unobtrusively for music-related applications. A challenge, however, is that such systems are often less accurate and precise for the spatial range of music-related motion. Thus acoustic tracking has received relatively little attention in music research, although there are some examples of its application in new electronic instruments [38.34, 35].

There are also some examples of the use of audible sound for motion tracking. One example is the walking experiment presented in [38.36], in which microphones were placed in the socks of participants, and periodicity peaks from the waveforms' amplitudes were used to measure the frequency of walking in relation to music.

38.4.3 Mechanical Tracking

Mechanical tracking systems are based on measuring angles, distances or forces, using potentiometers or sensors measuring flexing, stretching or force (Fig. 38.9). One advantage with mechanical tracking is that the sensors can easily be added to or embedded in suits, shoes and gloves, thus allowing for fairly unobtrusive tracking of body motion. Due to this versatility, mechanical systems have been popular for a lot of music applications, both for analysis and particularly for various types of electronic instruments and in interactive performance systems [38.37].

38.4.4 Magnetic Sensors

Motion capture systems using magnetic sensing are based on the idea of measuring disturbances in the mag-

Fig. 38.9 Examples of small and large force and bend sensors (*left*) and a custom-built glove with similar sensors built in (*right*)

netic field around the sensor. The perhaps simplest and cheapest of such sensors, *magnetometers*, are similar to a compass and measure the direction and strength of the Earth's magnetic field. Magnetometers are widely used in combination with inertial sensors (Sect. 38.4.5).

Active magnetic systems, on the other hand, are based on setting up a magnetic field around an electromagnetic source. Then one or more sensors can be used to measure the position of an object through sensing the induced electric current at a point in space (Fig. 38.10).

One advantage with magnetic tracking is that such systems can often track the three-dimensional orientation of an object (with each of the rotation axes often being referred to as *yaw*, *pitch* and *roll*) in addition to the three-dimensional position (with the axes being called *X*, *Y*, *Z*). Furthermore, magnetic tracking is generally quite accurate and precise, and allows for high sampling rates. Since such systems are cable-based, there are no problems related to occlusion of markers such as for camera-based systems.

Having to deal with cables is also one of the main negative aspects of magnetic systems, since the cables severely limit the physical range of the tracking. The perhaps biggest challenge, still, is that the systems are suspect to interference from ferromagnetic objects within the magnetic field [38.38]. This can be highly problematic in a musical context, since many musical instruments, including pianos, are constructed fully or partly with metal components.

Magnetic sensing has been used for a number of musical applications, both performance [38.39–41] and analysis [38.42–44]. However, with advancements in other tracking types, and particularly that of optical systems, the use of magnetic sensing has been in decline in recent years.

38.4.5 Inertial Sensors

Besides camera-based systems, *inertial* sensing is currently one of the most popular types of motion tracking.

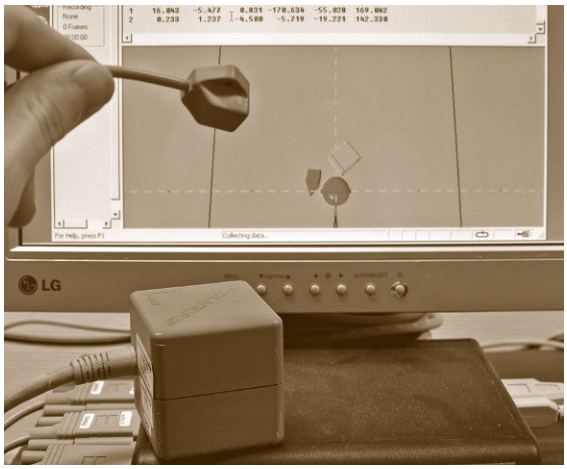

Fig. 38.10 One six-dimensional sensor (held in the hand) and the electromagnetic transmitter (on table) from a Polhemus Liberty magnetic tracking system. The image on the screen displays the position and orientation of the object in real time

The two main types of inertial sensors are *accelerometers* and *gyroscopes*, and both of these sensor types are based on measuring the displacement of a small *proof mass* inside the sensor. Accelerometers measure the positional displacement of an object, while gyroscopes the rotational. By combining three accelerometers and three gyroscopes it is possible to capture both three-dimensional position and three-dimensional rotation in one sensor unit.

One of the most compelling features of inertial sensors is that they rely on physical laws (gravity), which are not affected by external factors such as ferromagnetic objects or lighting. Since they do not contain any transmitters (like infrared cameras and acoustic and magnetic sensors) they can also be embedded in very small and self-contained units (Fig. 38.11), with low power consumption, and high sampling rates. These are probably some of the reasons why inertial sensors are now becoming integrated in a lot of technologies, further driving down the cost of single units and securing even broader integration in all sorts of electronic devices.

The downside to inertial sensing is that accelerometers do not measure the *position* of objects, but rather the rate of change of the objects. It is possible to estimate the position through integration, and, combined with the data from gyroscopes and magnetometers, this can lead to satisfactory results [38.45]. However, while the relative position estimates may be good, such position data often suffer from a considerable amount of drift [38.46]. One way to overcome some of the

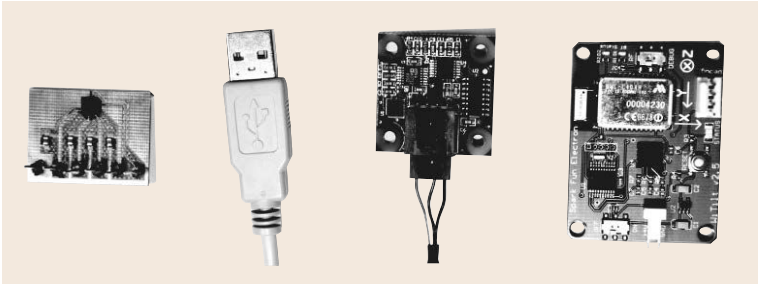

Fig. 38.11 Different types of home-made and commercial inertial sensing systems

Fig. 38.12 Yago de Quay performing with the Xsens MVN suit in Oslo, Norway (after [38.48])

Fig. 38.13 An example of music interaction with the commercially available Myo armband, which contains eight EMG sensors, accelerometers and gyroscopes (Photo: Kristian Nymoen)

drift problems is by combining inertial sensors with one or more of the other sensing solutions mentioned above [38.47]. One example of this can be found in the commercially available motion capture suits from Xsens, that combine a number of accelerometers, gyroscopes and magnetometers with a kinematic model of the body (Fig. 38.12).

38.4.6 Electrical Sensors

Sensors measuring the electrical current of *biosignals* have become increasingly popular for musical applications over the last decades [38.49]. Many such sensors, often also called *physiological* sensors, share the same sensing principle but are optimized to detect different types of biosignals:

- *Electromyograms* (EMGs) are used to measure muscle activity, and are particularly effective on the arms of musicians to pick up information about hand and finger motion [38.50]. Figure 38.13 shows an example of the commercially available Myo armband, with integrated EMG sensors, used for musical interaction [38.51].
- *Electrocardiograms* (ECGs) measure the electrical pulses from the heart, and can be used to extract information about heart rate and heart rate variability. The latter has been shown to correlate with emotional state [38.52].
- *Galvanic skin response* (GSR) refers to changes in skin conductance, and is often used on the fingers. The GSR signal is highly correlated with emotional changes, and such sensors have been used to some extent in music research [38.53, 54] as well as in music performance [38.49, 55]. However, the signals may not be entirely straightforward to interpret, and elements like sweat may become an issue when worn for longer periods of time.

- *Electroencephalograms* (EEGs) are used to measure electrical pulses from the brain, using either a few sensors placed on the forehead, or hats with numerous sensors included. Due to the weak brain signals, such sensors need to have strong amplifiers and are therefore also subject to a lot of interference and noise. Nevertheless, such sensors have also been applied in both music analysis and performance [38.56].

38.5 Synchronization and Storage

As mentioned in the introduction, some important challenges for music researchers working with any of the above-mentioned motion tracking solutions are to ensure synchronization with other types of data and to store the data in a structured way [38.57]. We will here briefly look into some possible solutions to these problems.

38.5.1 Motion Data Formats and Protocols

A number of formats exist for storing motion data, most of which were designed to solve the needs of a specific hardware system and/or research problem. The BRD format, for example, is used with electromagnetic trackers from Flock of Birds, while the C3D format is used for infrared motion capture systems from Vicon [38.58]. Several formats have also emerged for using motion capture data in animation tools, such as the BVA and BVH formats from Biovision, and the ASF and AMC formats from Acclaim, as well as formats used by animation software, such as the CSM format used by 3D Studio Max. There have been several attempts at creating XML-based (XML) standards for motion capture and animation data, such as the Motion Capture Markup Language (MCML) [38.59] and Multimodal Presentation Markup Language (MPML) [38.60]. But none of these nor the structures included in the MPEG-4 [38.61] and MPEG-7 [38.62] formats seem to have achieved widespread usage. Of all these, the C3D format seems to be the one that is supported by most software, although its implementation and number of features varies somewhat between different software solutions.

Since none of the other formats available solve the problems of music researchers, there have been several initiatives to create new formats and standards specifically targeted at music applications. The Gesture Motion Signal (GMS) format [38.63] is a binary format based on the Interchange File Format (IFF) standard [38.64], and was mainly developed for storing raw motion data. The Gesture Description Interchange File Format (GDIF) was proposed as a structure for handling everything from raw motion data to higher-level descriptors within other data formats [38.65], and has been successfully used within namespaces for the Open Sound Control (OSC) protocol [38.66] and as an extension to the Sound Description Interchange Format (SDIF) [38.67]. The Performance Markup Language (PML) was developed as an extension to the Music Encoding Initiative (MEI) [38.68] and focused on creating a structured approach to annotate performance data in relation to musical notation.

All of these formats and protocols solve some problems, even though none of them have emerged as de facto standards within the music research community.

38.5.2 Structuring Multimodal Data

Besides choosing a format for handling data, there are numerous conceptual and practical issues to deal with when working with music-related motion data. Different hardware devices use different protocols, formats and standards. They also work at different sampling rates, bit rates, with different numbers of sensors, different degrees of freedom, etc. Adding to this is the need to synchronize and store such data together with other relevant data, including MIDI data, audio and video files, as well as qualitative descriptors and various layers of analysis.

Fortunately, several software solutions have been developed for multimodal data acquisition and analysis, including the EyesWeb platform [38.69, 70], the MoCap Toolbox for Matlab [38.71], and various toolboxes for the graphical programming environment Max [38.44, 72]. There are also initiatives for creating online repositories for multimodal data storage and analysis, such as Repovizz [38.73]. In addition to helping in structuring and storing data, such systems also allow for carrying out collaborative and comparative studies on the same material.

38.6 Conclusion

In this chapter we have looked at a number of analytical approaches and technologies available for studying music-related motion, ranging from qualitative to quantitative, cheap to expensive, small to large, and simple to advanced. To simplify, we may differentiate between two main types of technologies used for motion tracking:

- Camera-based systems: this includes cameras of any sorts, recording in gray-scale, color or infrared, and recording with or without markers on the body.
- Sensor-based systems: this includes all sorts of sensors, including acoustic, mechanical, magnetic, inertial and electrical.

It is impossible to give one answer to what type of method or technology to use; they all have their strengths and weaknesses. For that reason it is important to decide on the right analysis method for the research question at hand. Perhaps the most decisive factor is whether to work in a laboratory setting or in a more ecological setting, say a concert hall, as this will to a large extent guide which methods and tools to use.

More specialized motion capture solutions, like infrared, marker-based systems, electromagnetic systems and various types of inertial sensors, often provide high recording speeds, and high spatial accuracy and precision, but they also come with several drawbacks. Price is one, although such systems have quickly become more affordable. More problematic is that the person being studied has to wear markers/sensors on the body, something that may be both alienating to the performer and obtrusive to the motion being performed. This is particularly problematic when using electromagnetic and mechanical systems with fairly large and heavy sensors and cables. But even the lightweight, reflective markers typically used in optical infrared systems are noticed by performers, albeit to a lesser degree.

Perhaps the biggest challenge with the larger systems is the nonecological setting they require. Small inertial systems, on the other hand, can be mobile, wireless, and more or less invisible, although the physical sensors need to be placed on the body. So if the aim is to study musicians in a real-world concert situation, regular video recordings may be the only realistic solution.

Apart from selecting the right technology, however, it is important to have a clear plan for what to record, have a structured approach to synchronizing the recordings with other data and media and to store the data using formats and protocols that maximize the potential for a diverse range of analytical approaches.

Part F Music and Media

Ed. by Isabel Barbancho

Music has been part of human beings since the very beginning. The opportunities for playing music, enjoying music, searching for music, producing music, learning music, composing music, etc. have evolved and changed through history in parallel with the developments of new technological possibilities and human knowledge itself.

Nowadays, digital technology has great impact on all aspects of our lives and music is one of them. Technology can enhance music in many ways. One of the key ways in which technology impacts music is that it makes lots of process related to music cheaper.

This section is devoted to showing how music, and people interacting with music in any sense, are affected by today's technology.

Digital technology used for music can be included in the music information retrieval (MIR) discipline. MIR is a truly interdisciplinary area, involving researchers, developers, educators, librarians, students and professionals from the disciplines of musicology, cognitive science, library and information science, computer science, electrical engineering and many others. This diversity gives an idea of how big the influence of music is in many aspects of life.

Specifically, in this section we will learn new approaches to finding music, new technologically driven possibilities for music learners, how technology can help hearing-impaired persons enjoy music, how the music industry has changed due to technology, new audio-signal processing approaches to better understand music evolution, new interactive possibilities for music, and how traditional music instruments can be enhanced to provide us with new possibilities.

Following this contextualization, a brief synopsis of each chapter now follows.

Chapter 39: *Juan Pablo Bello* et al., in their chapter *Content-Based Methods for Knowledge Discovery in Music*, present several computational approaches aimed at supporting knowledge discovery in music. They combine data mining, signal processing and data visualization techniques for the automatic analysis of digital music collections. They show how these techniques can be used to extract musically meaningful information from audio signals in order to identify their repetitive structures and representative patterns, and to characterize similarities within collections. With the help of illustrative examples, they show how these content-based methods facilitate the development of novel modes of access, analysis and interaction with digital content that can empower the study and appreciation of music.

Chapter 40: *Marshall Chasin* and *Neil S. Hockley*'s chapter, entitled *Hearing Aids and Musicians: Some Theoretical and Practical Issues*, focuses on the hearing assessment of musicians as well as how to recommend and specify the exact parameters for hearing aid amplification for hard-of-hearing people who either play musical instruments or merely like to listen to music. Music is typically listened to or played at a higher sound level than speech and there are some spectral and temporal differences between music and speech that have implications for differing electroacoustic hearing aid technologies for the two types of input. This involves a discussion of some hearing aid technologies best suited to amplified music as well as some clinical strategies for the hearing health care professional to optimize hearing aids for music as an input.

Chapter 41: *Estefanía Cano* et al. address the application of music information retrieval (MIR) technologies in the development of music education tools in their chapter *Music Technology and Education*. First, the relationship between technology and music education is described from a historical point of view. Then, three MIR technologies used within a music education context are presented: the use of pitch-informed solo and accompaniment separation as a tool for practice content creation, drum transcription for real-time music practice, and guitar transcription with plucking style and expression style detection. To conclude the chapter, some remaining challenges that need to be addressed to more effectively use MIR technologies in the development of music education applications are described.

Chapter 42: *Lorenzo J. Tardón* et al., in their chapter *Music Learning: Automatic Music Composition and Singing Voice Assessment*, focus on diverse aspects of how technology can be used for music learning. In this chapter, the goal is to describe a virtual environment that partially resembles the traditional music learning process and the music teacher's role, allowing for a complete interactive self-learning process. The complete chain of an interactive singing-learning system including tools and concrete techniques is presented. First, a set of training exercises is provided by the system and the user's performance is assessed, before the system provides the user with new exercises selected or created according to the results of the evaluation. Therefore, methods for the creation of user-adapted exercises and the automatic evaluation of singing skill is presented, together with techniques for the dynamic generation of musically

meaningful singing exercises, adapted to the user's skill.

Chapter 43: *Nadine Kroher* et al., in their chapter *Computational Ethnomusicology: A Study of Flamenco and Arab-Andalusian Vocal Music*, approach flamenco and Arab-Andalusian vocal music through the analysis of two representative pieces. They apply a hybrid methodology consisting of audio-signal processing to describe and contrast their melodic characteristics followed by musicological analysis. The use of such computational analysis tools complements a musicological-historical study with the aim of supporting the discovery and understanding of the specific characteristics of these musical traditions and their similarities and differences, while offering solutions to more general music information retrieval (MIR) research challenges.

Chapter 44: *Alexander Lerch*'s contribution is devoted to *The Relationship Between Music Technology and Music Industry*. The music industry has changed drastically over the last century and most of its changes and transformations have been technology driven. Music technology – encompassing musical instruments, sound generators, studio equipment and software, perceptual audio coding algorithms, and reproduction software and devices – has shaped the way music is produced, performed, distributed and consumed. This chapter describes technological innovations and trends in the past and their impact on musicians, listeners, and the music industry itself.

Chapter 45: *Jesús Corral García*, *Panos Kudumakis* et al. present a chapter entitled *Enabling Interactive and Interoperable Semantic Music Applications*. New interactive music services have emerged, although they currently use proprietary file formats. In order to enable interoperability among these services, the ISO/IEC Moving Picture Experts Group (MPEG) issued a new standard, the so-called, MPEG-A: Interactive Music Application Format (IM AF). This chapter reviews the IM AF standard and its features and provides a detailed description of the design and implementation of an IM AF codec and its integration into a popular open-source analysis, annotation and visualization audio tool, known as Sonic Visualiser. This is followed by a discussion highlighting the benefits of their combined features, such as automatic chord or melody extraction time-aligned with the song's lyrics. This integration provides the semantic music research community with a test-bed for enabling further development and comparison of new Sonic Visualiser plugins.

Chapter 46: *George Tzanetakis* and *Peter Driessen*, in their chapter *Digital Sensing of Musical Instruments*, describe hyperinstruments, which are acoustic instruments that are augmented with digital sensors for capturing performance information and in some cases offering additional playing possibilities. Direct sensors are integrated onto the physical instrument, which possibly requiring modifications. Indirect sensors such as cameras and microphones can be used to analyze performer gestures without requiring modifications to the instrument. Until recently, hyperinstruments were mostly used for electroacoustic music creation but, as stated in this chapter, they have a lot of potential in systematic musicological applications involving music performance analysis.

39. Content-Based Methods for Knowledge Discovery in Music

Juan Pablo Bello, Peter Grosche, Meinard Müller, Ron Weiss

This chapter presents several computational approaches aimed at supporting knowledge discovery in music. Our work combines data mining, signal processing and data visualization techniques for the automatic analysis of digital music collections, with a focus on retrieving and understanding musical structure.

We discuss the extraction of midlevel feature representations that convey musically meaningful information from audio signals, and show how such representations can be used to synchronize different instances of a musical work and enable new modes of music content browsing and navigation. Moreover, we utilize these representations to identify repetitive structures and representative patterns in the signal, via self-similarity analysis and matrix decomposition techniques that can be made invariant to changes of local tempo and key. We discuss how structural information can serve to highlight relationships within music collections, and explore the use of information visualization tools to characterize the patterns of similarity and dissimilarity that underpin such relationships.

With the help of illustrative examples computed on a collection of recordings of Frédéric Chopin's Mazurkas, we aim to show how these content-based methods can facilitate the development of novel modes of access, analysis and interaction with digital content that can empower the study and appreciation of music.

The rapid and sustained growth of digital music sharing and distribution is nothing less than astounding. A multitude of digital music services provide access to tens of millions of tracks, both legally and illegally. Such abundance of content, coupled with the relative ease of access and storage afforded by recent technologies, means that music is shared and listened to more than ever before in history.

Using computational methods to help users find and organize music information is a widely researched topic in industry and academia. Existing approaches can be coarsely divided into two types: in *content-based* methods the information is obtained directly from the analysis of audio signals, scores and other representations of the music, whereas *context-based* methods are based on information surrounding the music content, such as usage patterns, tags and structured metadata. While a significant amount of research has been devoted to the former strategy – see [39.1] for an early review – the latter has been historically favored in industrial applications such as music recommendation and playlist generation. Content-based analysis is sometimes seen as providing too little *bang for the buck*, with some observers going as far as wondering whether it is at all necessary for the retrieval of music information [39.2].

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_39

Yet, we argue that there are numerous data-mining problems for which context-based analysis is insufficient, as it tends to be low in specifics and unevenly distributed across artists and styles. Consider for example the issue of tracing back the original sources of samples used in electronic or hip-hop recordings; or of identifying the many derivations of George Gershwin's *I Got Rhythm* in the jazz catalog; or of finding quotations of a given Wagner motif in 20th century modernist music; or of quantifying which movements, artists and compositions are cited most often and are therefore the most influential. These problems are motivated by the needs of sophisticated users such as media producers, Foley artists, sound designers, film and game composers, copyright lawyers, musicologists, and professional and amateur musicians, for whom music search necessarily goes beyond the passive act of music recommendation. We believe that the development of robust and scalable solutions to these problems, and many others that could be listed instead, passes through the automated analysis of the musical content.

This chapter aims to introduce the reader to computational approaches to content-based analysis of digital music recordings. More specifically, we give an overview of a number of techniques for music structure analysis, i. e., the identification of the patterns and relationships that govern the organization of sounds in music, and discuss how the outcomes of this analysis can facilitate data mining in music. This review is intended for an audience interested in music search, organization and discovery, that is not steeped in the field of music information retrieval (MIR). Therefore the emphasis is not on technical details, which are published elsewhere in the literature, but on the presentation of examples and qualitative results that illustrate the operation and potential of the presented approaches.

The chapter is organized as follows: Section 39.1 familiarizes the reader with the basics of music structure analysis, discusses the fundamental role that repetition plays in it, and introduces the corpus of music that will be used throughout this chapter. Section 39.2 presents standard methods for music signals analysis. Section 39.3 introduces methods for temporal alignment of different representations of a given musical piece and shows how such alignments can be used to create novel user interfaces. Section 39.4 demonstrates how to characterize the patterns of repetition in music via self-similarity analysis, which has numerous applications in segmenting, organizing and visualizing music recordings. Section 39.5 introduces a powerful technique for structure analysis using matrix factorization with applications in identifying representative patterns and segmenting music signals. Finally, Sect. 39.6 presents our conclusions and outlook on the field.

39.1 Music Structure Analysis

The architectural structure of a musical piece, its *form*, can be described in terms of a concatenation of sectional units. The amount of repetition amongst these units defines the spectrum of possible forms, ranging from strophic pieces, where a single section is continuously repeated (as is the case for most lullabies), to through-composed pieces, where no section ever recurs. While repetition is not a precondition to music, it undeniably plays a central role (*the basis of music as an art form* according to [39.3]), and is closely related to notions of coherence, intelligibility and enjoyment in its perception [39.4]. Indeed, some observers estimate that more than 99% of music listening involves repetition, both internal to the work and of familiar passages [39.5].

However, the notion of repetition in structural analysis is not rigid and, depending on the composition, might include significant variations in the musical content of the *repeated* parts. This is even more true for recordings featuring changes in instrumentation, ornamentation and expressive variations of tempo and dynamics. In other words, an exact recapitulation of the content is not required in order for a part to be considered to be repeated. As a consequence, the analysis and annotation of musical structure is, to a certain degree, ambiguous [39.6, 7].

Take for example Frédéric Chopin's Mazurka in F major, Opus 68, No. 3, a piano work to which we will refer throughout this chapter as M68-3. One way to describe the structure of this piece is as: $\mathcal{A}_1\mathcal{A}_2\mathcal{B}_1\mathcal{B}_2\mathcal{A}_3\mathcal{T}\mathcal{C}_1\mathcal{C}_2\mathcal{A}_4\mathcal{A}_5$. In this description, each letter denotes a pattern and each subscript the instance number of a pattern's repetition. $\mathcal{T}$ is a special symbol denoting a transitional section. The four patterns are depicted, in score format, in Fig. 39.1.

Note that this annotation is by no means unique and implies a number of choices. First, grouping the music into a relatively small number of parts requires tolerating slight variations across repetitions. For example, pattern $\mathcal{A}$ presents with two alternative endings, with the last bar of segments $\mathcal{A}_1$ and $\mathcal{A}_4$ differing harmonically from the last bar of segments $\mathcal{A}_2$, $\mathcal{A}_3$

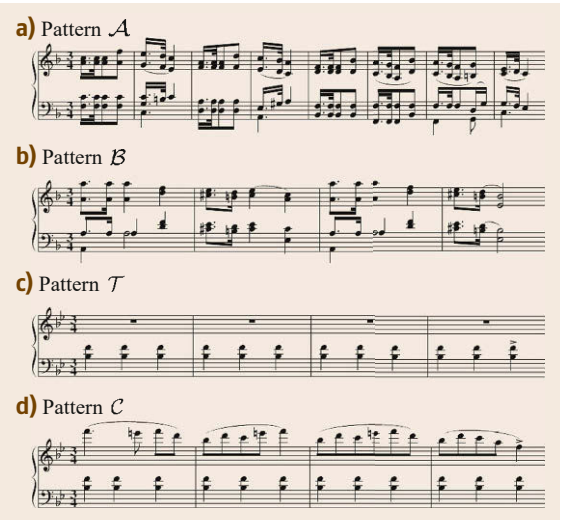

Fig. 39.1a–d Mazurka Op. 68, No. 3 (M68-3) in F major

and $\mathcal{A}_5$. We could have chosen to break these occurrences into two groups, but that would ignore the high degree of overlap that otherwise exists between them. Second, the description avoids patterns consisting of a small number of repeating subpatterns. For example, $\mathcal{T}$ and $\mathcal{C}$ are considered to be two different parts despite their strong harmonic similarities. The alternative would be to merge $\mathcal{T}\mathcal{C}_1\mathcal{C}_2$ into a single pattern of highly repetitive subpatterns. In the following sections we will illustrate how these decisions relate to the information within the music signals, and their implications for the proposed analyses.

Throughout this chapter we draw examples from the Mazurka dataset, compiled by the Center for the History and Analysis of Recorded Music in London [39.8]. The set includes 2919 recorded performances of the 49 Frédéric Chopin's Mazurkas, resulting in an average of 58 renditions per Mazurka. These recordings, featuring 135 different pianists, cover a range of more than 100 years beginning in 1902 and ending in 2008. This makes the dataset a rich and unique resource for the analysis of style changes and expressivity in piano performance, and of the evolution of recording techniques and practices [39.9].

Our analysis is mainly focused on a subset of 298 recordings that correspond to five Mazurkas. In addition to M68-3, mentioned above, these include: Opus 17, No. 4 in A minor (M17-4); Op. 24, No. 2 in C major (M24-2); Op. 30, No. 2 in B minor (M30-2); and Op. 63, No. 3 in C$^\sharp$ minor (M63-3). These recordings are chosen because they have been the subject of extensive musicological studies that resulted, amongst other things, in manually annotated beat positions [39.10]. Additionally, the musical structures of these Mazurkas are comparatively well defined, a fact that we have exploited to manually annotate their forms, as depicted in Fig. 39.2. Please note that the annotations were performed only once on the score representation, and then propagated to all recordings using the beat annotations mentioned above.

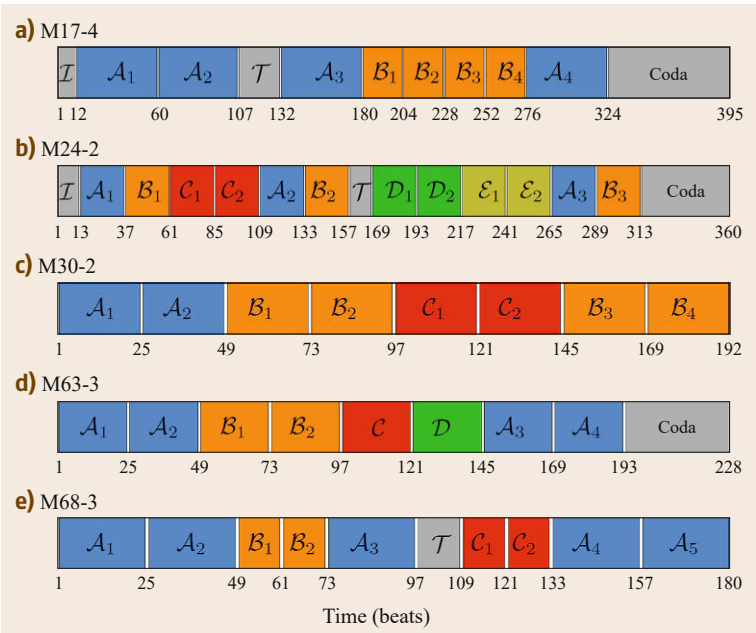

Fig. 39.2a–e Illustration of manually generated structural descriptions for five different Mazurkas

39.2 Feature Representation

All content-based music analysis begins with the extraction of a meaningful feature representation from the audio signal. This representation typically encodes information about one or more musical characteristics, e.g., harmony, melody, rhythm, or timbre as required by the specific task. There are numerous signal processing techniques that can be used to this end, such as the ubiquitous Mel-frequency Cepstral coefficients (MFCC), which are used for the analysis of timbre and texture (e.g., by [39.11, 12]). For a comprehensive list of audio features and their implementation, the reader is referred to [39.13].

In our work we use chroma features, introduced in Sect. 39.2.1, which can be used to derive information about chords. As shown in Sect. 39.2.2, these features are a powerful tool for music structure analysis, because repeating segments are often characterized by common chord progressions.

39.2.1 Chroma Features

Most musical parts are characterized by a particular melody and harmony. In order to identify repeating patterns in music recordings it is therefore useful to convert the audio signal into a feature representation that reliably captures these elements of the signal, but is not sensitive to other components of the signal such as instrumentation or timbre. In this context, *chroma features*, also referred to as *pitch class profiles* (PCPs), have turned out to be a powerful midlevel representation for describing harmonic content. They are widely used for various music signal analysis tasks, such as chord recognition [39.14], cover song identification [39.15, 16], and many others [39.17–19].

It is well known that human perception of pitch is cyclical in the sense that two pitches an integer number of octaves apart are perceived to be of the same type or class. This is the basis for the helical model of pitch perception, where pitch is separated into two dimensions: *tone height* and *chroma* [39.20]. Assuming the equal-tempered scale, and enharmonic equivalence, the chroma dimension corresponds to the twelve pitch classes used in Western music notation, denoted by $\{\mathrm{C}, \mathrm{C}^\sharp, \mathrm{D}, \ldots, \mathrm{B}\}$, where different pitch spellings such as $\mathrm{C}^\sharp$ and $\mathrm{D}^\flat$ refer to the same chroma. A *pitch class* is defined to be the set of all pitches that share the same chroma. For example, the pitch class corresponding to the chroma C is the set $\{\ldots, \mathrm{C0}, \mathrm{C1}, \mathrm{C2}, \mathrm{C3}, \ldots\}$.

There are several methods available for the computation of chroma features from audio, usually involving the warping of the signal's short-time spectrum or its decomposition into log-spaced subbands. This is followed by a weighted summation of energy across spectral bins corresponding to the same pitch class [39.15, 17, 19, 21]. Each chroma vector characterizes the distribution of the signal's local energy across the twelve pitch classes. Just as with the short-time Fourier transform (STFT), chroma vectors can be calculated sequentially on partially overlapped blocks of signal data, resulting in a so-called *chromagram*. The literature also proposes a number of ways in which the standard chroma feature representation can be improved by minimizing the effects of harmonic noise [39.22], by timbre and dynamic changes [39.19, 23], or by tempo variations via beat synchronization [39.15].

Figure 39.3a depicts the waveform of a 1976 recording of M68-3 performed by Sviatoslav Richter. Pattern labels are shown on the horizontal axis with boundaries marked as vertical red lines. Figure 39.3b shows the corresponding sequence of normalized chroma feature vectors, at a resolution of ten vectors per second, with the pitch classes of the chromatic scale starting in A, and ordered from bottom to top. As expected, most of the signal energy is concentrated on the classes corresponding to the F major key: F, G, A, $\mathrm{B}^\flat/\mathrm{A}^\sharp$, C, D and E. Additionally, careful inspection of the chromagram shows that the different patterns of this piece can be associated with distinct subsequences of chroma vectors.

39.2.2 Feature Trajectories

To make the latter point more evident we can use an alternative visualization of the chromagram in Fig. 39.3b. The values in a single chroma feature vector can be interpreted as a set of coordinates describing a point in the 12-dimensional space of pitch classes. Connecting those points over time results in a trajectory in feature space. Since this trajectory cannot be directly visualized in 12 dimensions, we use principal component analysis [39.24] to project this information onto its two principal components, resulting in the black line shown in Fig. 39.4. Since time is not explicitly encoded in this visualization, Fig. 39.4 also shows the two-dimensional (2-D) histograms of trajectory values, color-coded such that points contained within instances of patterns $\mathcal{A}$, $\mathcal{B}$, $\mathcal{C}$ and $\mathcal{T}$ are in blue, red, orange and gray respectively.

The projection clearly characterizes the main repetitions in the feature sequence as similar subtrajectories, i. e., segments of the main trajectory that are in close proximity to each other. Note that repetitions do not

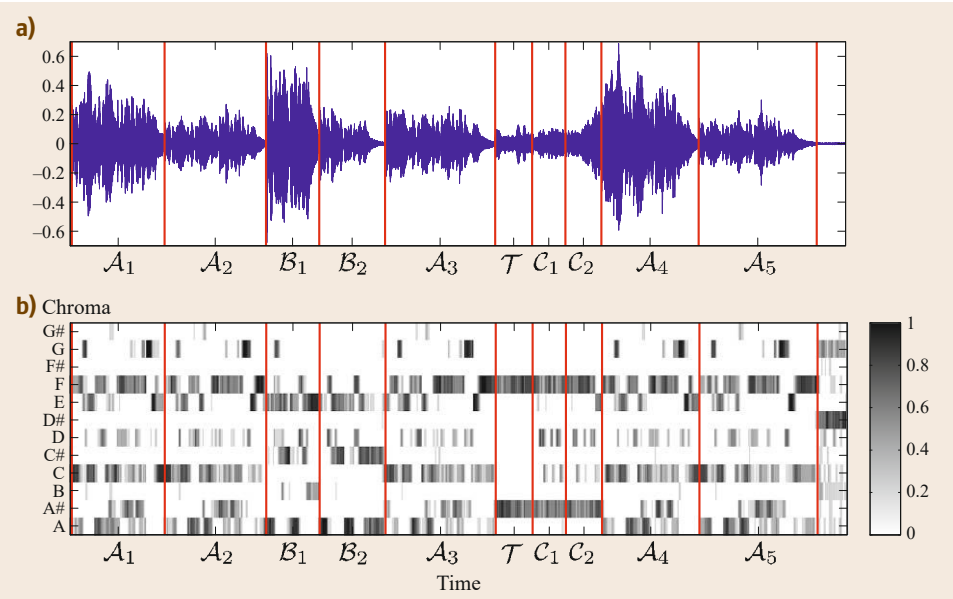

Fig. 39.3a,b Feature representations for a performance by Richter (1976) of M68-3. **(a)** Waveform. **(b)** Corresponding chromagram. Pattern boundaries are marked with *vertical red lines* and pattern labels are shown on the *time axis*

form fully overlapping subtrajectories due to expressive changes in tempo, timbre and dynamics. Despite this variability the histograms clearly show how each pattern results in distinct trajectory shapes. For example, pattern $\mathcal{A}$ has a multimodal distribution resulting from the six different chord types that are part of its progression: F major, C major, B♭ major and G major as well as D minor and A minor. In contrast, pattern $\mathcal{B}$, which is strongly dominated by A major chords (while also featuring some D minor and E major chords) has a much more narrow distribution. This is even more extreme for patterns $\mathcal{C}$ and $\mathcal{T}$, which are highly overlapping and almost exclusively dominated by a B♭-F dyad played ostinato, as can be seen in the score representation of Fig. 39.1.

This example illustrates how chromagrams successfully capture harmonic information in the signal. In the following sections we show how these features can be used to synchronize different instances of a musical work and enable new modes of music content browsing and navigation.

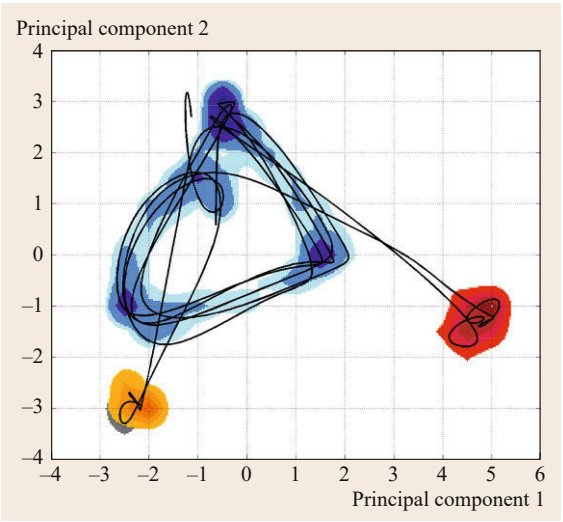

Fig. 39.4 Trajectory of 12-dimensional chroma features projected onto two dimensions using the chromagram shown in Fig. 39.3b

39.3 Music Synchronization and Navigation

Musical works can be represented in many different domains, e.g., in different audio recordings, MIDI (Musical Instrument Digital Interface) files, or as digitized sheet music. The general goal of music synchronization is to automatically align multiple information sources related to the same musical work. Here, *music synchronization* denotes a procedure which, for a given position in one representation of a piece of music, determines the corresponding position within another representation [39.19, 25]. The linking information produced by the synchronization process can be used to propagate information across these representations.

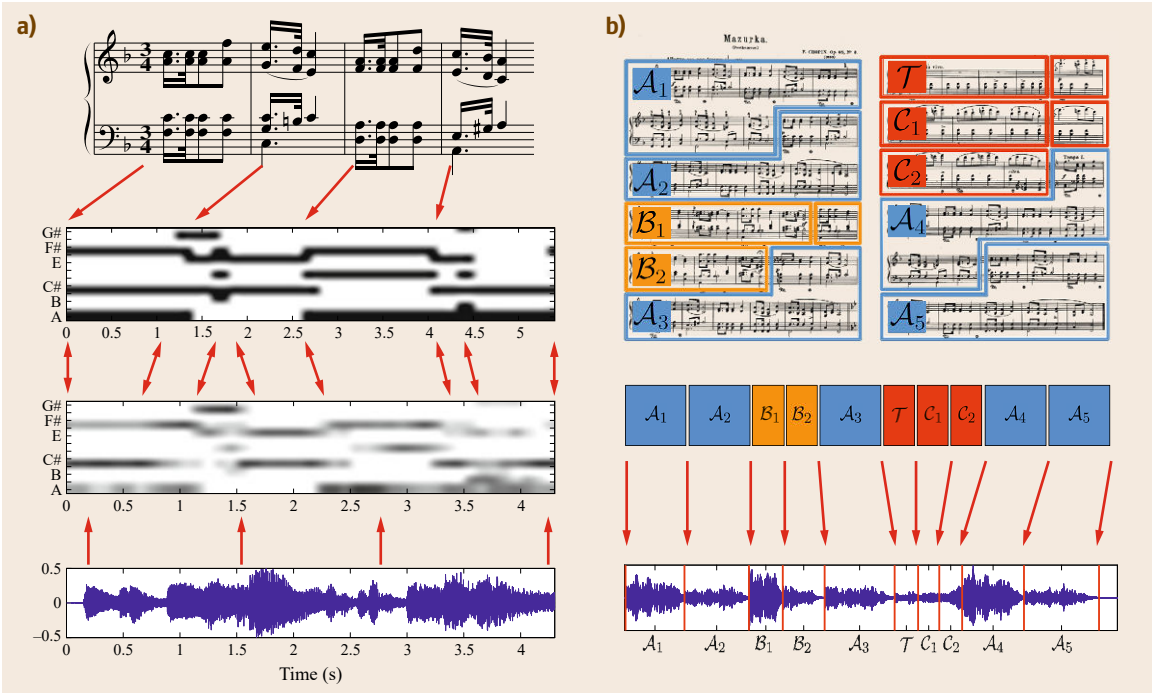

Fig. 39.5a,b Illustration of the score-audio synchronization pipeline used to transfer structure annotations from the score to the audio domain. **(a)** Score and audio representation with the corresponding chromagrams. The *red arrows* indicate the score-audio synchronization result. **(b)** The score-based annotations are transferred to the audio domain using the linking information supplied by the synchronization procedure

Consider the example in Fig. 39.5. The left column demonstrates the synchronization process between a musical score (top) and a recording of the same piece (bottom). Both the score and audio are converted to a common midlevel representation: the chromagram. While one would naturally expect the audio chromagram to be much noisier than the chromagram derived from the score, both representations are expected to contain energy in the pitch classes corresponding to the played notes, and to be organized according to the sequence of notes in the score. Therefore, standard alignment procedures based on dynamic time warping can be used to synchronize the two feature sequences. See [39.19, 25, 26] for details.

There are many potential applications of the synchronization process. For example, if the musical form of the piece has been manually annotated using the score representation – as shown in the right-hand side of Fig. 39.5 – the synchronization result can be used to transfer this, or any other annotation, to a recording of the same piece, regardless of variations of local or global tempo. This alleviates the need for the laborious process of manually annotating multiple performances of a given work. The same techniques can be applied to score following for automatic page turning or to adding subtitles to a video recording of an opera performance, to name only some further applications.

Another application is the creation of novel user interfaces for inter- and intradocument navigation in music collections. Figure 39.6 shows an interface (from [39.27–29]) that allows the user to interact with several recordings of the same piece of music, which have been previously synchronized. The timeline of each recording is represented by a slider bar, whose indicator (a small down arrow) points to the current playback position. Note that these positions are synchronized across performances. A user may listen to a specific recording by activating the corresponding slider bars and then, at any time during playback, seamlessly switch to another recording. Additionally, the slider bars can be segmented and color coded to visualize symbolic annotations common to all recordings, such as a chord transcription or a structure segmentation as shown in the figure. Furthermore, users can jump directly to the beginning of any annotated element simply by clicking on the corresponding block, thus greatly facilitating intradocument navigation. A similar functionality was introduced in [39.30].

The interface offers three different timeline modes. In *absolute mode*, shown in the top of Fig. 39.6, the

Fig. 39.6a,b User interface for intra- and interdocument navigation of music collections. The *slider bars* correspond to four different performances of M68-3. They are segmented and color-coded according to the structural annotations in Fig. 39.2. The *down arrows* point to the current playback time, synchronized across performances. The *absolute* (**a**) and *relative* (**b**) timeline modes are shown

length of a particular slider bar is proportional to the duration of the respective recording. In *relative mode*, shown in the bottom of the figure, all timelines are linearly stretched to the same length. The third and final mode, referred to as *reference mode*, uses a single recording as a reference. All other timelines are then temporally warped to run synchronous to the reference. In all cases, the annotations are adjusted according to the selected mode. Such functionalities open up new possibilities for viewing, comparing, interacting, and evaluating analysis results within a multiversion, and multimode, framework [39.29].

39.4 Self-Similarity in Music Recordings

Since their introduction to the music information community in [39.31], self-similarity matrices (SSM) have become one of the most widely used tools for music structure analysis. Their appeal resides in their ability to characterize patterns of recurrence in a feature sequence, which are closely related to the structure of musical pieces.

39.4.1 Self-Similarity Revisited

Given a sequence of N feature vectors, and a function to measure the pairwise similarity between them, the *self-similarity matrix* $\mathbf{S}$ is defined to be the $N \times N$ matrix of pairwise similarities between all feature vectors in the sequence. For the examples in this section we use the chroma features as introduced in Sect. 39.2.1 and the cosine similarity function, i. e., the inner product between the normalized chroma vectors.

Figure 39.7a shows the matrix $\mathbf{S}$ for the chromagram in Fig. 39.3. Both the horizontal and vertical axes represent time, beginning at the bottom-left corner of the plot. Hand-annotated pattern boundaries are marked by vertical and horizontal red lines. Note that if the similarity function is symmetric, the matrix $\mathbf{S}$ is also

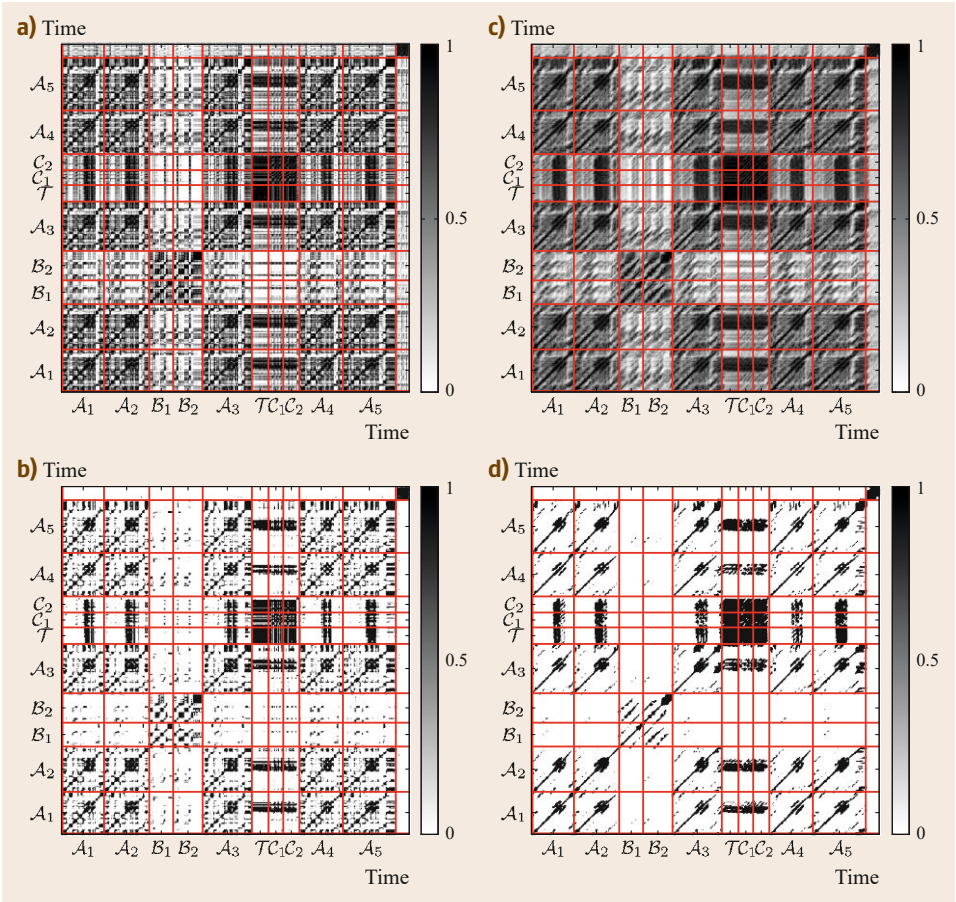

Fig. 39.7a–d Self-similarity matrices for M68-3 performed by Richter, 1976: **(a)** SSM, **(b)** thresholded SSM, **(c)** smoothed SSM, **(d)** thresholded smoothed SSM. Both vertical and horizontal axes represent time

symmetric with respect to the main diagonal, and that larger/smaller similarity values are represented respectively by darker/lighter colors in the plot. It can be readily observed that similar feature subsequences result in dark diagonal lines or stripes of high similarity. For example, all submatrices corresponding to the two instances of the $\mathcal{A}$ part contain a dark diagonal stripe. The segments corresponding to the $\mathcal{C}$ and $\mathcal{T}$ parts are rather homogeneous with respect to their harmonic content. As a result, entire blocks of high similarity are formed, indicating that each feature vector is similar to every other feature vector within these segments.

This example clearly illustrates how SSMs capture the repetitive structure of music recordings and reveal the location of repeating patterns in the form of diagonal stripes of high similarity. It follows that this information can be exploited for automatic segmentation [39.32], the extraction of musical form [39.19, 33], the detection of chorus sections [39.34], or music thumbnailing [39.35]. For a comprehensive review the reader is referred to [39.36]. However, the reliable extraction of such information from the SSM is problematic in the presence of distortions caused by variations in dynamics, timbre, note ornaments (e.g., grace notes, trills, arpeggios), modulation, articulation, or tempo. The following section describes how SSMs can be processed to minimize their sensitivity to such distortions.

39.4.2 Enhancing Self-Similarity Matrices

A number of strategies have been proposed to emphasize the diagonal structure information in SSMs. These strategies commonly include a combination of some form of filtering along the diagonals, and the thresholding of spurious, off-diagonal values. While many alternative approaches have been proposed in the literature (e.g., [39.33–35]), here we briefly discuss methods based on time-delay embedding, contextual similarity and transposition invariance.

The process of filtering SSMs along the diagonals can be framed in terms of *time-delay embedding*, a process that has been widely used for the analysis of dynamical systems [39.37]. In this process, the feature

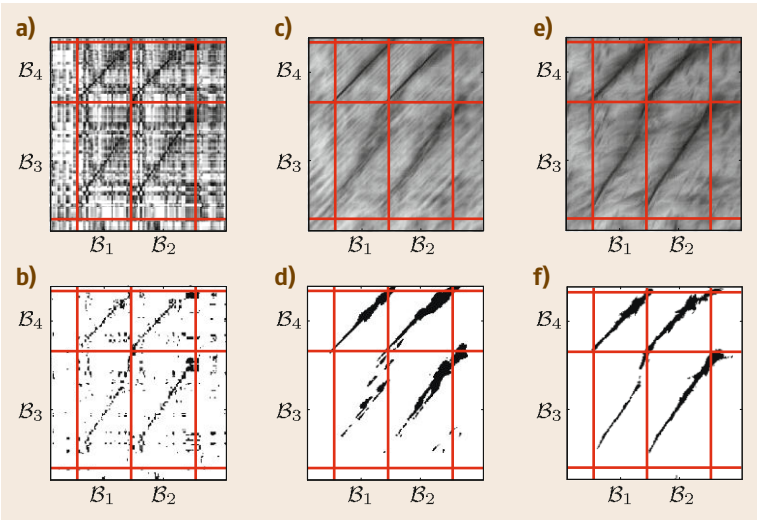

Fig. 39.8a–f SSM smoothing and thresholding in the presence of tempo variations for M30-2 performed by Jonas, 1947: **(a,b)** SSM, **(c,d)** smoothed SSM, and **(e,f)** smoothed SSM with contextual similarity

sequence is converted into a series of feature m-grams, each of which is composed of a stack of m feature vectors. These vectors can be taken from a contiguous window, or spaced by a fixed sample delay τ. In the context of the example in Sect. 39.2.2, setting $m > 1$ implies that pairwise similarities in the SSM computation are computed between subtrajectories instead of between individual feature vectors. Subtrajectories that are parallel to each other result in large self-similarity, and the effect of random crossings is minimized, generally resulting in a smoothed matrix. For $\tau = 1$, the time-delay embedding process is similar to textural windows [39.38] and audio shingles [39.39].

Figure 39.7a,b shows the traditional SSM (i. e., $m = \tau = 1$) computed from M68-3 before and after thresholding, respectively. Similarly, Fig. 39.7c,d shows the corresponding similarity matrices computed using $m = 15$ and $\tau = 1$. It is immediately apparent how the time-delay embedding emphasizes the diagonal line structure of the matrix and significantly minimizes the amount of off-diagonal noise that obscures the structure in the nonembedded matrix. It is worth noting that different methods can be used for thresholding, e.g., by simply ignoring distances larger than a predefined threshold (as was done in this example), by fixing the number of nearest neighbors per sequence element, or by enforcing a rate of recurrence in the thresholded SSM [39.37]. Recent studies show that the latter strategies can improve the applicability of SSMs to a variety of music analysis tasks [39.40, 41].

This form of filtering only works well if the tempo is (close to) constant across the music recording, i. e., where repeating segments have roughly the same length. Stripes corresponding to repeated patterns at the same tempo run diagonally with a slope of 1. Music structure analysis research has most commonly operated on popular music, in which this constant-tempo assumption is often reasonable. However, in other genres such as romantic piano music, expressive performances often result in significant tempo variations. Take for example Jonas' performance of M30-2, shown in Fig. 39.8, where $\mathcal{B}_3$ is played at nearly half the tempo of $\mathcal{B}_1$. This results in a diagonal stripe in the SSM with slope close to 2. Applying time-delay embedding to this data can result in broken stripes, as shown in Fig. 39.8c,d. One way to avoid this loss of information is to use a contextual similarity measure that filters the SSM along various slopes around 1 [39.42]. The resulting SSM, illustrated in Fig. 39.8e,f, has filtered out the off-diagonal noise present in the unprocessed SSM shown in Fig. 39.8a while successfully preserving diagonal structure in the presence of local tempo variations.

It is further possible to make the SSM transposition-invariant by computing the similarity between the original chromagram and its 12 cyclically shifted versions, corresponding to all possible transpositions. The invariant SSM is calculated by taking the point-wise minimum over the 12 resulting matrices [39.34, 43]. An example of the process from an excerpt of M7-5 is shown in Fig. 39.9. The excerpt contains repetitions of two patterns, $\mathcal{A}$ and $\mathcal{B}$, which are actually transpositions of each other, as shown in Fig. 39.9a,b. The standard SSM, shown in Fig. 39.9c,d, differentiates between the repetitions of $\mathcal{A}$ and $\mathcal{B}$, while the transposition-invariant SSM shown in Fig. 39.9e,f, successfully identifies the relationship between the two patterns.

The enhancement procedures described in this section are aimed at emphasizing the diagonal stripe structure of the SSM. In music structure analysis, the

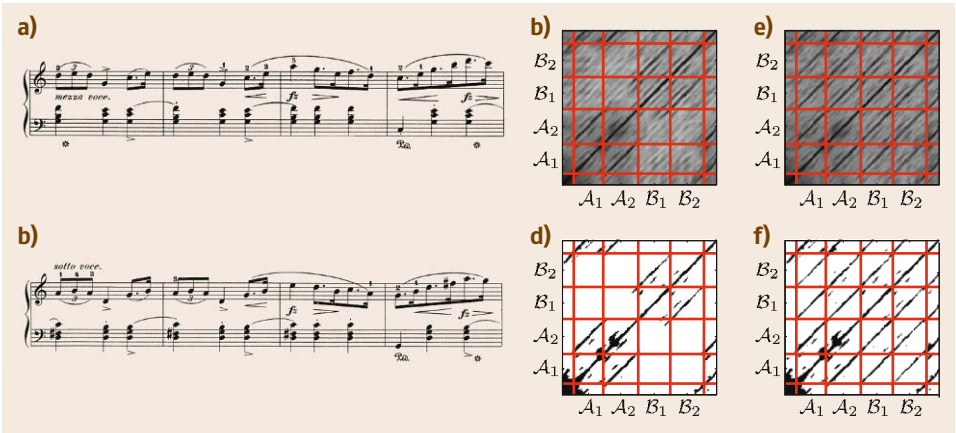

Fig. 39.9a–f Transposition invariance for M7-5 performed by Cohen, 1997: **(a,b)** Scores of patterns $\mathcal{A}$ and $\mathcal{B}$, **(c,d)** SSM before and after thresholding, and **(e,f)** transposition-invariant SSM before and after thresholding

computation of the self-similarity matrix is usually followed by a *grouping* step, where clustering techniques and heuristic rules are used to identify the global repetitive structure from the matrix, or to select representative segments for e.g., music thumbnailing. This is a large topic that we do not aim to fully review in this chapter. For a detailed review of these solutions and discussions of their advantages and disadvantages, the reader is referred to, e.g., [39.36, 44].

39.4.3 Structure-Based Similarity

In the previous sections, we discussed the computation of SSMs as an intermediate step towards the extraction of a piece's musical form or identification of representative excerpts. In this section, we use SSMs directly as a midlevel representation of a recording's structure. Distances measured in this domain can therefore be used to characterize the *structural similarity* between different music recordings [39.45, 46].

A similar problem in bioinformatics is concerned with measuring the similarity between protein structures on the basis of SSM-like representations known as *contact maps* [39.47]. One solution to this problem makes use of the *normalized compression distance* (NCD), an approximation of the joint Kolmogorov complexity between binary objects, to measure the amount of information overlap between contact maps [39.48]. The NCD is versatile, easy to implement using standard compression algorithms, and does not require alignment between the representations. In [39.46, 49], these ideas are transferred and applied to music information retrieval. Experimental results show that these measures successfully characterize global structural similarity for large and small music collections.

Figure 39.10 depicts the entire Mazurka dataset organized by structural similarity. The plot shows a two-

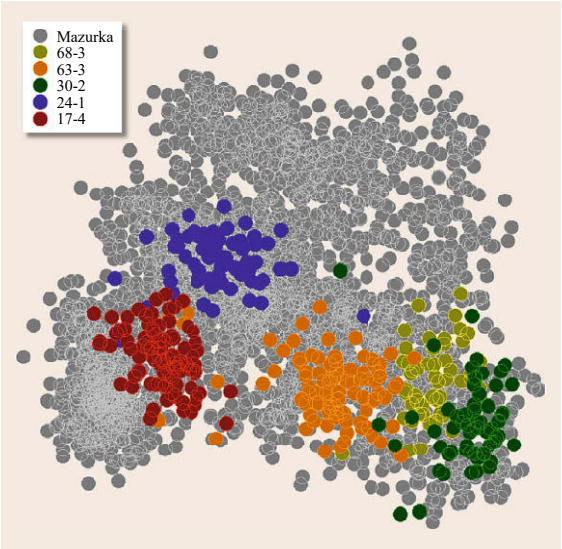

Fig. 39.10 The Mazurka dataset (*gray*) organized according to the NCD-based similarity of SSMs. *Colored points* correspond to recordings of the five Mazurkas considered in this chapter

dimensional projection, obtained using multidimensional scaling [39.50], of the matrix of pairwise NCDs between the SSMs of all 2919 recordings. Each recording is shown as a gray circle, except for those corresponding to performances of M17-4 (depicted in red), M24-1 (blue), M30-2 (green), M63-3 (orange) and M68-3 (olive green).

An informal inspection of this plot shows that most performances of a given work, which feature little or no variation in global structure, naturally form strongly knit clusters in this space. Note that the projection is deceptive in that it makes some of the clusters, e.g., the olive green and orange groups, appear closer to each other than they actually are. As

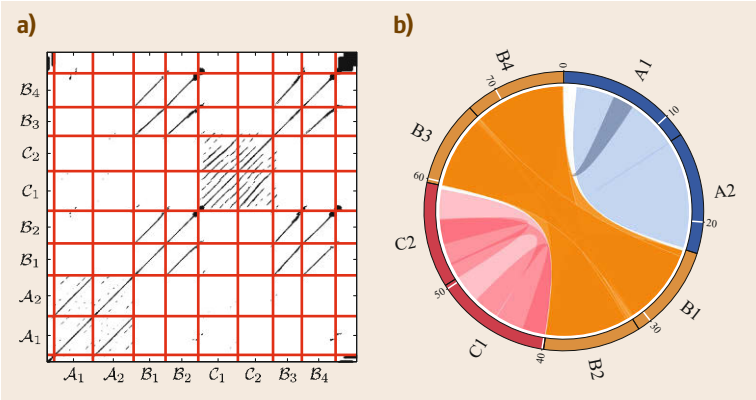

Fig. 39.11a,b Arthur Rubinstein's 1939 performance of M30-2: **(a)** thresholded SSM, and **(b)** radial convergence diagram

a result, works can be easily grouped by means of a simple nearest-neighbor search. However, the NCD is, predictably, sensitive to structural changes. This is typified by the M24-1 performance that appears the furthest from the blue cluster. This recording is part of a 1957 release of a master class by Alfred Cortot, where the pianist's spoken commentary alternates (and at times overlaps) with a partial performance of the piece including errors, nonscored pauses and repetitions. This results in a structure that diverges considerably from those of other performances. Likewise, the M30-2 (green) outlier corresponds to a 1945 performance by Vladimir Horowitz, in which the famous pianist repeats the entire second half of the piece, resulting in a unique $\mathcal{A}_1\mathcal{A}_2\mathcal{B}_1\mathcal{B}_2\mathcal{C}_1\mathcal{C}_2\mathcal{B}_3\mathcal{B}_4\mathcal{C}_3\mathcal{C}_4\mathcal{B}_5\mathcal{B}_6$ structure, see Fig. 39.2c. There are other such examples in this collection, whereby the performer took the liberty to deviate from the notated musical score by playing additional repetitions or leaving out certain parts. A structure-based similarity metric is a natural way to identify these variations.

39.4.4 Visualizing Structure

Self-similarity matrices have been used for visualizing structure in music [39.31, 51] and other domains such as programming [39.52] and computational biology [39.53]. However, SSMs are rarely used for data visualization outside of scientific research, possibly due to the nonintuitive presence of two temporal axes, which results in a complex and redundant representation.

Radial convergence diagrams [39.54] (RCDs) are an alternate vehicle for visualizing structural information derived from SSMs. These diagrams consist of a network of data points arranged on a circle. Groups of related points in the sequence are emphasized by connecting them via links or ribbons. We use the *circos* toolbox [39.55], a powerful and popular tool for information visualization based on circular graphs, to generate the RCDs shown in this section [39.54].

An example RCD and the associated SSM computed from a recording of M30-2 is shown in Fig. 39.11. To generate the RCD, the matrix is postprocessed as follows: the lower triangular part as well as the main diagonal and all points within a prespecified distance from it are ignored. The remaining repetitions (*ones* in the matrix) are stored as a list of *links* connecting pairs of elements in the feature sequence. Nearby links in time (i. e., those that form diagonal strips in the SSM) are grouped together. Small groups, either in temporal scope or in membership, are filtered out.

The remaining groups are used to construct the radial convergence diagram where time increases clockwise along the perimeter of the circle, beginning and ending at the topmost point. The outer ring shows the sequence of annotated sections as blocks, colored according to the schema in Fig. 39.2. Time markers are drawn as white lines and are placed at ten-second intervals along the ring, and section boundaries are drawn in black. Groups are represented using translucent ribbons connecting two time segments such that each ribbon edge connects the beginning of the first segment to the end of the second. If they link two instances of the same pattern, these ribbons assume the color of that pattern. Otherwise they are depicted in gray, which is also used to denote special sections such as introductions, interludes, transitions and codas.

As is shown in Fig. 39.11b, the RCD seamlessly combines information from the SSM with the piece's structural annotation, resulting in a rich and appealing visualization. The annotation in this example was manually generated on the basis of a musical score and propagated to audio recordings using the synchronization approach described in Sect. 39.3. Alternatively, the annotations can be automatically generated

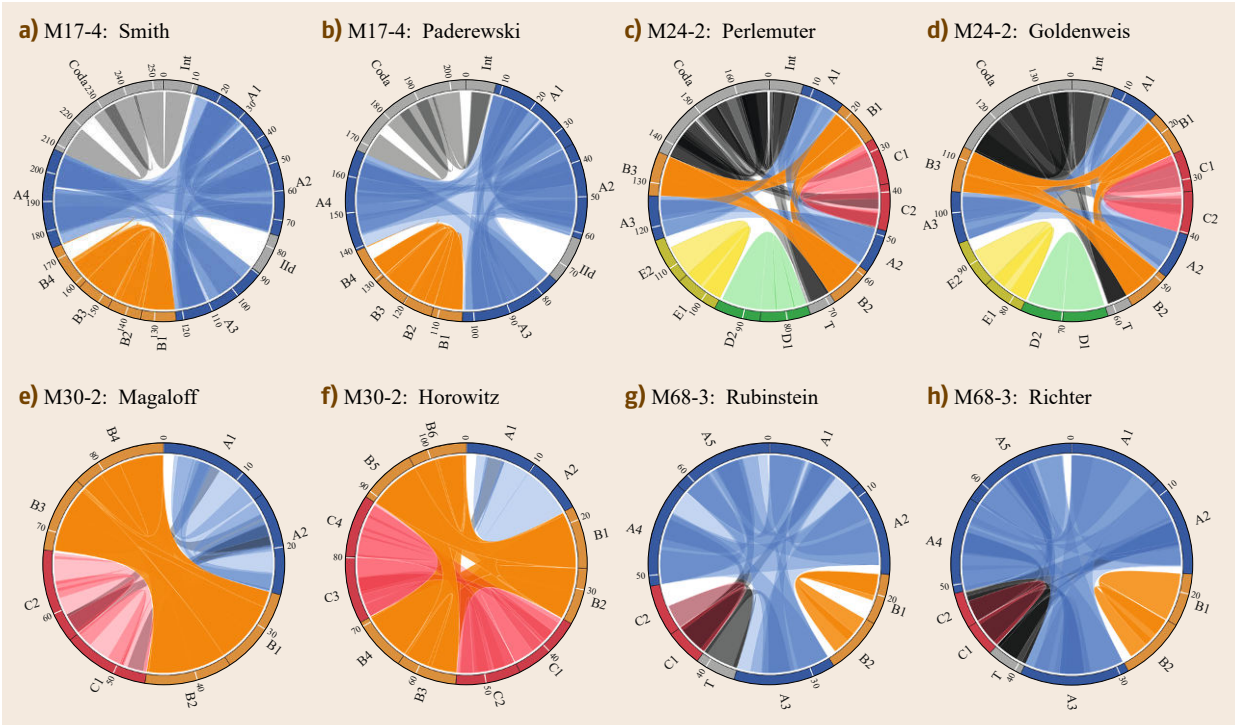

Fig. 39.12a–h Radial convergence diagrams for various Mazurka performances

by, e.g., analyzing the SSM (Sect. 39.4.2), or using the factorization approach that will be introduced in Sect. 39.5.

To illustrate the RCD's potential for qualitative analysis, Fig. 39.12 shows diagrams for two recordings of each of the following four Mazurkas: M17-4 in Fig. 39.12a,b, M24-2 in Fig. 39.12c,d, M30-2 in Fig. 39.12e,f, and M68-3 in Fig. 39.12g,h. The presence or absence of repetitive patterns results in distinctive shapes inside the diagrams that complement the information in the block-based structural annotations. These shapes highlight, for instance, the unique (nonrepetitive) character of the interlude (bottom-right gray segment) in M17-4, the significant overlap between introduction, transition and coda (gray sections) in M24-2, and the strong predominance of pattern $\mathcal{A}$ in the structure of M68-3.

Note that the gray ribbons linking different patterns depict relationships that are absent from the structural annotations. For example, they highlight the high similarity between instances of pattern C and the transition section in M68-3, both of which are dominated by a B$^\flat$ major chord as described previously in Sects. 39.1 and 39.2. The gray ribbons also connect the C and $\mathcal{T}$ sections with instances of the same chord in pattern $\mathcal{A}$, a link that results from the piece's only key modulation, in the transition, from F major to B$^\flat$ major.

The RCD representation can also be used to qualify stylistic differences in performance practice. Take for example one of the outliers identified in the analysis in Sect. 39.4.3. Figure 39.12f shows the unique structure of Vladimir Horowitz's performance of M30-2 when compared to performances that more closely follow the original score in Figs. 39.12e or 39.11b. Likewise, the varying-length gaps at the end of section C_2 (the final red segment) in M68-3, indicate a ritardando and an expressive pause in Rubinstein's performance (Fig. 39.12g), which is not present in Richter's (Fig. 39.12h).

Please note that an in-depth musicological analysis based on these diagrams is beyond the scope of this chapter. These simple observations are only intended to illustrate some of the capabilities of the RCD representation.

39.5 Automated Extraction of Repetitive Structures

Section 39.4.2 describes some general strategies for identifying repetitive structure within music recordings using self-similarity matrices. Example approaches include the clustering of diagonal elements in the SSM representation into sets of disjoint segments, and selecting the first of the most similar pair of segments, or choosing an arbitrary occurrence of the most frequent segment as a representative pattern. In this section we present an alternative approach based on matrix factorization, which jointly identifies repetitive patterns and derives a global structure segmentation from audio features.

39.5.1 Structure Analysis Using Matrix Factorization

In [39.56, 57] we propose a novel approach for the localization and extraction of repeating patterns in music audio. The idea underlying this method is that a song can be represented through repetitions of a small number of patterns in feature space. For example, recall that M68-3 has the form $\mathcal{A}_1\mathcal{A}_2\mathcal{B}_1\mathcal{B}_2\mathcal{A}_3\mathcal{T}\,C_1C_2\mathcal{A}_4\mathcal{A}_5$, i. e., the piece exhibits repetitions of three parts ($\mathcal{A}$, $\mathcal{B}$, and C) as well as a transition $\mathcal{T}$ that occurs only once. The only information needed to represent this piece are the feature sequences corresponding to each of the four patterns and the points in time of their occurrences.

This observation can be exploited to identify the main parts of a music recording and its overall temporal structure using an approach known as *shift-invariant probabilistic latent component analysis* (SI-PLCA). The process is illustrated in Fig. 39.13 for a performance of M68-3 by Gábor Csalog from 1996. The chromagram in Fig. 39.13a is approximated as the weighted sum of K ($K = 4$ in this example) components, each of which corresponds to a different part. Each component is further decomposed into a short chroma *basis pattern* (shown in Fig. 39.13b) and an activation function defining the location of each repetition of that pattern in the chromagram (shown in Fig. 39.13c). The peak positions in the activation function denote occurrences of the corresponding basis pattern in the feature sequence. Given a chromagram, this decomposition into basis patterns and activations can be computed iteratively using well-known optimization techniques [39.57].

There are many advantages to this model. First, it operates in a purely data-driven, unsupervised fashion: outside of a few functional parameters, the only prior information it requires is the length of the patterns L and the number of patterns K to extract. Second, the probabilistic formulation makes it straightforward to impose sparse priors on the distribution of basis patterns and mixing weights, enabling the model to learn optimal values for L and K. In addition, the framework can be easily extended to be invariant to key transpositions using a technique similar to that described in Sect. 39.4.2. Finally, the method jointly estimates the set of patterns and their activations, thus avoiding the need for heuristics for pattern extraction, grouping and selection. The versatility of the model is demonstrated in [39.57], where it is successfully applied to riff finding, meter identification, and segmentation of popular music.

39.5.2 Representative Patterns

The SI-PLCA model can be easily extended to extract patterns jointly from all available recordings of a piece by sharing the bases across recordings but using different activation functions for each one. This

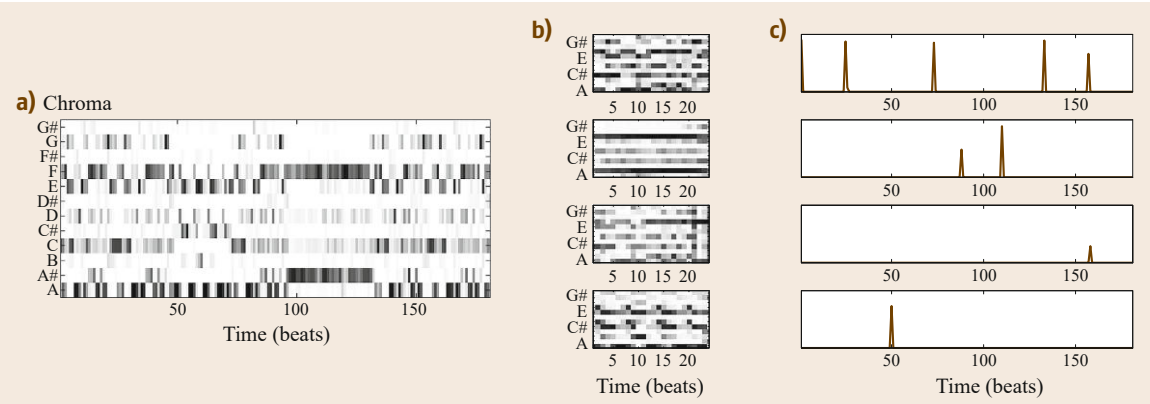

Fig. 39.13a–c Illustration of the SI-PLCA decomposition. **(a)** Chromagram. **(b)** Set of four basis patterns. **(c)** Respective activations in time

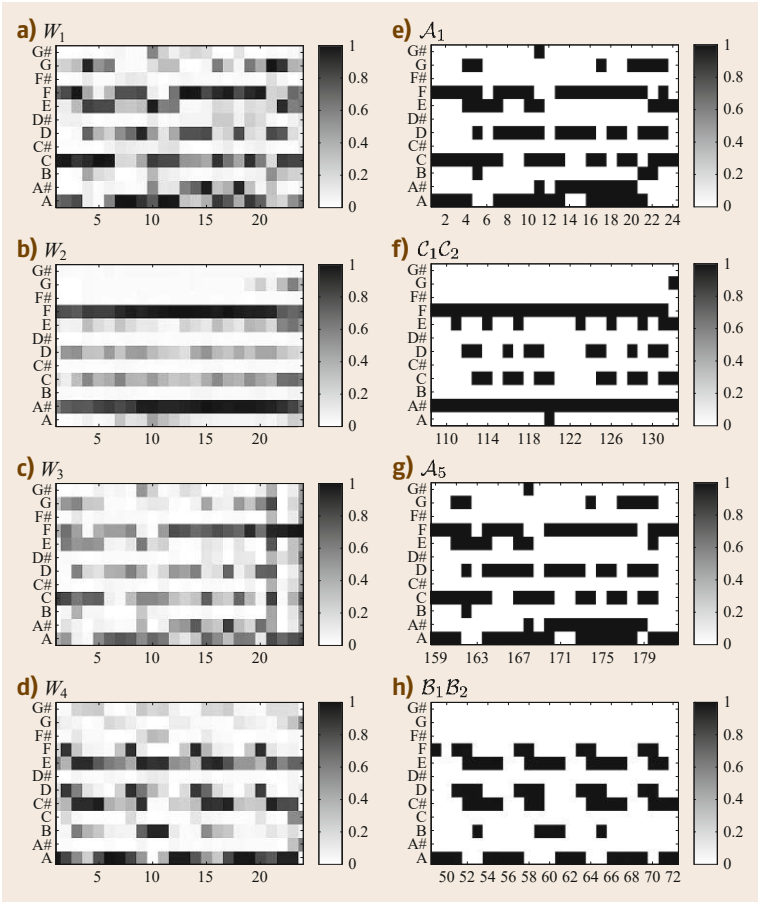

Fig. 39.14a–h Extracted patterns $W_k, k \in [1:4]$ for M68-3 and the corresponding MIDI-generated ground-truth patterns for the different parts. To facilitate comparison, **(f)** and **(h)** show both instances of the parts $\mathcal{C}$ and $\mathcal{B}$ respectively. The vertical axis shows time information given in beats. For the ideal patterns, the absolute beat numbers indicate the position of the pattern in the piece, see Fig. 39.2e

allows the model to identify the patterns of the piece rather than capture the idiosyncrasies of a single performance. In order to facilitate this cross-recording analysis we use beat-synchronous chromagrams, where features are averaged within beat segments [39.15]. This leads to a representation containing one feature vector per beat. We employ the manually annotated beat positions available for the Mazurka dataset to generate the chromagrams shown in this section.

Figure 39.14 shows patterns extracted for M68-3. The number of patterns in the decomposition is set to $K = 4$ and the pattern length is set to $L = 24$ beats, the length of $\mathcal{A}$, the longest part in the piece. The extracted patterns, denoted W_k, are shown in the left column of Fig. 39.14. The right column shows *ideal* chromagrams for the parts of M68-3, extracted from a symbolic (MIDI) representation. These sequences are paired with the basis that is most similar.

Upon close examination, it can be seen that W_1 matches every chord in $\mathcal{A}_1$, aside from some ambiguity in beats 21, 23 and 24. This is due to the alternation of endings of different instances of the $\mathcal{A}$ pattern: $\mathcal{A}_1$ and $\mathcal{A}_4$ finish with Gmaj-Cmaj-Cmaj-Cmaj chords at beats 21–24; while $\mathcal{A}_2$, $\mathcal{A}_3$ and $\mathcal{A}_5$ end with a Gmin-Cmaj-Fmaj-Fmaj sequence. Correspondingly, beat 21 shows energy in pitch classes G, B, $B^{\flat}/A^{\sharp}$ and D; while beats 23 and 24 show activity for classes A, C, E and F. Likewise, W_4 matches $\mathcal{B}_1\mathcal{B}_2$ almost perfectly, aside from a slight shift: W_4 starts in beat 2 of $\mathcal{B}_1$ and finishes in the first beat of $\mathcal{A}_3$, which contains a transitional C major seventh chord.

The melodic components of W_2 are also shifted by a couple of beats, although the transitional C dominant seventh chord at the end is well aligned. However, most of the energy of the matrix is concentrated in the $B^{\flat}$ fifth chord that dominates the $\mathcal{C}$ and $\mathcal{T}$ patterns. As a result, W_2 matches activations of both these patterns, as can be seen in the corresponding activation vectors in Fig. 39.13c. The unintended consequence of this is that the remaining pattern W_3, which must be assigned to some portion of the signal, absorbs a small amount of the energy from the last instance of pattern $\mathcal{A}$, mostly from the long F major chord at the end. W_3 is largely redundant with W_1, and could therefore be easily discarded. This is also indicated by the low value of the corresponding activation in Fig. 39.13c.

39.5.3 Segmentation Analysis

The work in [39.56] also describes a method for segmenting an audio signal based on the contribution of each basis to the chromagram. This is done by computing a temporal localization function ℓ_k from the extracted bases and activations that represents the energy contribution of each component to the overall chromagram at each point in time. Figure 39.15 shows the localization functions for the five Mazurkas in Fig. 39.2. These results are obtained for $L = 24$ beats and the optimal setting of K for each piece.

Figure 39.15e shows ℓ_k for M68-3, our running example. Given the similarity between patterns C and $\mathcal{T}$, discussed in previous sections, we have chosen to set $K = 3$, which removes the spurious component depicted in Fig. 39.14c. The resulting analysis shows a strong correspondence between the localization function and the annotated parts. The annotations for all $\mathcal{A}$ and $\mathcal{B}$ parts align perfectly with ℓ_2 and ℓ_1 respectively. ℓ_3 corresponds primarily to the C and $\mathcal{T}$ parts, and also makes a small contribution to $\mathcal{A}_3$.

As shown in Fig. 39.15c, the localization functions for M30-2 correlate closely with the manual annotation, given an optimal choice of $K = 3$. Similarly for M17-4 in Fig. 39.15a, there is high correlation between ℓ_k and the annotated parts. However, there is a constant shift in the segmentation that is mainly caused by the 12-beat long introduction. Additionally, the choice of $K = 3$ results in the grouping of the introduction and interlude sections (and some of the coda) with the $\mathcal{A}$ pattern.

The segmentation is less straightforward for M24-2 and M63-3, shown in Fig. 39.15b,d. In the case of M24-2, the choice of $K = 7$ closely matches the number of distinct parts in this piece, also visualized in the diagrams in Fig. 39.12c,d. As a result, C, $\mathcal{D}$, $\mathcal{E}$, the introduction and coda are slightly shifted but well segregated. However, the decomposition combines the contributions of $\mathcal{A}$ and $\mathcal{B}$, which always occur in sequence, into ℓ_2. Similarly, the ending of $\mathcal{B}$ and the transition are merged together in ℓ_4. For M63-3, the choice of $K = 6$ is larger than the number of parts in the annotation. This is a consequence of strong variations between the annotated $\mathcal{A}$ parts, where only the first 12 beats are common to all instances. These variations lead to a separation of the $\mathcal{A}$ parts into different components.

To further alleviate possible errors, we apply temporal smoothing to the localization functions, and select the maximal contributing pattern for each time position. This results in segmentation results comparable to state-of-the-art methods [39.56]. It is important to note that, while the results discussed in this section reveal a sensitivity to the setting of K, our research shows that it is possible to decrease this sensitivity by imposing additional sparsity constraints on the model parameters.

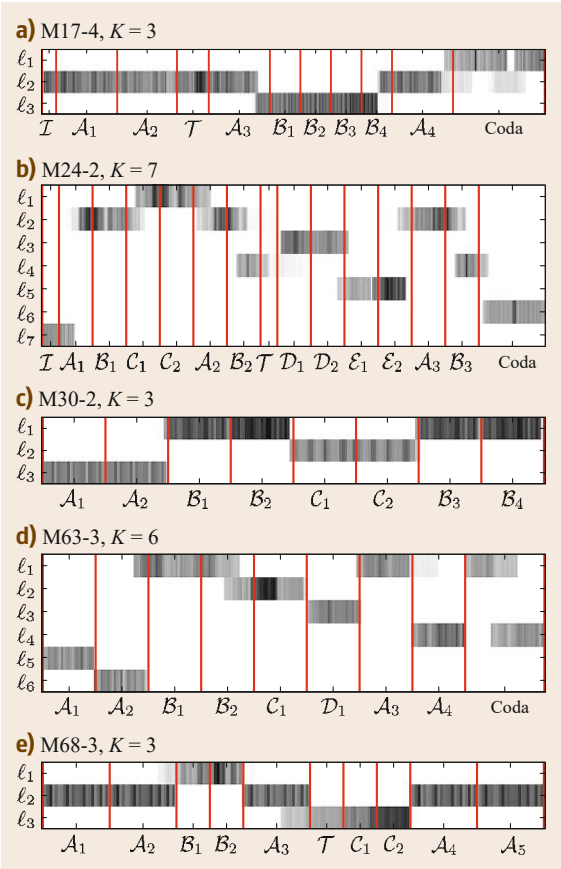

Fig. 39.15a–e Contribution ℓ_k of the basis patterns W_k to the different parts using $L = 24$ and the optimal setting of K for each of the five Mazurkas

It is also important to observe that the above analysis assumes that all patterns are of the same length. This is of course unrealistic for most music. When analyzing popular music this is partly alleviated via beat-synchronous analysis. However, extending this strategy to the analysis of piano music of the classical and romantic canon is problematic, because the variability introduced by expressive tempo changes negatively affects the performance of beat tracking systems. See [39.58] for an in-depth discussion of this problem in the context of the Mazurka dataset. The examples in this section have avoided such complications by making use of beat-synchronous chromagrams based on manually annotated beat positions. In order to analyze music for which such annotations are not available, we could, in the future, extend the SI-PLCA model to be invariant to tempo changes by allowing the basis patterns to be stretched in time.

39.6 Conclusions

In this chapter, we have reviewed the general principles behind several computational approaches to content-based analysis of recorded music and discussed their application to knowledge discovery. For example, we demonstrated how chroma-based audio features can be used as a robust midlevel representation for capturing harmonic information, and to compute similarity matrices that reveal recurrent patterns. By including temporal contextual information, we showed how these matrices can be enhanced to reveal repetitions in the presence of local tempo variations as occurring in expressive music recordings. Furthermore, we discussed how these techniques can be applied to music synchronization, to automate audio annotation and to realize novel user interfaces for inter- and intradocument music navigation. Finally, we demonstrated how structure-based similarity measures can be used to classify music collections based on their global structural form, and how matrix factorization techniques can be used to identify the most representative building blocks of a recorded performance.

Our aim was to highlight the implications of the various approaches for the analysis and understanding of recorded music, and to demonstrate how they can empower the work of music professionals and scholars. In addition we showed how these tools facilitate novel modes of interaction with digital content that could be integrated with music distribution services as ways to enhance the listeners' understanding and appreciation of music. Throughout the text, we illustrated the potential of content-based analysis via many concrete and intuitive examples taken from a collection of recorded piano performances of Chopin's Mazurkas. However, the presented techniques and underlying principles are applicable to the analysis of a wide range of tonal music and, with appropriate modifications of the feature representation, to percussive music or other types of time-dependent structured multimedia data.

Of course, this chapter has only covered a small part of the breadth of techniques and problems in the area of automated music processing. There are numerous challenges and open issues for future research. For instance, many of the examples shown here rely, to some extent, on the use of manually generated expert data such as beat positions or structural annotations. Despite significant research efforts, the automated generation of such annotations using purely content-based analysis techniques still poses challenging and open research problems for large parts of the existing digital music catalog. State-of-the-art algorithms often lack the robustness, accuracy and reliability needed for many music analysis applications. This is especially true for highly expressive music recordings such as the Mazurka performances described in this chapter, which exhibit subtle differences and variations in tempo, articulation, and note execution.

As the amount of digitally available music-related data grows, so does the need for efficient approaches that can scale up to the processing of millions of tracks. As automated procedures become more and more powerful they tend to gain computational complexity, making scalability an increasingly important issue. In addition to improvements in robustness and accuracy, issues related to time and memory efficiency will progressively come into the focus of future research.

Acknowledgments. This material is based upon work supported by the National Science Foundation, under grant IIS-0844654, and the Cluster of Excellence on Multimodal Computing and Interaction at Saarland University. The authors would like to thank Craig Sapp for kindly providing access to the Mazurka dataset and beat annotations.

40. Hearing Aids and Music: Some Theoretical and Practical Issues

Marshall Chasin, Neil S. Hockley

This chapter focuses on the hearing assessment of musicians as well as how to recommend and specify the exact parameters for hearing aid amplification for hard-of-hearing people who either play musical instruments or merely like to listen to music. Much of this is based on the differences between the acoustic features of music and of speech. Music is typically listened to, or played at, a higher sound level than speech and there are some spectral and temporal differences between music and speech that have implications for differing electro-acoustic hearing-aid technologies for the two types of input. This involves a discussion of some hearing aid technologies best suited to amplified music as well as some clinical strategies for the hearing health care professional to optimize hearing aids for music as an input.

The key limitation concerning the capability of current digital hearing aids to accommodate the more intense elements of music is the analog-to-digital (A/D) converter. Expending research and development efforts on the other elements within the hearing aid will not really improve the fidelity of music unless the limitations of the A/D converter are first solved. The topic of music as an input to hearing aids and the technologies that are available is a rapidly changing one. New technologies are on the horizon such as better A/D converters that may be implemented by various manufacturers.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_40

The study of systematic musicology is concerned with how human beings hear and process complex auditory signals. What happens, however, when there is impairment in the auditory system that disrupts an individual's ability to perceive and potentially process acoustic information? In such cases the individual may need to seek help and this may or may not require the use of hearing aids. This chapter will address the topic of hearing aids and musicians.

Hearing aids are primarily designed to amplify speech to address issues of communication for those individuals whose hearing loss is not of a degree that requires the use of a cochlear implant. Issues of communication after all are why hearing-impaired individuals, or in many cases their families, seek assistance [40.1–3]. The amplification of music is often perceived to be less important by the hearing-aid industry [40.4]. When music is a person's livelihood, lifelong passion, or even a new interest then the priority given to music is increased. This chapter will focus on what can be done with hearing aids to help these individuals. There will be a focus on the assessment of musicians, followed by a brief discussion of the acoustic differences between speech and music. This will be followed by a discussion of the technical solutions that are currently available in hearing aids as well as some practical suggestions about what can be done by the clinician in order to optimize the hearing-aid fitting for music.

40.1 Assessment of Musicians

During a typical diagnostic audiological assessment, a number of tests are performed to examine the capabilities and limitations of an individual's auditory system. These tests are designed to establish the location and type of pathology within the auditory pathways, as well as to provide a reliable measure of the degree of this pathology. These tests, however, are best suited to assess problems arising from the peripheral auditory pathway.

The peripheral auditory pathway consists of the outer ear, the middle ear, and the inner ear. Any subsequent neural involvement is considered to be the central auditory pathway. While there are some tests and assessment procedures that can assess any dysfunction within the central auditory pathway, these tend to be more complex and are not routinely performed in a typical clinical setting. Some of these tests are performed as part of a behavioral central auditory processing (or CAP) assessment [40.5, 6]. It is also possible to evaluate any neural involvement with more objective means that include electrophysiological techniques such as the auditory brainstem response (ABR) [40.7] and imaging assessment procedures such as magnetic resonance imaging (MRI) [40.8].

This chapter will only deal with the assessment of peripheral auditory pathology, specifically conductive and sensory issues. And to be more precise, we are mostly interested in cochlear pathology (the primary peripheral sensory location) as a result of music and/or noise exposure along with presbycusis, which is hearing loss associated with the aging process. Neural issues and other more central problems will not be covered. The reader is referred to [40.9] for an introduction to neural pathology and its effects.

40.2 Peripheral Sensory Hearing Loss

Depending on the clinic, routine audiological testing can include air conducted pure-tone testing under headphones or insert earphones, bone conducted pure-tone testing, speech recognition thresholds, word recognition scores, and immittance testing. With the exception of immittance testing, which is an objective physiological measurement battery that provides information about the healthy functioning of the middle ear [40.10], the other tests involve the active participation of the individual. The classic manifestation of a sensory type of hearing loss includes normal immittance results that indicate normal middle ear function, and pure-tone thresholds that are the same (within ten or 15 dB) regardless of whether they have been presented via air or bone conduction. All of these tests are used to rule out various locations of hearing loss but with musicians, it is the cochlear function that interests us most [40.11].

Musicians are exposed to a sound pressure level (SPL) that can potentially cause long-term hearing loss as part of their profession. This has been shown not only for players of amplified music (e.g., [40.12–15]) but also for those playing classical music (e.g., [40.16–23]). Like industrial noise exposure, music exposure will have its greatest effect in the cochlea, and like noise exposure, the greatest effect will be in the 3000–6000 Hz region [40.24]. In most cases it is quite difficult to de-

termine whether a sensory hearing loss can be attributed to noise or to music. A case history is typically the most important differentiating element where the clinician can document the duration and type of exposure to intense sound pressure levels that the individual has been exposed to. Figure 40.1 shows an audiogram showing the poorest pure-tone sensitivity at 4000 Hz. This is fairly typical of sensory peripheral hearing losses from industrial noise exposure and also from long-term music exposure.

In addition to routine audiological testing, two other types of specialized tests can be used with musicians: the assessment of cochlear dead regions [40.25] and otoacoustic emission (OAE) testing [40.26]; these two techniques will be discussed next.

Dead regions refer to areas of significant cochlear damage to the inner hair cells where amplification of any sort does not provide any benefits for the individual and filtering or transposing amplified acoustic energy away from this location in the cochlea would be strongly advised [40.27]. In cases of normal or mild sensory dysfunction, the assessment of cochlear dead regions is not normally performed. There are a number of assessment paradigms to determine if cochlear dead regions exist but many of these approaches, such as the use of psychophysical tuning curves [40.28], are time consuming and are therefore impractical to use in a clinical setting [40.29]. The threshold equalizing noise test in dB HL (TEN (HL)) [40.30, 31] is a much less time-consuming and easy-to-administer test, which involves the detection of a sinusoidal tone presented within a specially constructed noise – the threshold equalizing noise (TEN). An alternative assessment procedure to the TEN test, which many musicians and other individuals who might have a significant sensory hearing loss seem to prefer, is to have them play the notes on a piano (or electronic keyboard) in a slowly ascending fashion. The task is to determine whether any two adjacent notes on the piano keyboard are considered to be the *same* or *different* in pitch. If two adjacent keys are judged to be the same, then this is potentially an area of significant cochlear pathology i. e., a cochlear dead region, and therefore the use of amplification should be minimized in this frequency region.

Another assessment technique that can be routinely performed on musicians in the clinic is otoacoustic emission (OAE) testing. This procedure assesses the neural feedback route, specifically that which involves the outer hair cells in the cochlea. Changes in the level of the OAE can provide information regarding cochlear (outer hair cell) pathology. There are a number of different types of OAEs that can be measured and are defined based on how they are elicited.

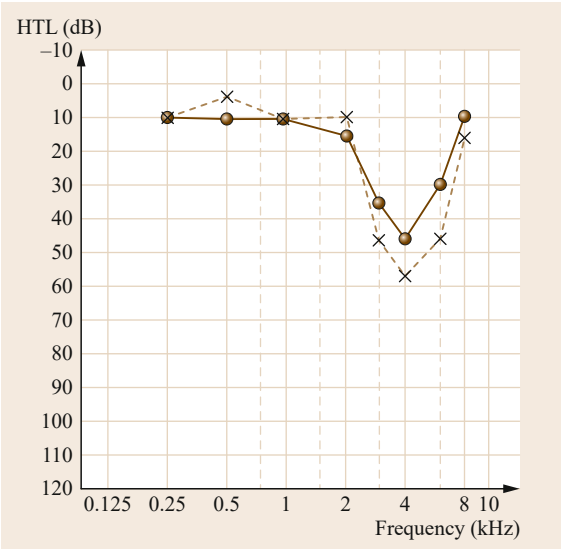

Fig. 40.1 Audiogram showing a typical music (and noise)-induced hearing loss (reprinted with permission from the Musicians' Clinics of Canada)

The first type is spontaneous OAEs (SPOAE), which are not the result of a specific stimuli, but are just a sign of a normal physiological state [40.32]. Transient evoked OAEs (TEOAE) are elicited by brief signals such as a broadband click [40.33]. Distortion product OAEs (DPOAE) are the result of an intermodulation distortion product produced by the cochlea when presented with two simultaneous pure tones that are close in frequency. The distortion product signal produced by the cochlea is a tone that is not present in the eliciting stimulus, hence the use of the term distortion [40.34]. Each OAE measurement type has its own advantages and disadvantages, depending on the desired goal of the assessment, which is either a basic assessment of a normal hearing individual or differential diagnosis with regards to abnormal hearing. In many cases, changes in OAE thresholds are observed prior to changes in pure-tone thresholds. These changes can be viewed as an early warning sign and the results could be used to counsel the musician regarding the use of appropriate hearing protection [40.26]. An inherent feature of OAE testing is the large intersubject variability in responses, which would limit the large-scale use of this type of testing in a large population. The variability could be so large as to obliterate any real changes in the mean results of the OAEs. However, longitudinal changes within an individual i. e., intrasubject variability, in combination with an established history of intense sound exposure, can provide important indications of any early changes in cochlear function.

40.3 Direct Assessment of Music with a Peripheral Hearing Loss

So far in our look at hearing loss and musicians there has been no real discussion about using music as a stimulus to assess the auditory system. Currently, to the best of the authors' knowledge, there are no dedicated assessment tools used widely on a routine basis within the clinic to assess the perceptual needs of hearing-impaired individuals wearing hearing aids to listen to music. There are a number of studies that have looked at the perception of music through cochlear implants [40.35–38] and there have been a number of clinicians who have developed their own methods to program hearing aids based on their own musical experience [40.39]. Some work has been made to develop assessment tools to evaluate music for the hearing-aid user, or potential user [40.40, 41]. *Uys* and *van Dijk* [40.42] developed a comprehensive music perception test (MPT) with a number of subscales that directly address discrimination, and identification of musical elements. The subscale categories include rhythm, timbre, pitch, and melody. Within each subscale there are specific tests to examine the number of instruments heard, the identification of melodies, or pitch discrimination using short melodic sequences. It is hoped that further development of the MPT continues and that the use of this and other tools gain acceptance within clinical settings.

40.4 Acoustic Properties of Music versus Speech

So far in this discussion we have looked at the assessment of the individual musician's auditory system. It is now important to look at how music and speech differ so that we can further discuss the use of hearing aids with musicians.

There are three primary differences between music as an input and speech as an input to a hearing aid. These are the sound level of the music, the shape of the spectra, and the crest factor [40.43]. Each of these three differences have ramifications for the electro-acoustic design of the hearing aid, the selection of the hearing aid for the individual end user, and lastly, the programming of the various software parameters such as compression within the hearing aids.

Before delving into the differences between speech and music, we must first recognize that there are some primary similarities between speech and music. Both are periodic in nature, with the possible exception of percussive music and certain linguistic obstruents such as fricatives, affricates, and stops. There can be a rich harmonic structure where higher frequency energy is found at integer multiples of the fundamental frequency. Speech energy can have a wide bandwidth, with linguistic sonorants (e.g., vowels and nasals) having most of their speech energy in the low- to mid-frequency regions and higher frequency energy deriving from the linguistic obstruents (e.g., fricatives, affricates, and stops). Similarly, music can have significant fundamental energy in the lower frequency region and higher frequency harmonic information in the higher frequency region.

Music can be generated by a number of instruments including the vocal tract. The sound levels of instrumental music are not limited by the same slow-moving neurology and musculature found in and around the human vocal tract. Music can be percussive with a resulting broadly tuned, high-frequency biased spectrum, and music can be quite vocal-like such as a violin. Both the human vocal tract and the violin function acoustically as one-half wavelength resonators and, depending on the note being played, can have similar spectra.

40.4.1 Sound Level Differences

One of the primary differences between speech and music lies in their spectral levels. Music tends to be much more intense than speech and this includes even quieter forms of acoustic folk music. Speech, because of the inherent physical limitations of the human vocal mechanism, is typically limited to sound levels below about 80 dB(A) (with peaks on the order of 90 dB SPL) [40.44]. The dB(A) scale is used to account for the perceptual abilities of the human auditory system. This is in contrast to the physical sound pressure level (SPL). Filters for dB(A) are found on most commercially sound level meters and are defined according to an IEC standard [40.45]. The highest sound level of speech in any language of the world is the low back vowel /a/ as in 'father'. Because the vocal tract is wide open during the articulation of this vowel, there is minimal damping and minimal loss of energy.

In contrast, music can be in excess of 120 dB(A) (with peaks being on the order of 140 dB SPL). Even *quiet* orchestral music can easily reach sound levels in excess of 110 dB(A). Table 40.1 shows some data for sound levels of musical instruments (adapted from [40.46]). These data are based on the assessment of over 1000 musical instruments from a distance of 3 m in the horizontal plane. The top and bottom 25th percentile data has been removed.

Table 40.1 Average sound levels of a number of musical instruments measured from 3 m. Also given is the sound level for the violin measured near the left ear of the players (adapted from [40.46], used with permission)

Musical instrument	dB(A) ranges measured from 3 m
Cello	80–104
Clarinet	68–82
Flute	92–105
Trombone	90–106
Violin	80–90
Violin (near left ear)	85–105
Trumpet	88–108

40.4.2 Crest Factor Differences

Another element that differentiates human speech from many musical instruments is the crest factor. This is the difference in decibels between the instantaneous peak of a signal and its average or long term RMS (root mean square) value.

There is a significant loss of energy during speech production for the highly damped human vocal tract. Acoustic losses typically occur as a result of small openings, or soft highly damped structures such as the tongue, lips, and cheeks [40.47]. Human speech is characterized by all of these things. Additionally, different sounds are articulated with differing positions of the tongue and lips. Opening of the small port at the back of the mouth to the nasal cavity (velopharyngeal port) allows for the articulation of nasal sounds (e.g., /m/ and /n/). In short, human speech has a highly damped energy spectrum such that the levels of the instantaneous peaks are significantly reduced. The resulting crest factor is therefore lower, typically on the order of 12 dB. That is, with speech the difference between the average RMS and any peak is roughly 12 dB.

In contrast, for musical instruments we are dealing with mechanical and acoustical systems that have a relatively low level of damping. A violin or a trumpet does not have soft walls, nor does it have a narrow opening. Subsequently the crest factor of the sound energy emanating from these instruments tends to be higher than that for speech – typically on the order of 18–20 dB. That is, with many musical instruments the difference between the average RMS playing level and any peak is roughly 18–20 dB.

If the playing level is examined in combination with the crest factor, the peaks of music are much higher in level than even shouted speech. As discussed, speech is associated typically with a 12 dB crest factor while instrumental music is associated with an 18–20 dB crest factor.

The crest factor calculation requires some assumptions. The primary one relates to the selection of the bandwidth of the analyzing window. Whenever the instantaneous peak is assessed, which is one part of the crest factor calculation, it is necessary to be able to assess it in a well-defined manner. The hearing-aid industry frequently uses a window of analysis of 125 ms (1/8 of a second). This value was derived initially from work that was undertaken in the 1940s [40.49, 50], and this work has been replicated [40.51, 52]. The choice of a 125 ms window of analysis is related to the temporal integration constraints of the human cochlea, and so it can be referred to as a *time constant* of the human cochlea.

When we discuss the crest factor, with regards to hearing-aid amplification, we are not talking about the characteristics of cochlear time constants. The input to a hearing aid is the microphone and this is before this amplified sound reaches the cochlea. The microphone and the associated digital network that follows it can be thought of as the sound detector. The system, colloquially referred to as the front end of a hearing aid [40.53], in most cases utilizes a 16 bit digital architecture that has a theoretical upper limit to its dynamic range of 96 dB. That is, the range of sounds that can be integrated and transduced through the analog-to-digital (A/D) converter is 96 dB. Because of some engineering decisions, this range can be less than the 96 dB limit and effective dynamic ranges of only 80–85 dB have been found with current technology. This is more than adequate for the processing of speech, however, we need to address the question of what is needed for music?

Of importance is that this front end of a hearing aid is not limited to the 125 ms time constant of the cochlea; it is merely a microphone, A/D converter, and associated components. Table 40.2 shows some data

Table 40.2 With different length windows of analysis and for one music sample, the difference between the RMS of the signal and its instantaneous peak (crest factor) is given. For shorter analysis windows the instantaneous peak is higher than for longer windows of analysis with a resulting higher crest factor. Adobe Audition 1.0 (San Jose California) was used to calculate the difference between the average value of the signal and the instantaneous peak. Used with permission (after [40.48])

Analysis window (ms)	500	400	300	200	125	100	50	25
Crest factor (dB)	16.45	16.43	16.45	16.44	16.45	18.22	21.68	21.68

(from [40.54]) of how the crest factor may change as a function of the analysis time window for the same signal. The only parameter that changes in Table 40.2 is the window of analysis and not the signal.

Table 40.2 clearly demonstrates that for the same signal, the crest factor (specifically the instantaneous peak component) increases significantly as the window of analysis becomes shorter. The assumption of speech having a 12 dB crest factor (at the level of the microphone and input to the A/D converter) is therefore potentially erroneous. Taking these higher crest factor values implies that even the more intense elements of speech, especially the level of an individual's own voice, may have instantaneous peaks that are in excess of what current hearing aids can handle. This is an input-related phenomenon and has nothing to do with the output of the hearing aid or the cochlear function of an individual hearing-aid user.

40.5 Some Strategies to Handle the More Intense Inputs of Music

Given the limitations that most currently available digital hearing aids have in handling the more intense inputs that are characteristic of many forms of music, there are a number of strategies that a clinician can use to alter the electro-acoustic characteristics of hearing aids that otherwise work quite well for speech. That is, given an individual who already has hearing aids that work well for speech, what are some clinical modifications that can be implemented to improve the hearing aids for the listening and playing of music? Four clinical strategies that can improve the usability of hearing aids for music will now be discussed.

40.5.1 Clinical Strategy #1: Reduce the Input to the Hearing Aid, and if Necessary, Increase the Volume

This strategy is based on the idea of bending over slightly to avoid the A/D converter ceiling. Recall that many hearing aids have a front end that has an operating range that cannot handle overly intense inputs. If the input was reduced in level, and then is compensated for later on in the circuitry with an increase made via the hearing-aid volume control, then this may be a more optimal solution than the converse, where the input is left high and the volume control is reduced. In both cases, the output to the individual's ear is the same; it is just that the first case has less front-end distortion associated with it.

There are other clinical approaches that are based on this same approach. For example, an assistive listening device (with its own volume control) can be coupled either wirelessly or via a direct audio input route to the hearing aid. In this scenario, the input to the hearing aid's A/D converter is at a quieter level thereby providing the hearing aid with a signal that is more within its front-end operating range. The assistive listening device can be as simple as a remote microphone with (reduced) volume or a wireless instrument such as a frequency modulation (FM) listening system, again with the volume turned down.

Another scenario to consider is that when riding in a car or other vehicle with an audio system, again, turn down the volume of the audio system, and if necessary, increase the volume of the hearing aid, rather than the converse.

40.5.2 Clinical Strategy #2: Removal of the Hearing Aid for Music

While this may seem counterintuitive, in some situations it may be best to simply remove the hearing aids and listen to, or play the music, unaided. This strategy is based on the finding that loudness growth in our auditory system is not linear and tends to have a more gradual increase with more intense inputs [40.55]. A person who has a moderate sensorineural hearing loss may require 30 dB of gain for soft level inputs (55 dB), 25 dB of gain for medium level inputs (70 dB), and perhaps only 15–20 dB of gain for loud inputs (80 dB). These are the typical ranges of speech. However, music, even quiet music, can have playing levels that are typically much more intense. This same individual, who requires 30 dB of gain for soft speech levels, may require no amplification, or only a couple of decibels of amplification for louder music. Table 40.3 shows the amount of gain prescribed at 1000 Hz by the FIG6 fitting formula [40.56] as a function of how intense the input to the hearing aid is. At high input levels such as with many forms of music very little hearing-aid amplification may be required, if at all. It can therefore be concluded that, in some cases the hearing instrument can and should be removed for music.

40.5.3 Clinical Strategy #3: Use a (Tape) Covering of the Hearing-Aid Microphone

This may seem like an incredibly *low-tech* solution and indeed it is. Placing several layers of household adhesive tape over the hearing-aid microphone(s) will serve to reduce the microphone sensitivity. The exact number

Table 40.3 Calculated amounts of gain required for a given hearing loss at 1000 Hz (column 1) (based on FIG6 after [40.56]). For average levels of music (95 dB(A)) inputs, virtually no amplification may be required even for very significant hearing losses (after [40.48], used with permission)

dB HL at 1000 Hz	65 dB input	80 dB input	95 dB input
15	0	0	0
25	2	1	0
35	8	4	0
45	14	7	0
55	20	10	1
65	28	15	2
75	36	20	3
85	44	24	4

of layers of tape will have to be experimented with because different brands use different thicknesses of tape, however typically three or four layers will suffice. As far as the front end of the hearing aid is concerned, the input is now 10–12 dB less intense and in many cases will be within the optimal operating range of the A/D converter. The user may need to adjust the volume control upwards slightly, depending on the level of the modified music input. This strategy provides for a flat attenuation of the input by about 10–12 dB up to 4000 Hz. There is a slight roll-off in the response above that. The exact nature of the effects of the tape on the frequency response can be measured by the clinician using probe microphone equipment.

40.5.4 Clinical Strategy #4: Change the Musical Instrument

This is typically one of the last suggestions that a clinician may make to a musician but it can be quite useful, especially in the case of the original instrument generating significant output in a frequency region of significant inner hair cell damage, such as a dead region in the cochlea. Changing to a similar but more bass-oriented instrument may be quite useful. A violinist can change to a viola, which is about a fifth lower. And an E flat saxophonist may change to a tenor B flat saxophone. For those readers who would like more information on this strategy, they are referred to an excellent resource put out by the Association of Adult Musicians with Hearing Loss (www.AAMHL.org) called *Making Music with a Hearing Loss* edited by *Cherisse W. Miller* [40.57]

40.6 Some Hearing-Aid Technologies to Handle the More Intense Inputs of Music

If an individual is seeking new hearing aids or have yet to obtain their first set of hearing aids, there are a number of technical innovations that are hearing-aid-hardware based and should be considered. That is, these are not software adjustment that can be made but are inherent in the hearing-aid design. Over the past several years, the hearing aid manufacturing field has transitioned to a post-16 bit architecture that has allowed a larger input dynamic range. In order to handle some of the higher level inputs associated with music, an 18 or 19 bit system should be sufficient. Many of these manufacturers also use one or more of the following digital techniques mentioned below in their algorithm and/or hardware design. Some of these technical innovations are mentioned below and have been on the market for quite a while.

40.6.1 Technical Strategy #1: K-AMP Analog Hearing Aid

Analog hearing aids are no longer widely available today but an advantage of this approach to amplification is that analog hearing aids do not require an A/D converter and may therefore not be limited with regard to the input as discussed earlier. One analog hearing aid, the K-AMP [40.58–60], has shown itself to be a good choice for music and speech for over 25 years. This technology has a specially designed front end that can handle inputs of up to 115 dB SPL, which is the limit of the hearing-aid microphone. Hearing aids with the K-AMP circuitry were the mainstay of working with hearing-impaired musicians in the 1990s and early 2000s.

40.6.2 Technical strategy #2: Changing Where the Dynamic Range of the A/D Converter Operates

There are now a number of technologies in the hearing-aid industry that either automatically adjust to the input signal to ensure that the input level is within the capability of the A/D converter, or increase the dynamic range of the A/D converter to be optimized for the more intense inputs characteristics of music. The first technological approach is analogous to the strategy of bending over slightly under a low bridge. The input level is reduced or compressed after the microphone but before the A/D converter, and then amplified or expanded digitally after the A/D converter. The final digitized input

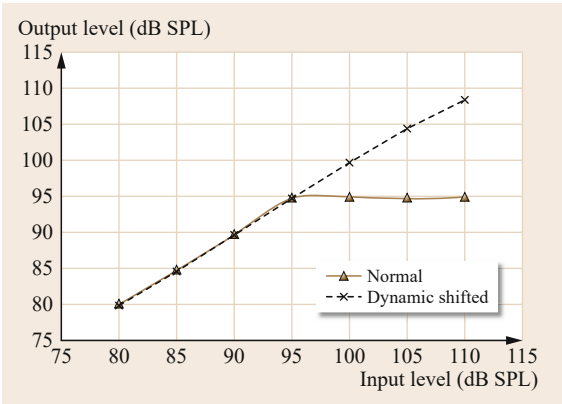

Fig. 40.2 Input/output function with compression settings of 110 dB (dynamic shifted) and 95 dB (normal) before the A/D converter for a 1 kHz sinusoidal signal (reprinted from [40.61], with permission from Elsevier)

is essentially identical to what would have been received had it been generated at a lower level initially. The second technological approach is derived from the definition of *dynamic range*. As the name suggests, it is not 96 dB SPL that is the maximum input to a hearing aid before distortion occurs, but that this is the (maximum) range that is characteristic of the 16-bit architecture in current digital hearing aids. This range can go from 0 dB SPL to 96 dB SPL, or from 15 dB SPL to 111 dB SPL. In both cases the dynamic range is 96 dB but the second one is more appropriate for listening to and playing of music. Both of the above technological solutions are currently in the marketplace and new ones, based on similar approaches, are being developed. For more information please see [40.61–65].

If the level that is permitted to enter the hearing aid is adjusted before the A/D converter, then this can have large effects on the input to the hearing aid. The differences in behavior of an input compression system when the levels are changed are shown with an input/output graph in Fig. 40.2. In the reference situation, seen as a gray line, the threshold of the input compressor becomes active at 95 dB SPL, whereas the black line shows the condition where the level has been shifted to have an effect at 110 dB SPL. This measurement was made with a 1000 Hz pure-tone sinusoidal signal swept in level.

We should next examine what happens with music, using an excerpt from *Eine kleine Nachtmusik* (Serenade No. 13 for strings in G major), K. 525 by Mozart (CD EMI records) played at 110 dB SPL (peak). The first waveform in Fig. 40.3 shows the music with the threshold for compression set to 95 dB SPL. The resulting output, in gray, is compressed in comparison to the original recording, seen in black. In Fig. 40.4 however, the level before compression takes place is shifted to 110 dB and this compressed effect on the waveform is not seen. The dynamic range of the music is therefore preserved and will be converted into the digital domain.

The adjustment to the compressor is being made before the A/D converter and therefore before any amplification is applied [40.63]. The peaks of the music are not increasing the output levels of the hearing aid and therefore the maximum output levels have not changed. The maximum power output (MPO) in the hearing aid is always set based on the real or calculated uncomfortable loudness levels (UCL) to prevent any potential damage to the hearing-impaired listener's residual hearing.

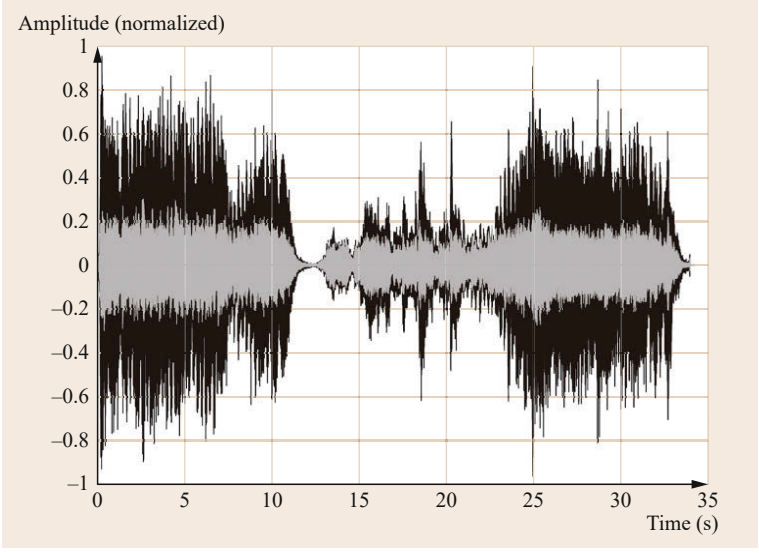

Fig. 40.3 Recording with the threshold of the compressor set to 95 dB before the A/D converter; input level 110 dB SPL. The *black waveform* is the original input file (reprinted from [40.61], with permission from Elsevier)

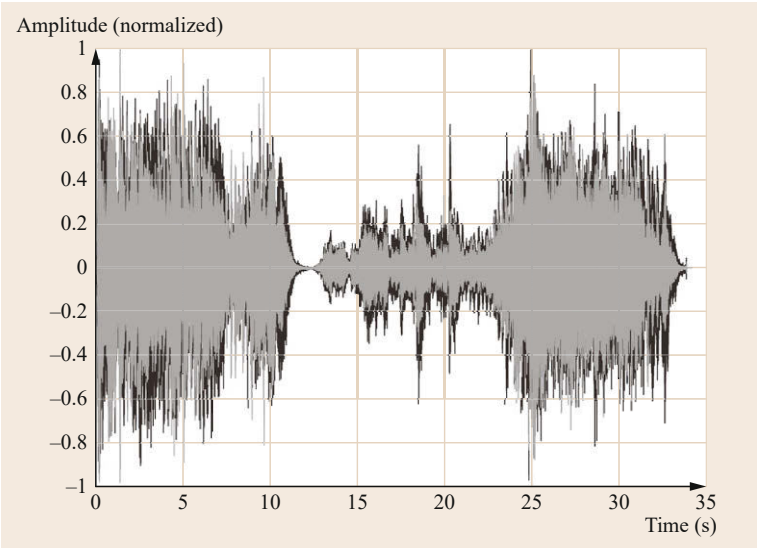

Fig. 40.4 Recording with the threshold of the compressor set to 110 dB before the A/D converter; input level 110 dB SPL. The *black waveform* is the original input file (reprinted from [40.61], with permission from Elsevier)

40.6.3 Technical Strategy #3: Use of a Less Sensitive (or −6 dB/Octave) Microphone

The use of a hearing-aid microphone that is less sensitive to lower frequency sound energy, which can be quite intense, has been shown to be quite useful for those musicians who do not require significant low-frequency amplification. In this approach, a −6 dB/octave low cut (i. e., high pass) hearing-aid microphone system is used in place of the broadband hearing-aid microphone that is typically used. This hearing-aid microphone is less sensitive to 500 Hz energy by 6 dB and to 250 Hz energy by 12 dB (i. e., a 6 dB/octave roll-off). High-level, low-frequency music energy that would otherwise cause the front end to distort will now be reduced, thereby allowing the input to be more within the optimal operating range of the A/D converter and associated circuitry. For those individuals who require a significant amount of low-frequency amplification, this can be compensated for within the fitting software (after the A/D converter) by adding back in the 6 dB of lost input at 500 Hz and 12 dB at 250 Hz. More information on this process can be found in [40.66, 67].

It is important to reiterate that none of these technologies or clinical strategies are simply a matter of adjusting the fitting software provided by the hearing-aid manufacturer. These technologies are built into the hearing-aid hardware and cannot be adjusted within the clinic. Fitting software adjustments are therefore not the primary approach that should be taken whenever music is considered as an input to a hearing aid.

40.7 General Recommendations for an Optimal Hearing Aid for Music

If the clinician has been able to select or modify the hearing aid appropriately to ensure that the more intense components of music are transduced through the front end with minimal distortion, then what types of software manipulations would be useful for a *music program*? We will now review four general clinical recommendations.

40.7.1 Recommendation #1: Similar WDRC Parameters for Speech and for Music

When looking at the compressions settings in a hearing aid, it is quite possible that no changes would need to be implemented for a *music program* that would be different from a *speech in quiet program* [40.43, 68–70]. This could also be attributed to the fact that it is quite difficult to make generalized statements concerning the many differences in the implementation of compression architecture used by the different manufacturers of hearings aids. The use of the wide dynamic range compression (WDRC) circuitry is primarily an attempt to reestablish normal loudness growth due to outer hair cell damage. WDRC can apply more amplification to softer signals than to louder signals so that the dynamic range at the input can be fitted into each individual's personal dynamic range [40.71]. Therefore, audibility and comfort

are maintained. WDRC addresses the damage to the auditory system rather than the nature of the input stimuli per se. *Davies-Venn* et al. [40.68, p. 696] supported this notion and noted that

> *WDRC* [...] *may be just as good for music as for speech* [... and] *that* [this] *hypothesis was supported by the present data.*

40.7.2 Recommendation #2: Gain Settings Within a Dedicated Music Program – the – 6 dB rule

Assuming that both of the *speech in quiet* and *music* programs utilize similar WDRC parameters then the *music program* should be set with about a 6 dB lower OSPL90 (OSPL90) and a 6 dB lower gain than the individual's *speech in quiet* program. Since the OSPL90 is a measure of the maximum amplification that can be applied via a hearing aid within the limitations of using only pure-tone stimuli, then we want to ensure that the peaks of the signal do not exceed the tolerance level of the individual. If the crest factor for music is roughly 6 dB higher than that of speech (18 dB versus 12 dB), then the OSPL90 for music should account for this. As can be seen from Table 40.2 this can vary significantly depending on how one analyzes the crest factor, but generally in order to prevent the peaks of music from causing discomfort, the OSPL90 and the gain should be 6 dB less intense than for the *speech in quiet* program setting.

40.7.3 Recommendation #3: Bandwidth for a Music Program

There is no definitive research that has been performed specifically concerning the bandwidth within the hearing aid that is necessary for music, but here is a summary of what the most relevant studies indicate. Essentially, given the limitations of an individual's hearing loss there is no reason to set the bandwidth differently for a *speech in quiet* program as there is for a *music* program. Any change in bandwidth has more to do with the degree and configuration of the audiometric hearing loss. Examining the work of *Moore* et al. [40.72], *Moore* [40.70] and the work of *Ricketts* et al. [40.73] several general recommendations can be made. A broad bandwidth should be specified (to the limits of the capability of the hearing aid) if there is only a mild to moderate sensorineural hearing loss, and if the configuration is relatively flat. However if the hearing loss is greater and/or the configuration of the audiogram is steeply sloping, that is, the hearing loss is milder in the low frequencies and is much worse in the high frequencies, then a narrower bandwidth may be desirable.

40.7.4 Recommendation #4: Disable the Feedback Cancellation and Noise Reduction Systems

Noise reduction systems and feedback management systems are designed to remove acoustic information that is judged to be undesirable, or even uncomfortable for the hearing-aid user. For this reason a general recommendation can be made to disable the feedback cancellation system and noise reduction system, to the extent that they can be disabled via the hearing-aid fitting software, so they do not affect the musical signal. Noise reduction systems are designed to classify noise on the basis that signals with low modulation are generally less interesting (e.g., steady state noise), than signals with high modulation such as human speech [40.74]. With some genres of music the noise reduction system may actually remove part of a musical signal that could be of interest to the listener based on this classification scheme. A subset of noise reduction systems may also reduce the intrusive nature of transient signals such as cutlery sounds in a restaurant. Again this could affect music depending on the genre and the instrument played. In some cases, feedback cancellation systems can remove periodic signals similar to that produced by some musical instruments such as a flute or a piccolo [40.27]. They may also produce other audible artifacts such as *chirping* in the case of phase cancellation technology for feedback management [40.27, 75]. Although this is becoming less of a problem as these algorithms are improved, it is still possible that a hearing aid might confuse a feedback signal with a harmonic of the music. Some manufacturers have limited the feedback management algorithms to only function in the higher frequency region (e.g., above 2000 Hz) although this, to date, has only been a partial solution. Given the wide variety of implementations of feedback reduction cancellation and noise reduction algorithms that are currently available, it is generally desirable that they should be disabled if at all possible.

40.8 Conclusions and Recommendations for Further Research

Amplification with hearing aids has been shown to reduce the negative effects of hearing loss faced by individuals who have a hearing impairment but who do not require a cochlear implant [40.76–78]. In this chapter we have explored the topic of enhancing the listening experience for music with hearing aids for musicians and enthusiastic concert goers. We first looked at the basic assessment of the auditory system, primarily the periphery where damage is clearly identifiable due to prolonged exposure to noise or loud music. We then explored some key acoustical differences between speech and music and how these differences need to be taken into account when looking at hearing aids for music. Hearing-aid technology was then examined and solutions to make music not only sound better but also be more useful for the musicians were discussed. The key limitation concerning the capability of current digital hearing aids to accommodate the more intense elements of music is the A/D converter. Expending research and development efforts on the other elements within the hearing aid will not really improve the fidelity of music.

As in most areas within the field of audiology the realm of music as an input to hearing aids and the technologies that are available is a rapidly changing one. New technologies are on the horizon, such as better A/D converters that may be implemented by various manufacturers. New assessment techniques such as the MPT discussed earlier could potentially lead to better and more personalized evaluation of the hearing-impaired musician. The authors both hope that music becomes more of an issue within audiology and also that hearing impairment becomes more of an issue within the field of musicology. Researchers and clinicians in two fields could potentially create common solutions to overcome the setbacks that musicians face when confronted with a hearing loss.

41. Music Technology and Education

Estefanía Cano, Christian Dittmar, Jakob Abeßer, Christian Kehling, Sascha Grollmisch

In this chapter, the application of music information retrieval (MIR) technologies in the development of music education tools is addressed. First, the relationship between technology and music education is described from a historical point of view, starting with the earliest attempts to use audio technology for education and ending with the latest developments and current research conducted in the field. Second, three MIR technologies used within a music education context are presented:

1. The use of pitch-informed solo and accompaniment separation as a tool for the creation of practice content
2. Drum transcription for real-time music practice
3. Guitar transcription with plucking style and expression style detection.

In each case, proposed methods are clearly described and evaluated. Objective perceptual quality metrics were used to evaluate the proposed method for solo/accompaniment separation. Mean overall perceptual scores (OPS) of 24.68 and 34.68 were obtained for the solo and accompaniment tracks respectively. These scores are on par with the state-of-the-art methods with respect to perceptual quality of separated music signals. A dataset of 17 real-world multitrack recordings was used for evaluation. In the drum sound detection task, an F-measure of 0.96 was obtained for snare drum, kick drum, and hi-hat detection. For this evaluation, a dataset of 30 manually annotated real-world drum loops with an onset tolerance of 50 ms was used. For the guitar plucking style and guitar expression style detection tasks, F-measures of 0.93 and 0.83 were obtained respectively. For this evaluation, a dataset containing 261 recordings of both isolated notes as well as monophonic and polyphonic melodies with note-wise annotations was used. To conclude the chapter, the remaining challenges that need to be addressed to more effectively use MIR technologies in the development of music education applications are described.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_41

41.1 Background

The rapid development of music technology in the past few decades has inevitably changed the way people interact with music today. The means of music consumption have changed, most notably due to the constant availability of digital music via the Internet and mobile applications. Additionally, the technology for music production has moved almost entirely to the digital domain. This evolution made music production technology affordable for individuals and put the ability to create and distribute music in the hands of the average music lover. It was only to be expected that these technology changes would also influence other fields of research, and the application of music technologies in music education began to draw further attention. However, the development of new applications for music education faces many challenges:

1. Development of robust and efficient algorithms that can help in practicing music
2. Bridging the methodical gap between music education and music technology
3. Design of appealing and entertaining applications that motivate the user while developing real musical skills.

When talking about music technology in music education, two important points that need to be addressed are:

1. The development of mechanisms to give users automatic feedback about their performances
2. The possibility to automatically generate relevant practice content.

Several technologies, mainly developed within the music information retrieval (MIR) community, are relevant here. Automatic pitch detection, for example, deals with the extraction of fundamental frequency (f_0) sequences from a given music recording. In a music education context, pitch detection algorithms take an audio signal of the user's performance, and determine which notes the user plays over time. In this way, systems can compare the user rendition to a reference (ground-truth). In terms of automatic content creation, music transcription technologies attempt to automatically extract time and pitch information necessary to recreate the underlying musical score from recorded music. Also relevant for content creation are sound separation technologies that attempt to extract the sound of a particular musical instrument from an audio mixture. In a music education context, music transcription would allow the automatic creation of music scores for pieces whose score is not available, such as improvisations, live performances, etc. Sound separation would allow, for example, the creation of backing tracks that the user can use during practice time or concert preparation.

In Fig. 41.1 an example of music technology applied in a music education context is displayed. Figure 41.1a shows a spectrogram with the results of a pitch detection algorithm. Figure 41.1b shows how this algorithm can be used inside a music education application to to give the user real-time feedback on their performance.

This chapter presents a general overview of the use of music technology in music education. Three specific cases of the use of music information retrieval (MIR) technologies in a music education context are presented:

- Sound source separation
- Drum transcription
- Guitar transcription.

The chapter is organized as follows: Sect. 41.2 gives an overview of existing applications and projects and Sects. 41.3–41.5 present the three aforementioned cases of MIR research and their application to music education. Finally, Sect. 41.6 presents a discussion and outlines future challenges in the field.

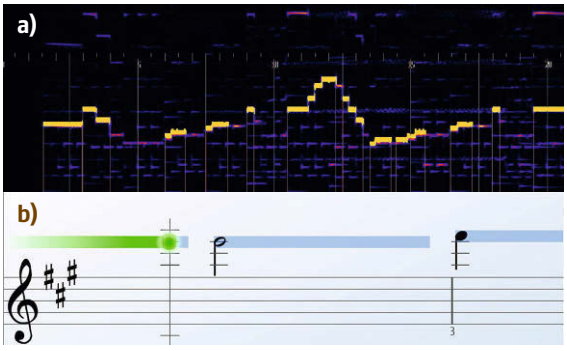

Fig. 41.1a,b From music technology to music education. **(a)** Spectrogram showing the results (in *yellow*) of a pitch detection algorithm. **(b)** Example of a music game with real-time pitch detection functionalities

41.2 Music Education Tools

This section provides a general overview of commercially available music education applications. These applications can be broadly classified into four categories:

- Published music education material
- Music video games
- Software for music education
- Music-learning mobile applications (apps).

For a thorough list of corresponding online references, please refer to [41.1].

41.2.1 Published Music Education Material

Play-along CDs became very popular in the 1980s. They allow the user to practice popular musical pieces in sync with specially recorded (e.g., piano or orchestral) accompaniments. In most cases, the accompaniment and the solo instrument are panned to the left and right stereo channels, so the user can directly choose the mixing ratio. In this way, users can familiarize themselves with the musical piece while developing musical skills. The main drawback of such practicing tools is the limited amount of available content: each track needs to be produced and recorded, leading to high production costs. Therefore, play-along CDs are mainly limited to some representative concerts of the instrumental repertoire and very famous songs. Popular jazz play-alongs have been published by *Jamey Aebersold* [41.2] in the jazz series with over 100 items, and by the Hal Leonard Corporation [41.3] featuring different artists, instruments, playing techniques, jazz standards, and thematic editions. A larger catalog of play-alongs for different genres is offered by Music Minus One [41.4] including different instruments and ensembles.

Instructional videos started as an educational tool, where particular topics like instrument playing techniques are shown and explained by renowned professional musicians, covering important points like proper warm-up exercises, improvisation, and ways to play certain sections of a musical piece. Later on, the popularity of some musicians was used as a marketing tool, moving the focus of the videos from the musical content itself to the featured artist giving instructions. This appealing idea led to a vast and growing catalog of instructional videos. Initially released on VHS tapes in the 1980s and 1990s, modern videos are published on digital media formats like DVD or online resources like YouTube. Educational videos have been published amongst others by Alfred Music Publishing [41.5], Berklee Press [41.6], Icons of Rock [41.7], and Homespun [41.8].

Even though published materials are very popular for practicing at home, they all share the same disadvantage: lack of direct feedback of the users' performance and progress. Therefore, users have to be completely self-motivated and rely on their own perception. This can be very challenging especially for beginners.

Moving away from traditional content distribution, some websites such as Drumeo [41.9] or Get2Play [41.10] focus on offering online instructional videos as their main service. Compared to physically distributed instructional videos, Drumeo tries to avoid the missing feedback by offering community features, custom lesson plans, and feedback by instructors for which students have to submit a video of their performance.

41.2.2 Music Video Games

Music video games were first recognized as a genre in 1996 with the release of the music rhythm game PaRappa the Rapper for Sony PlayStation 1. Rhythm games can be seen as a subgenre of music video games, which had their commercial breakthrough with the release of Guitar Hero in 2005 for Sony PlayStation 2 [41.11]. Its specialized controller simulates a real guitar in shape, replacing strings and frets with five buttons and a strum bar. Later installments of the series extended the game by supporting simplified drums, bass guitar, and vocals. A comparable popular video game is Rock Band, which covered guitar, drums, bass and vocals already in its first release. The third installment added a three-part harmony recognition feature for vocals and a keyboard-shaped controller. Both game series offer new songs as downloadable content and are available on various gaming platforms.

While being entertaining and successful in fostering interest in music, rhythm games fail to develop musical skills transferable to real musical instruments due to their overly simplified instrument controllers.

Karaoke music video games focus on vocal performance, displaying lyrics and the reference melody (often displayed in piano-roll notation) while rating the users' vocal performance. One popular example in this subgenre is SingStar [41.12], released for Sony PlayStation 2 and 3.

The first commercially viable music video game designed to be controlled with a real musical instrument was Rocksmith, released in the United States in September 2011 for Microsoft Xbox 360, Windows, and Sony PlayStation 3 by Ubisoft [41.13]. It supports electric guitar and electric bass guitar. The audio signal is captured with an USB audio interface connected

to the output plug of the instrument. The performance of the user is rated in real-time by means of pitch detection and compared to the reference notation of the backing track. The difficulty adapts to the skill level of the player, adding and removing notes depending on performance. Additional mini games with scales or chord exercises are available to further improve the playing skills of the user. This feature moved the game away from mere entertainment towards music education. The latest installment, Rocksmith 2014, released in November 2013, moves even more in an educational direction by adding a session mode where players can jam with a virtual band. The virtual band members, musical genre, tempo and key of the jam session can be selected and the band adjusts to the user's performance.

While most of the mentioned games have a large database of available content already delivered or available for download, the possibility of including original content is not supported and mostly it is popular rock/pop songs that are available. Therefore, pleasing all users' personal tastes is not possible.

41.2.3 Music Education Software

While music video games focus mainly on entertaining the user, music education software aims at an interactive educational approach.

An example web-based system developed by Grieg Music Education is Music Delta [41.14]. It is available in two different versions:

1. Music Delta Planet, developed for teaching music history, artists, and composers to elementary-school children in an entertaining way
2. Music Delta Master, consisting of modules for creating a deeper understanding of music theory, composition, history, and performance.

When it comes to musical skills, sight reading and dexterity, Synthesia [41.15] and Gigajam [41.16] are software applications that allow users to play along to exercise pieces with Musical Instrument Digital Interface (MIDI) instruments, such as keyboards and drum sets.

SmartMusic is aimed at orchestras, woodwind, brass, percussion, and string musicians as well as vocalists of all levels [41.17]. While students can access the SmartMusic database that contains numerous musical pieces, educators can assign tasks to their students for a more guided learning approach. SmartMusic includes several practice tools, e.g., for displaying fingerings, reducing tempo and recording for self-assessment.

Apple's interactive learning software GarageBand teaches piano and guitar with specially designed content [41.18]. The system uses the computer microphone or USB audio devices to provide direct feedback. Even though it is released for both Mac and iPad, the mobile version lacks the practicing content included in the desktop version.

Songs2See is an application that supports both real-time feedback during practice, as well as importing of custom exercises [41.19]. It was originally developed in an MIR research project [41.20]. In contrast to the above-mentioned music video games, it has a more thorough approach to instrumental learning and lets users choose between common music notation, piano-roll, and tablature.

41.2.4 Music-Learning Mobile Apps

The market for tablets and smartphone applications is growing steadily, with a considerable number of music learning apps published so far. With the rapid and vast development of apps nowadays, keeping an updated list of music-related apps can be very challenging. Here, a series of representative apps have been described that have presented important developments in the music app context. However, this list is by no means extensive and a great number of relevant and valuable apps, which have not been described in this chapter, are also available for the user.

An application targeting guitar players is Rock Prodigy, which started as a pure download product for iPad, iPhone and iPod touch [41.21]. It was later released for Windows and Mac as well. The user is recorded while playing and immediate performance feedback is given. It offers courses about chords, rhythm, scales, technique, and music theory. The courses can be purchased as downloadable content depending on the user's needs.

A more classical approach is taken by the interactive score sheet app Tonara available for iPad [41.22]. The main feature is automatic score page turning by means of score-following, which adjusts to the user's progress by analyzing the microphone input. Content must be purchased in the app store and offers mostly popular and classical music tracks.

The company Yousician – previously called Ovelin – initially brought to the market two games particularly aimed at beginners: Wild Chords and Guitar Bots. While Wild Chords tried to familiarize the user with guitar chords using and animal-themed interface, Guitar Bots came as a followup product also targeting more advanced performers. The company has now completely focused on their latest app Yousician, marketed as a personalized music teacher and first released in 2014. Yousician currently supports guitar, ukulele, bass, and piano.

41.2.5 Research Projects

A few research projects have dealt with the development of electronic learning systems for music education in the past years. Projects funded by the European Commission include the Interactive Multimedia Environment for Technology Enhanced Music Education and Creative Collaborative Composition and Performance (i-Maestro), the Virtual European Music School (VEMUS), the Interactive Music Tuition System (IMUTUS), the aforementioned Songs2See [41.19, 23–25], and Emused.

Focusing on the violin family, i-Maestro offered enhanced and collaborative practice tools by analyzing gesture and posture based on audiovisual systems and sensors attached to the performer's body. IMUTUS' main goal was to develop a practice environment for recorder where students would get immediate feedback about their performance. The follow-up project VEMUS extended the approach with the inclusion of more musical instruments and tools for self-practicing, music teaching, and remote learning.

The Music Representation Research Group at IRCAM developed Antescofo [41.26], a score-following system and a language for musical composition that automatically recognizes the player's position and tempo in a musical score. Therefore, it can be used as a tool for tempo and performance analysis by researchers and as a practicing tool with interactive accompaniment by music students. Furthermore, it assists the user during the composition process by synchronizing computer-generated sounds with instrumental performances.

Moving the focus from music learning to automatically generated computer accompaniments, Music Plus One [41.27] intended to increase the aesthetic and perceptual quality of the generated music. This is achieved by listening to the users and following their timing and expression. This system, developed by the School of Informatics and Computing in Indiana University, consists of three main steps:

1. *Listen*: It identifies the note onsets and matches them to the reference via a hidden Markov model (HMM).
2. *Play*: The audio output is generated by phase vocoding a pre-existing playback.
3. *Predict*: It tries to predict the future timing by using a Kalman filter-like model.

KOPRA-M (Entwicklung und empirische Validierung eines Modells musikpraktischer Kompetenzen) [41.28] focused on the measurement of music competencies of German secondary-school students. The students have to solve a set of tasks that can be grouped into singing, melody and rhythm tasks. The melody and rhythm tasks have to be performed on a tablet with the purpose-built color music grid app, for the purpose of avoiding differences in rating due to prior skills on certain instruments like piano. The audio input of all tasks is recorded on the system's server for automated ratings. The system consists of a main server that communicates with the client software on the students' machines. The system attempts to model ratings from human experts by employing MIR methods.

41.3 Sound Source Separation for the Creation of Music Practice Material

As explained in Sect. 41.2.1, play-along versions are very popular for music practicing. Due to their expensive production costs, only very popular musical pieces are available and finding play-along versions for individual tastes can be very hard. An alternative way to obtain play-along versions is sound source separation of original music recordings. Sound source separation is an umbrella term for diverse signal processing methods used to extract *source signals* from an audio *mixture*. In the music context, sound source separation refers to the extraction of a given musical instrument from a polyphonic, multitimbral music recording. This section focuses on a particular case of sound source separation called *solo* and *accompaniment* separation. For this specific task, the goal is to separate the audio mix into two sources only: the main (or solo) instrument and the accompaniment. Ideally, this process yields a play-along version of any music recording [41.29].

41.3.1 State of the Art

As of today, the use of prior information about the sources has proven to be advantageous for the separation quality, which is especially true for music signals. The inclusion of known information about the sources in the separation scheme is referred to as *informed source separation* (ISS). ISS comprises, among others, the use of MIDI-like musical scores, the use of pitch tracks of one or several sources, and the extraction of model parameters from training data of a particular sound source [41.30].

In a very general sense, a sound source separation process can be divided into three main processing stages. This process is depicted in Fig. 41.2:

1. *Source parameter estimation*: Before any separation can be performed, all methods need to estimate the parameters corresponding to the desired source. Depending on the method used, different parameters might be required, such as magnitude envelopes, frequency locations of harmonic components, activation coefficients, etc.
2. *Prior information*: The estimation stage often makes use of prior information about the sources to guide and make the estimation more robust.
3. *Separation procedure*: After having estimated the source parameters, this stage refers to the actual separation of the spectral content from the different sources.

In Fig. 41.2, a general block diagram of a sound separation process is illustrated. For each of the processing stages of a common sound source separation process, different methods have been applied in the literature.

Prior information of different types has been used for sound separation. Some approaches make use of pitch sequences of the sound sources to perform separation. In some cases, automatic methods for pitch detection such as the ones presented in [41.31, 32] have been used to extract the f_0 sequence of the main instrument [41.33]. Other approaches have proposed pitch-informed separation methods that extract pitch information directly during the parameter estimation stage (Fig. 41.2) of the separation process [41.34, 35]. Other methods have used available symbolic scores (e.g., MIDI-files) of the music piece as prior information [41.36, 37]. Some systems make use of instrument-specific prior information to perform separation [41.38–40]. These approaches naturally lean towards instrument-specific separation and attempt to model a given musical instrument as accurately as possible.

In the parameter estimation stage, a great diversity of models and techniques have been used to characterize the target source before the final separation procedure. Two signal models, for example, have been frequently used in the separation context. Some systems have used a *sinusoidal model* to characterize sound sources as a sum of sinusoids with varying amplitudes and frequencies [41.41, 42]. Other systems have used the *source/filter model* for separation [41.43]. Some systems have taken advantage of signal sparsity to perform separation [41.44], or have used the repetitive structure of some music signals to differentiate them from other sources [41.45].

A very commonly used technique applied in sound source separation is *nonnegative matrix factorization* (NMF). NMF takes advantage of the nonnegativity of the magnitude spectrogram, and attempts to represent the spectrogram audio mixture as a time-varying weighted sum of spectral bases. Some systems that have used NMF in the separation scheme are [41.46–48]. *Nonnegative tensor factorization* (NTF), which can be understood as a generalization of NMF, has been applied in separation of stereo and multichannel signals [41.49, 50].

After the parameters of the sources have been estimated, the goal of the last stage of a separation process is to obtain a spectral representation of each of the sources to separate. This is the separation procedure block in Fig. 41.2. In this stage the most commonly used procedure is generalized Wiener filtering, which can be applied both in a single-channel scenario [41.51] and as a multichannel approach [41.52].

41.3.2 Proposed Method

The proposed method extracts pitch sequences of the solo instrument and uses them to guide parameter estimation. The main characteristic of the proposed method is that it gathers information of tone objects and uses known characteristics of musical instrument tones to improve estimation. The proposed solo/accompaniment separation method is composed of five processing stages:

1. Pitch extraction
2. Tone formation
3. Harmonic series refinement
4. Spectral masking
5. Postprocessing.

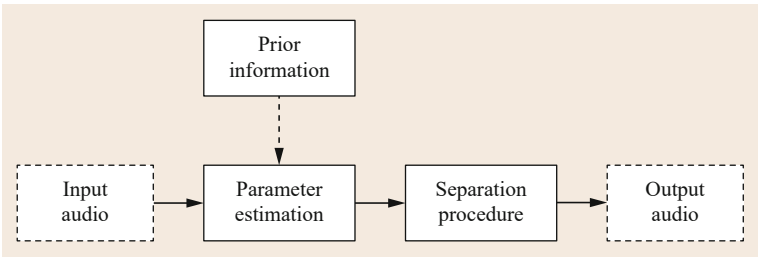

Fig. 41.2 Block diagram of a sound source separation process where prior information about the sources is available

The method operates on spectrograms of the music recordings that are computed via *short-time Fourier transform* (STFT) and its inverse.

Pitch Detection

The pitch detection algorithm described in [41.31] is used to extract frame-wise fundamental frequency sequences $f_0(n)$ of the solo instrument. The algorithm is based on a pair-wise evaluation of spectral peaks that detects partials with successive harmonic numbers. Voices are created from detected pitch candidates and are characterized by a magnitude threshold and frequency range. The most salient voice is selected as the main melody. During pitch extraction, an analysis frame of 46 ms is used in conjunction with a hop size of 5.8 ms. Unpitched frames are marked with $f_0(n) = 0$ Hz.

Tone Formation

The raw f_0 estimates from the pitch detection stage are analyzed over time to create tone objects. A new tone is started when an f_0 value in the range between 65–2000 Hz is found. After the start of a tone has been detected, a moving average filter of length $L = 3$ frames is used to calculate the mean frequency value $\hat{f}_0(n)$ in the time interval defined by the filter length L. The end of a tone is defined either by a new $f_0 = 0$ Hz (no tone was detected) or by a mean frequency variation larger than a semitone (a new tone has started). A minimum tone length of 100 ms is defined. Each tone object is defined by its initial frame n_i, final frame n_f, and its frame-wise *instantaneous frequency* (IF).

Harmonic Series Refinement

This stage estimates the harmonic series of the solo instrument for each tone. Let $k_p(n)$ be the frequency bin of the ideal location of partial p calculated as an integer multiple of the fundamental frequency. The maximum frequency deviation of each partial p from its ideal harmonic location is defined as δ_max. For each time frame n in the range defined by $[n_\mathrm{i}, n_\mathrm{f}]$, a frequency band given by $[k_p(n) - \delta_\mathrm{max}, k_p(n) + \delta_\mathrm{max}]$ is defined where the observed partial location $\hat{k}_p(n)$ is searched. For each partial index $p = 2, \ldots, p_\mathrm{max}$, the search returns the frequency bin $\hat{k}_p(n)$ where the observed harmonic with the largest amplitude is observed. Each partial is allowed to have individual deviation from the ideal harmonic location.

Spectral Masking

After the complete harmonic series has been estimated, initial binary spectral masks for the solo $M_\mathrm{S}(k, n)$ and accompaniment $M_\mathrm{A}(k, n)$ are created. Each time-frequency bin is defined either as part of the solo instrument or part of the accompaniment. To compensate for spectral leakage in the time–frequency transform, a tolerance band $\Delta = 1$ centered at the observed partial location $\hat{k}_p(n)$ is included in the masking procedure.

Postprocessing

This stage refines the initial estimation of the spectral representation of the solo instrument. Three main processing stages are proposed:

1. *Attack refinement*: As clear spectral peaks are mostly observed in the sustained part of the tone, the pitch detection algorithm requires a few processing frames before a valid f_0 value can be detected. To compensate for this inherent delay, the observed harmonic structure $M_\mathrm{S}(k, n_\mathrm{i})$ in frame n_i is replicated in all the frames 70 ms ahead of n_i.
2. *Transient interference reduction*: Transient interferences are assumed to be vertical events in the spectrogram that are common to several (if not all) harmonics and occur in a short time interval [41.53]. In order to detect transients in the solo signal, the temporal envelopes of the partials are smoothed with a median filter of length $L = 3$ and normalized to the [0, 1] range. The lowest partial index considered for the detection of transients $p_\mathrm{low} = 9$. A magnitude threshold $\gamma_L = 0.6$ is defined and frames where the normalized smoothed magnitude envelopes are larger than γ_L are detected as possible transients. The minimum number of partials where a magnitude value larger than γ_L has to be observed for the event to be considered a transient is defined as $\mathrm{min}_p = 6$. To remove a detected transient, the value of $M_\mathrm{S}(k, n)$ in the time frame where the transient was detected is replaced by the mean magnitude value of the normalized smoothed magnitude envelope in the L time frames before the transient was detected. The accompaniment mask is recalculated as $M_\mathrm{A}(k, n) = 1 - M_\mathrm{S}(k, n)$ and the new postprocessed masks are no longer binary.
3. *Common amplitude modulation* (CAM): Partials of a musical instrument tone tend to exhibit highly correlated temporal envelopes. This phenomenon is known as common amplitude modulation [41.54]. Data-driven CAM is enforced in the estimation by weighting the temporal envelopes of the partials with a reference curve. To obtain the reference envelope only the first $p_\mathrm{CAM} = 5$ partials are considered as estimation is always more accurate for lower partials. The reference curve is the normalized temporal envelope of the partial with the highest mean cross-correlation $\bar{r}_p$ with the other $p_\mathrm{CAM} - 1$ en-

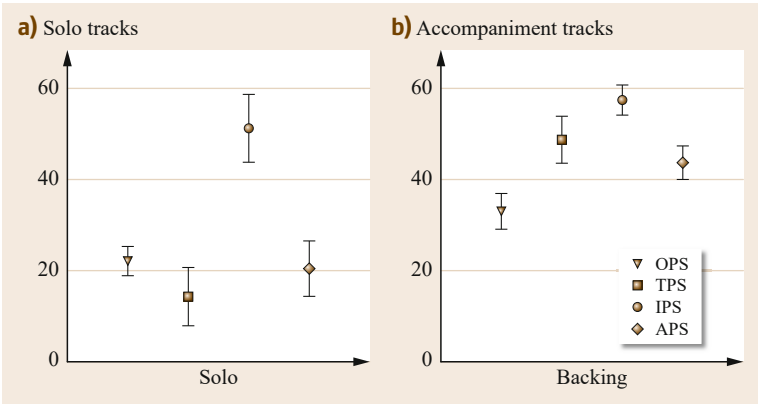

Fig. 41.3a,b Objective perceptual quality measures obtained with the proposed method: overall perceptual score (OPS), target-related perceptual score (TPS), interference-related perceptual score (IPS), artifact-related perceptual score (APS). **(a)** Solo tracks, **(b)** accompaniment tracks

velopes. That is,

$$p_{\text{ref}} = \underset{p}{\text{argmax}}(\bar{r}_p) \,.$$

All the partial envelopes are weighted with the temporal envelope of partial p_{ref}.

41.3.3 Evaluation and Results

The proposed method was evaluated with a dataset composed of 17 multitrack recordings: 10 tracks with vocal solos, and seven tracks with different instrumental solos freely available in [41.29]. The Perceptual Evaluation methods for Audio Source Separation (PEASS) toolbox [41.55] was used to evaluate quality of resulting signals. Resulting quality measures are presented in Fig. 41.3. Mean values with 95% confidence intervals are presented.

The algorithm shows particularly high IPS scores both for the solo and the accompaniment. These results suggest good isolation of the solo instrument. High IPS scores often come hand in hand with lower APS and TPS scores. This can be more clearly observed in the results for the solo tracks. Perceptual quality scores are in general higher for the accompaniment track than for the solo. Larger confidence intervals can be observed for the solo, suggesting that the algorithm can handle some instruments better than others.

The proposed method was submitted to the *Signal Separation Evaluation Campaign* (SiSEC 2013) in the *professionally produced music recordings* task. The algorithm obtained comparable quality ratings to other state-of-the-art approaches with an average processing time of 0.25 s per 1 s of audio on a 2.6 GHz computer. The full table of results can be found on the campaign's website [41.56].

The use of the proposed method in a music education context was also studied in [41.57], by means of a listening test setup specially designed to evaluate the level of comfort of music students when playing to different types of separated signals as audio reference. The main goal was to determine which type of signal distortions (artifact distortions, interference distortions, or target distortions) were most disturbing for musicians during practice. Results from this study can be used as guidelines for optimizing algorithms to better suit the music education context. They indicate that preferences are different for solo and backing tracks. While target distortions were found to be most annoying in backing tracks, artifact distortions proved to be most important for separated solo signals.

41.4 Drum Transcription for Real-Time Music Practice

As shown in Sect. 41.2.3 a small number of music video games and music education software also offer the possibility to play along and practice drums. In all cases, this functionality is enabled by using MIDI-fied drum sets. However, none of the existing applications enable the user to practice using a real-world acoustic drum set. Our goal is to have the drum students play along to a given rhythm pattern or song, while their performances, in terms of hitting the correct drums to the correct metric positions, are assessed in real-time. As a prerequisite, it is necessary to recognize the different drum sounds in a monaural drum recording. In MIR, this task is called automatic drum transcription or drum detection (agnostic to the metric position). Having beginners in mind, we constrained ourselves to detection of onset times for the most basic drums, namely kick drum, snare drum, and hi-hat.

41.4.1 State of the Art

In this section, the most important directions of research for automatic drum transcription are presented. As described in [41.58], the existing approaches can be divided into three different categories depending on the signal model and processing steps taken in the analysis.

Source Separation Methods

The first category is also known as *separate and detect* because the signal is first separated into individual streams and subsequently onset events are detected in each individual stream. The prerequisite is typically a time–frequency transform (e.g., via STFT). The generic signal model decomposes the resulting magnitude spectrogram X into a linear superposition of individual component spectrograms. The components are usually represented by fixed spectral bases B and corresponding time-varying amplitude gains G. The known approaches mostly differ in the decomposition method as well as the constraints and initialization imposed on B and G.

Independent component analysis (ICA) computes a factorization $X = BG$, such that the separated source spectra are maximally independent and non-Gaussian. *Independent subspace analysis* (ISA), first described in [41.59], applies *principal component analysis* (PCA) and ICA in succession for decomposing X. This combination makes it possible to extract multiple sources from fewer observations than normally possible with ICA [41.59]. In order to classify the arbitrarily permuted and scaled components afterwards, feature extraction and classifiers such as *k-nearest-neighbor* (k-NN) or *support vector machines* (SVM) can be used [41.60]. An extension to ICA called *nonnegative independent component analysis* (NICA) has the constraint that the matrix B must be nonnegative [41.61]. In [41.62], how to use NICA for transcription of kick, snare and hi-hat from polyphonic music is shown.

Prior subspace analysis (PSA) was first proposed in [41.63] and utilizes prior knowledge about the sources that should be separated. A starting point for the algorithm is the collection of template spectrum basis functions in a matrix B_p. These consist of the averaged spectra drawn from a large collection of isolated kick and snare sounds. Once the template basis functions are computed, one can get a first approximation of the amplitude gains by

$$\hat{G} = B_\mathrm{p}^{+} X \,,$$

where B_p^{+} denotes the pseudo-inverse. The rows of matrix $\hat{G}$ contain the temporal activations of the template sources in the signal, but are not independent. To make them independent, ICA is applied. This results in an unmixing matrix W transforming $\hat{G}$ into independent amplitude gain functions $G = W\hat{G}$. Subsequently, an improved estimate of the source spectra can be computed by $B = XG^{+}$, which now contains the source spectra adapted to the actual signal. Using this method, [41.64] reports an F-measure of 75% on the detection of kick and snare drums.

An early work applying NMF (Sect. 41.3.1) for the separation of drums from polyphonic music is presented in [41.65]. It uses NMF minimizing the Kullback–Leibler divergence, with random initialization of B and G. From the resulting components, spectral and temporal features are computed and classified by an SVM trained on the classes drums versus harmonic. The reported results show that the NMF and SVM approach performed better than ISA and SVM. Another variant of NMF for drum transcription is described in [41.66]. The NMF is first applied to individual drum spectrograms for kick, snare and hi-hat to get template basis spectra, which are later fixed during the NMF iterations. The method shows good performance on drum loops, yielding an average F-measure of 96% for kick, snare and hi-hat detection. However, one might expect that the quality is largely determined by providing appropriate basis spectra for the initialization. Recently, NMF-based methods have also been applied to real-time drum detection [41.67], where each drum onset is identified with probabilistic spectral clustering based on the Itakura–Saito divergence.

Template Matching

The second category of drum transcription techniques follow a so-called *match and adapt* approach. It relies on temporal or spectral templates for the events that should be detected. In a first approximation the occurrences of events that are similar to the template are detected. Afterwards, the templates are iteratively adapted to the given signal. In turn, this can then be used for a more detailed search. As an example of such an algorithm, the work presented in [41.68] uses template spectrograms for kick and snare, called *seed templates*, which are constructed from a collection of isolated drum sounds. First, onset detection determines possible candidates for drum sounds. At each onset candidate, a spectrogram snippet with the same size as the template is kept and compared with the template. At this stage, the spectrum is filtered according to the typical frequency range of kick, snare or hi-hat and smoothed, so that a rough estimation with the template takes place. The reciprocal of the distance between the observed spectrogram and the template describes the reliability that an onset candidate contains a drum sound. In the adapt stage, the seed templates

are updated by taking the median power over all selected frames. This suppresses more volatile spectral peaks from harmonic instruments. The process of template adaption is used iteratively, so that the output of this median filtering is used as the next seed template. The final stage determines whether the drum sound actually occurs at the onset candidate. As a result of applying the template matching in conjunction with harmonic structure suppression, an F-measure of 82% for kick and 58.3% for snare was reported. A combination of template matching and sound separation is described in [41.69], where the candidates for template extraction are first detected using NMF decomposition. Another example of template matching is given in [41.70], where characteristic band pass filter parameters are learned. The training process is realized through the evolution of the characteristic filters with the *differential evolution* (DE) algorithm and fitness evaluation measures for determining each filter's ability to correctly detect the onset of the respective drum. The output of each filter represents the activations of the single drums and can be processed by means of peak picking.

Machine Learning

The last category of drum transcription algorithms is referred to as *segment and classify*. It first uses temporal segmentation of the audio track into musically relevant parts. Usually, a certain number of frames after each detected onsets is kept or a temporal grid of fixed periodicity is aligned to the audio track. Subsequently, each temporal event is identified by a classifier. Often, well-known machine learning methods such as SVM are used in conjunction with features extracted from each segment. The method in [41.71] uses a set of features comprising averaged Mel-frequency cepstral coefficients (MFCCs), various spectral shape parameters and the log-energy in six frequency bands chosen to mimic the spectral content of different drum instruments. The features are classified by a set of eight binary SVMs that have been trained on the classes kick, snare, hi-hat, clap, cymbal, rim shot, tom and percussion. Evaluated on a dataset of drum loops, the best configuration gave a recognition rate of 83.9%. The method proposed in [41.72] uses a similar approach, but applies it to drum transcription from polyphonic music. The algorithm achieved an average F-measure of 61.1% for the classes kick, snare and hi-hat. Finally, *hidden Markov models* (HMM) are a machine learning method that can be used to model drum sequences. Although they are often counted as part of the *segment and classify* approach, they stand out as they are able to perform the segmentation and detection jointly. HMMs model temporal sequences by computing the probability that a given sequence of observed states were generated by hidden random variables, i. e., the activations of the drum classes. In [41.58], HMMs are used to model MFCCs and their temporal derivatives. The method achieves an F-measure of 81.5% in the recognition of kick, snare and hi-hat for pure drum loops and 74.7% for polyphonic music.

41.4.2 Proposed Method

A block diagram describing the proposed method is presented in Fig. 41.4. A similar approach as the one described in [41.67] is taken, assuming that an initial training phase is possible where the specific drum sounds are presented to the detection system. Instead of using elaborate *gamma mixture models*, the spectral bases B are simply initialized with the average over all spectra of the isolated drum sounds. The number of components per drum is denoted c_d. Each drum gets at least one basis vector assigned, but this number can be increased. In order to achieve real-time capability, the NMF decomposition is applied to each spectral frame

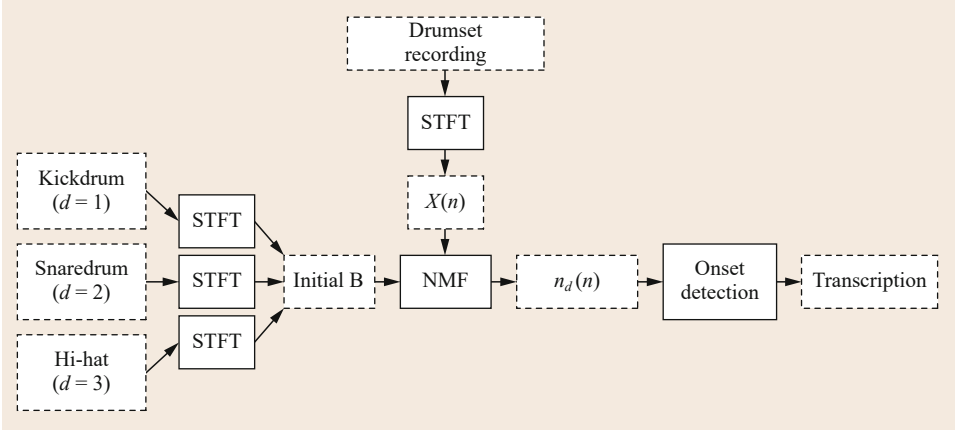

Fig. 41.4 Overview of the proposed method. Initial basis vectors B are trained on isolated drum sounds. Drum set recordings are split into spectral frames $X(n)$ and subjected to NMF. Individual novelty curves $n_d(n)$ are extracted and subjected to onset detection

individually, thus generating a succession of activations for kick, snare and hi-hat in G approximately every 10 ms. The *Kullback–Leiber divergence* (KL) is used as an update rule. As a special trick, the spectral basis functions B are kept semifixed, i. e., they are allowed to deviate more from the initial value the closer the decomposition is to the iteration limit. This is achieved by a linear blending between the initial values and the new ones. This way, the NMF is initially pushed into the direction of the desired drums sounds. Later on, actual deviations of the incoming spectra from the prior spectral templates are accounted for by the update rule.

For drum loops, multiplying each of the activations in G corresponding to a single drum with the corresponding columns in B yields well separated individual spectrograms for kick, snare and hi-hat. On visual inspection, they exhibit very small cross-talk between the different drums. Based on these, onset detection is performed in a straightforward manner. Following the approach proposed in [41.73], a novelty curve $n_d(n)$ is extracted from the successive spectrogram frames for each drum d by differentiating along time in each bin of the logarithmic spectrogram. All bins per frame are summed up and half-wave rectification is applied – only salient positive peaks corresponding to onsets are relevant here. Inevitably, cross-talk artifacts will lead to erroneous spikes and thus, an adaptive threshold on the novelty curve is applied. The threshold is derived by nonlinear compression $n_d(n)^{0.5}$, application of an exponential moving average filter and nonlinear expansion of the result $n_d(n)^{2.0}$. A variable boost factor b can be used to adjust the threshold manually. If the novelty curve is above the adaptive threshold and fulfills other plausibility criteria [41.67], it is marked as an onset. Thus, the whole procedure generates a list of onset times per drum.

41.4.3 Evaluation and Results

In order to assess the transcription performance, experiments with manually annotated real-world drum loops were conducted. The F-measure with an onset tolerance of 50 ms was used as the evaluation metric. A training set was created for initialization of single drums (kick, snare, hi-hat). In order to capture the individual characteristics, the drums were hit separately with varying velocity. For recording, an overhead microphone at a fixed height of 1 m was used. The recordings were made with 10 different drum kits, consisting of different drum sizes and a broad range of materials. The size of the kick drum ranges between 18−24 in in diameter and 16−22 in in depth. Materials were birch, mahogany or maple. The snare drums all had the same size of 14 in in diameter and 6.5 in in depth but differed in their materials (such as metal, wood or acrylic). The sizes for hi-hats differed from 13 to 15 in.

The test set consisted of 30 drum sequences, which were fairly simple groove patterns of kick, snare and closed hi-hat. The tempo of the performed drum grooves varies between 100−140 BPM. Overall, 33 min of audio were recorded (in 44.1 kHz, mono, 16 bit) resulting in 3219 annotated onsets. The shortest annotated interval between consecutive onsets is 107 ms (16th notes at 140 BPM).

With the described data, a grid search to come up with the optimal set of parameters was run. The best average F-measure of ($F = 0.98$) across all drums was obtained with $c_d = 2$ basis vectors per drum, threshold boost $b = 1.5$ and 20 NMF iterations during decomposition. Striving for a more efficient computation, a favorable working point was found around ($F = 0.96$) F-measure when using only $c_d = 1$, $b = 1$ and five iterations.

41.5 Guitar Transcription Beyond Score Notation

As reported in Sect. 41.2.2, the guitar is very popular among musical beginners since it allows relatively quick progress. Hence, algorithms for the automatic transcription of guitar recordings can be used in various music education applications. For fretted string instruments such as the acoustic guitar and electric guitar, a popular way of writing music is called *tablature*. It encodes the notes to be played based on the geometric position on the fretboard, i. e., the string number and fret number. Due to the string tuning of guitars, certain notes with the same pitch can be played on different positions of the fretboard. The tablature notation resolves this ambiguity and provides clear playing instruction to the guitar player. An example of tablature notation is shown in Fig. 41.5. The traditional music score is also shown for reference.

Fig. 41.5 Example of tablature notation and its corresponding score. This figure was originally published in [41.74]

Tablatures gained an especially high popularity among music amateurs since they allow users to circumvent the process of learning to read common music notation. Large amounts of tablatures are freely available online. However, since they are not standardized, they are often incomplete and erroneous. Thus, the goal of this study is the automatic transcription of guitar recordings into tablature notation.

41.5.1 State of the Art

This section describes related works that have dealt with guitar transcription, particularly those concerning tablature extraction.

Sensory Modalities for Data Acquisition

Different *sensory modalities* are used in the literature for analyzing guitar performances or recordings. As discussed in [41.75], the acquisition of physical and perceptual parameters from musical instruments can be categorized into *direct acquisition methods*, which are based on *sensors* that are attached to the instrument, and *indirect acquisition methods*, which are based on *audio* and *visual* analysis of recorded musical performances on the instrument. In addition, some authors propose *multimodal approaches* that combine different sensory modalities in a complementary way.

Audio analysis methods only require an instrument pickup or a microphone for data acquisition. In addition to regular electromagnetic pickups, *hexaphonic pickups* are often used to analyze electric guitar recordings. They allow the capture of the vibration of each individual string, which reduces the problem of polyphonic transcription to a number of parallel monophonic transcription tasks [41.76].

Visual analysis often relies on cameras that are attached to the instrument or positioned close to the performing musician. If the fretboard is recorded, the detection performance can be impaired by bad lighting, masking of the fretboard by the playing hand, or the musician's movement itself.

Mechanically enhanced instruments are extended by sensors that allow a very precise measurement of the spatial hand position. The main disadvantage is that *most of these methods, while accurate, are obtrusive* to the musicians [41.77] since they constrain the natural hand movement on the instrument.

Sensory analysis provides very accurate time-continuous measurements. Also, the movement data measured by motion capturing is closely related to the musician's playing gestures. Signals from capacitive sensors that are used to measure the hand pressure on the instrument fretboard are often noisy and exhibit crosstalk between spatially adjacent sensors.

Guitar Transcription

In order to transcribe a guitar recording and to generate a tablature notation, both the score-level parameters (note pitch, onset and offset) as well as the geometric position (string number and fret number) must be estimated for every note. The first group of publications analyze *monophonic guitar recordings*, i. e., melodies and single notes [41.78, 79]. In order to classify the *string number*, *Barbancho* et al. [41.78] compute various timbre-related spectral audio features such as the inharmonicity, relative magnitude of the overtones, and the temporal decay factor of harmonics. The classification of the *string number* is performed using machine learning algorithms based on the extracted features. The second group of publications focus on *polyphonic guitar recordings*. The estimation of the guitar voicing, i. e., the fretboard position of each finger, is done using *audio analysis* [41.76, 80–82], *visual analysis* [41.83–85], or by combining both modalities in a *multimodal approach* [41.77]. *O'Grady* and *Rickard* perform music transcription on the individual output signals of the hexaphonic guitar pickup [41.76].

Barbancho et al. [41.80] distinguish 330 different fingering configurations for the most common three-voiced and four-voiced guitar chords. Using a multipitch estimation algorithm and an HMM, the most likely chord sequence in a guitar recording is obtained. In *Fiss* and *Kwasinski* [41.81], a multipitch estimation algorithm tailored towards the guitar is presented. Two metrics based on relationships between harmonic frequencies are used to assign the most likely spectral peaks to potential fundamental frequency candidates. *Hrybyk* and *Kim* first estimate the pitch values of all notes in a guitar chord using audio analysis and then estimate the chord voicing using computer vision techniques by tracking the guitar player's hand [41.77]. Different *constraints* are applied in the literature to improve the estimation of spatial parameters. *Yazawa* et al. use the results of the *latent harmonic allocation* (LHA) multipitch estimation and apply three constraints that are tailored to the geometry of the guitar to extract tablatures [41.82]. For instance, the metrics used in [41.81] are based on specific knowledge about the instrument such as the highest possible degree of polyphony (six simultaneous notes) as well as the maximum stretch span of the playing hand within a fixed fretboard position. *Barbancho* et al. use two additional models to constrain the transitions between different HMM states: a musicological model, which captures the likelihood of different chord changes, and an acoustic model, which measures the physical difficulty of changing the chord fingerings [41.80]. In *Dittmar* et al. [41.74], an algorithm capable of real-time guitar string de-

tection is presented, which is also the base for our work.

Estimation of Playing Techniques

The sound production of the guitar can be separated into two *physical gestures* – a *plucking gesture* and an *expressive gesture*. These gestures affect the sonic properties of the recorded instrument notes in a unique way, which allows human listeners to recognize and distinguish different playing techniques. *Frequency modulation techniques* allow the musician to change the note pitch continuously [41.86]. Various publications analyze the estimated fundamental frequency course of single notes to detect the playing techniques *vibrato* [41.87, 88], *bending* [41.89], or *slides* [41.89–91]. In between consecutive note events, different *note transition techniques* can be applied. Common techniques are for instance the *slide* or the *hammer-on* and *pull-off* techniques as investigated in [41.88–90]. *Erkut* et al. analyze repeated string plucks in [41.87] and *Guaus* et al. studied the hand movement if *grace notes* are played [41.88].

41.5.2 Proposed Method

In continuation of the work in [41.74], a guitar transcription algorithm was developed that combines the conventional score-level transcription with the note-wise estimation of the fretboard positions and the playing techniques. The algorithm can be used to transcribe isolated monophonic and polyphonic guitar recordings. A block diagram of the proposed method is shown in Fig. 41.6.

The note onset detection is based on a combined analysis of the spectral flux, the rectified complex domain, as well as a novel onset detection function, which detects beginning overtones [41.92]. Based on a reassigned spectrogram (using the IF spectrogram), the Blind Harmonic Adaptive Decomposition (BHAD) multipitch estimation algorithm [41.34] is applied to get a multipitch estimate for each note event. In order to cope with frequency modulation techniques such as vibrato, bending, and slides, the fundamental frequency is tracked frame-wise over the note duration. The note offset is obtained by tracking the decaying note magnitude envelope.

For each note, the plucking style, i. e., the playing technique used to pluck the guitar string, is separately estimated from the the expression style, i. e., the way in which the playing hand is used to manipulate the string vibration. Based on various audio features that describe the inharmonicity and the magnitude and frequency relationship between overtones, the string number is automatically classified using a SVM classifier. Due to

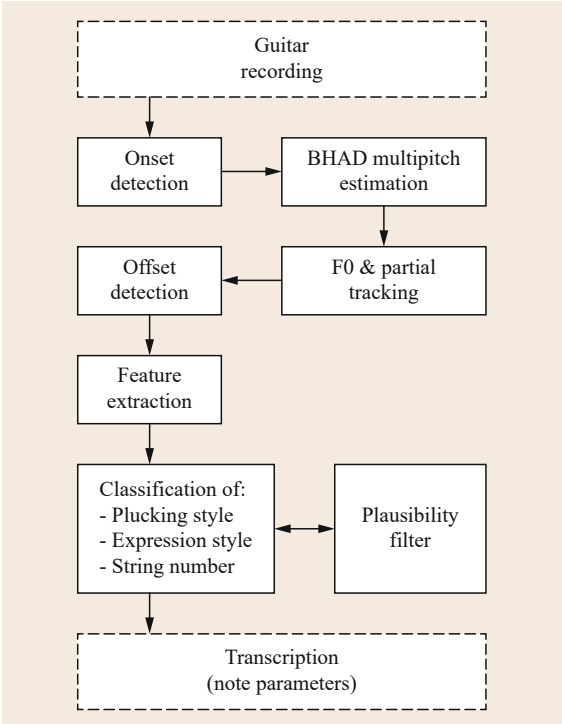

Fig. 41.6 Block diagram of the proposed method

the instrument geometry and the string tuning, different constraints can be applied if multiple notes sound at the same time. This allows corrections to be performed for both the pitch and string estimation. Similarly to the string number, the plucking style and the expression style are also automatically classified using a large set of note-wise audio features. A plausibility filter is applied to correct meaningless classification results based on the estimated note parameters of the previously detected notes.

41.5.3 Evaluation and Results

For the purpose of evaluation, a novel database of guitar recordings was created. It contains 261 audio recordings of both isolated notes as well as monophonic and polyphonic melodies, licks, and chord sequences with extensive note-wise annotations of all discussed parameters. Three different plucking styles (finger-style, picked, palm muted) as well as six different expression styles (normal, vibrato, slide, bending, harmonics, dead-notes) are included. Three different electric guitars were used in the recording session. In total, around 4700 guitar note events are contained in the database.

The score-level transcription steps perform very well as indicated by very high F-measure values for onset detection ($F = 0.985$), pitch detection ($F = 0.96$),

and offset detection ($F = 0.977$) on both monophonic and polyphonic guitar licks in the dataset. High accuracy values were achieved in cross-validation experiments for the classification of the plucking style ($A = 0.93$), expression style ($A = 0.83$), and sting number ($A = 0.82$) [41.93].

41.6 Discussion and Future Challenges

A general overview of the use of music technology in music education has been presented. Additionally, three special cases of technologies developed within the MIR community, successfully applied to music education, have been described. Even when research in the past years has given a tremendous push to the development of music application and education tools, there are still many challenges faced by the research community that need to be overcome before a seamless conjunction between music education and technology can be achieved.

The field of sound source separation has produced very promising results in the last years, especially with different types of informed source separation. Some systems are commercially available and specialized sound separation services are offered by some individuals and audio processing companies. However, the performance of the technologies also very closely depends on the type of audio recording to be processed and on the separation task itself. In most cases, even when solutions for certain types of signals and tasks have been developed, a great amount of manual refinement and detailed postprocessing is still needed to obtain good quality of separated signals. To date, a general solution to the sound separation problem is not available.

In drum transcription research, methods still need to be enhanced to be able to handle a full drum set with all its components. Even though the most popular drum choices have been addressed (kick drum, snare drum, and hi-hat), other commonly used drums like ride cymbals, toms, crash cymbals, and splash cymbals have not been studied. Additionally, other commonly used percussion instruments such as the cowbell, woodblock, tambourine, gong, and triangle also present their own spectral and acoustical characteristics and need to be studied before a robust transcription can be achieved. Furthermore, extensive research efforts need to be directed towards guaranteeing performance robustness when the complexity of the drum patterns is higher and more challenging tempi are used. Lastly, the difficulties of performing the same type of processing in polyphonic audio, where several instruments simultaneously play, greatly increase the complexity of the task.

Guitar transcription research also presents its own particular challenges. The differences between acoustic guitars and electric guitars need to be addressed to guarantee robustness of results for all users. Not only do the audio capturing methods for the two types of guitars usually differ, but the performance style, fingering, and expression style can also be considerably different. Additionally, similarly to drum transcription research, more studies have to be conducted to extend these technologies to polyphonic audio where more complex scenarios occur.

Generally speaking, there are broader challenges that both the music technology and music education communities need to address in order to have technologies and applications that can truly and effectively benefit music education. A critical point of current research is the fact that for the great majority of technologies developed, performance is greatly dependent on the type of audio file processed. Different instrumentations, musical genres, recording conditions, and musical styles still represent a major challenge for MIR research. Even when good results can be achieved under a determined set of conditions and with clear constraints, general solutions capable of handling audio files of various characteristics are still far from being available. After many years of research in the field, results and the current state-of-the-art methods tend to suggest that more instrument-specific algorithms and studies are needed to properly capture the specific characteristics, not only acoustical but also stylistic, of the different musical instruments. Performance possibilities of musical instrument are so diverse and rich that a general algorithm that can handle all instruments under all conditions is hard to conceive.

When it comes to the usability of music technologies in music education, more user studies and listening tests need to be conducted that can properly evaluate users' responses to the technologies. Additionally, the effectiveness of the technologies to achieve a learning goal also needs to be evaluated. For this matter, a very close collaboration between music education, MIR, psychology, and musicology is required.

A final note has to be made regarding the importance of algorithm optimization in the MIR field. Even though technologies have progressed tremendously in the last years, it is still fairly common for algorithms to be too time consuming and computationally demanding

for them to be applicable and helpful in real-world applications such as music education. There is still a lot of work ahead of us in the endeavor of optimizing algorithms and reaching real-time functionalities necessary for technologies to be truly effective in many fields.

42. Music Learning: Automatic Music Composition and Singing Voice Assessment

Lorenzo J. Tardón, Isabel Barbancho, Carles Roig, Emilio Molina, Ana M. Barbancho

Traditionally, singing skills are learned and improved by means of the supervised rehearsal of a set of selected exercises. A music teacher evaluates the user's performance and recommends new exercises according to the user's evolution.

In this chapter, the goal is to describe a virtual environment that partially resembles the traditional music learning process and the music teacher's role, allowing for a complete interactive self-learning process.

An overview of the complete chain of an interactive singing-learning system including tools and concrete techniques will be presented. In brief, first, the system should provide a set of training exercises. Then, it should assess the user's performance. Finally, the system should be able to provide the user with new exercises selected or created according to the results of the evaluation.

Following this scheme, methods for the creation of user-adapted exercises and the automatic evaluation of singing skills will be presented. A technique for the dynamical generation of musically meaningful singing exercises, adapted to the user's level, will be shown. It will be based on the proper repetition of musical structures, while assuring the correctness of harmony and rhythm. Additionally, a module for singing assessment of the user's performance, in terms of intonation and rhythm, will be shown.

In this chapter, we present several methods and techniques to implement a complete educational tool for learning to sing. Typically, singing skills are improved by rehearsing a set of appropriate exercises under the supervision of a music teacher. The role of this music teacher is to evaluate the user's performance, and to recommend new exercises according to the user's evolution. Therefore, the presented methods allow the creation of user-adapted exercises and evaluation of the singing skills of the user automatically right after the performance. The goal of this combined approach is to create a virtual environment that partially resembles the music teacher's role, leading to a faster self-learning process.

Two main submodules are presented in this chapter: (1) an automatic generator of singing exercises, and (2) a singing assessment module, which analyses the user's voice in order to rate the quality of the singing performance. In the first, the generated singing exercises are musically meaningful, based on repeated structures, and can be adapted to suit the level of the user. In the second, the module for singing assessment compares the user's performance with respect to the automatically generated singing exercise, and rates the user's performance with two criteria: intonation and rhythm. In Fig. 42.1, a block diagram of the complete system is shown.

Using these methods, the singing learning process becomes an iterative self-guided process. First, the system provides a set of exercises. Second, the user sings the suggested practices. Third, the system asseses the user's performance. And finally, it suggests new scores according to the grade obtained. Note that the scores generated are not precomposed but dynamically generated according to the current level of the user. In this way, a gradual and fully adapted learning process is assured.

This chapter is organized as follows. In Sect. 42.1 and 42.2, we present the related work on melody com-

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_42

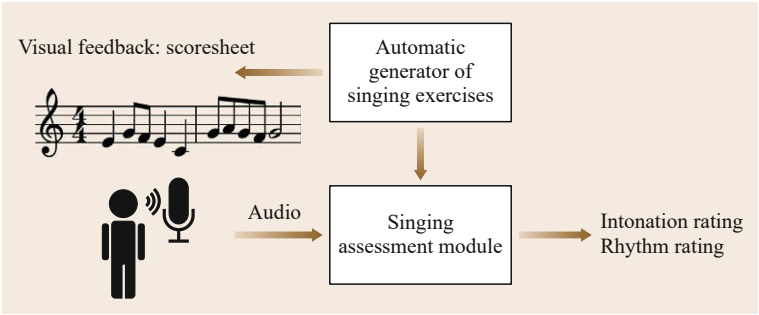

Fig. 42.1 Block diagram of the complete system

position and automatic singing assessment respectively. Then, in Sect. 42.3 an automatic generator of singing exercises is described. A scheme for automatic singing assessment is described in Sect. 42.4. Finally, Sect. 42.5 draws some conclusions about the tool for singing learning presented in this chapter.

42.1 Related Work on Melody Composition

The incorporation of different skills in the field of music information retrieval related to the computational analysis and description of musical pieces allows us to face different tasks like automatic music transcription [42.1], or the identification of relations between songs [42.2], among others. Furthermore, the computational model of the human experience in the musical field and the human brain processes in this field are of great interest for psychology and musicology [42.3].

In this context, the automatic generation of musical content is the topic considered. Often, music is defined as *organized sound* [42.4] with order and structure. Thus, systems to generate music must be trained beforehand to learn a logic composition style as stated in [42.5]. For this reason, an algorithm for learning composition rules and patterns is outlined.

A set of descriptors must be analyzed in order to model the style of the melodies. Concerning the temporal descriptors, tempo and time signature, previous works can be found. The work presented in [42.6] is focused on the onset estimation based on the spectral analysis. In [42.7], histograms to find the most repeated interonset values are employed. Recently, methods for structural analysis such as [42.8] based on a timespan tree for the structural similarity detection, which can be addressed making use of the autosimilarity matrix [42.9], were found.

In this chapter we consider an innovative approach for tempo estimation based on the interonset interval (IOI) histogram inspired by [42.6], followed by a fine adjustment stage.

Regarding music composition, apart from composition schemes based on pattern reallocation and variations, other methods are described in the bibliography. In [42.10–12] Markov models are used for the modeling and composition processes. The use of genetic algorithms such as *Biles*' GenJam system [42.13] are also present in the field of automatic music composition. Methods based on probabilistic approaches such as *Cope*'s experiments in musical intelligence (EMI) [42.14, 15] also focus on the creation of an automatic music composition framework. Inmamusys [42.16] is another composition scheme based on probabilistic structures. This method is very similar to the one considered here, since both use previously learned patterns to generate a new composition from the reallocation of them. However, we considered the presence in the composition system of a postprocessing stage, intended to make all the motives in the database learned fit in the composition. Note that Inmamusys restricts the combination of motives to subsets previously tagged as compatible.

42.2 Related Work on Voice Analysis for Assessment

Regarding the evaluation of singing voice, the literature reports a number of schemes for automatic singing assessment [42.17–27]. These schemes are able to provide feedback about the user's singing performance.

Commonly, in order to attain the desired objectives, the audio is processed according to the following steps. First, a low-level feature extraction process is performed to find a set of frame-level vectors with

meaningful information about the input. In the case of singing analysis, the most important feature is fundamental frequency F_0, although most of the approaches also use other features such as energy, aperiodicity, zero-crossing rate or certain auditory-based features. In the literature, a wide set of approaches for F_0 estimation have been proposed, some of which are based on the time domain, whereas others are based on the frequency domain (see [42.28] for a comprehensive review). One of the most-used approaches is the Yin algorithm [42.29], since it is simple, effective and easily accessible. The Yin algorithm was developed by de *Cheveigné* and *Kawahara* in 2002 [42.29], and it has been found to be effective in many monophonic music transcription systems [42.26, 30–32].

Then, the feature(s) extracted is postprocessed in order to identify voiced regions (the *voicing* process) and, in many cases, a later note-level segmentation is also performed. The estimation of voiced sounds can be performed using a wide variety of descriptors at frame-level: F_0 stability [42.33], root-mean square (RMS) [42.34], aperiodicity [42.35], or zero-crossing rate [42.36], etc.

Additionally, a note-level segmentation process of the singing voice (also called singing transcription) must be performed. To this end, some systems analyze the low-level feature(s) using heuristic rules and a set of thresholds [42.34, 37], whereas other approaches are based on probabilistic models, especially hidden Markov models [42.35, 38].

Finally, the assessment of singing skill is performed by analyzing the postprocessed low-level features and/or the note-level segmentation of the audio input. Prior works have led to various solutions for automatic singing rating. In general, all these systems focus on intonation assessment with visually attractive real-time feedback. Some of these systems use a reference melody (considered the target performance) in order to assess the user's performance, whereas other approaches are melody independent.

42.3 Music Composition for Singing Assessment

In order to be able to accurately design automatic music composition methods, it is necessary to know the parameters involved in the composition. In this section, we present both the parameters used by a novel autonomous music compositor that generates new melodies using a statistical model and the composition scheme itself. Different aspects related to the traditional way in which music is composed by humans such as harmony and structure repetitions will be considered.

The approach is focused on an educational context. The student should be able to automatically generate reinforcement melodies according to a particular musical level enlarging the number of available training exercises.

42.3.1 Learning Musical Parameters

The approach designed for the generation of contents is based on the music theory method called *ostinato* [42.39]. This method considers the composition of music on the basis of pattern repetition with harmonic variations in such a way that the repetition of the motives creates the melody structure.

Thus, rhythm patterns, pitch contours, harmonic progressions and tempo structures must be learned [42.40].

Thus, a database of musical parameters can be used to model the training level of certain musical pieces, as in [42.41]. Since the main objective is to develop a music model for the automatic creation of compositions with style replication, the discovery of this type of information and the development of specific procedures to make use of the different pieces of information to model music corresponding to different training levels are considered. This can be done on the basis of a probabilistic analysis of rhythm and pitch patterns stored in a database filled with music samples of different complexity levels. In Fig. 42.2, a diagram of a suitable analysis system is presented.

According to the characterization parameters required, the database can be divided into three levels

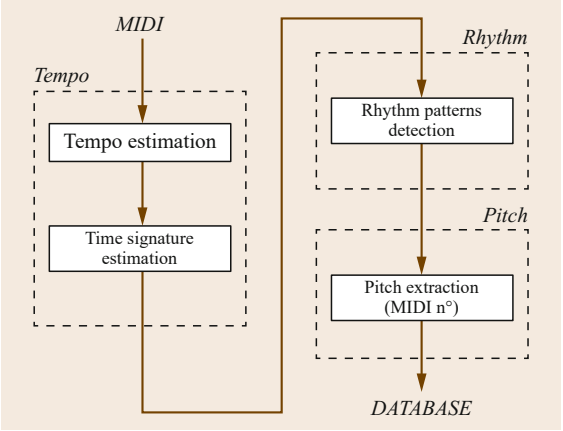

Fig. 42.2 Illustrative scheme of the music analysis system

hierarchically organized corresponding to: (L-1) time signatures, (L-2) rhythm patterns and (L-3) pitch contours (Fig. 42.3).

The measures the training samples will be split into will be the elements stored in the database. These elements will be used for the composition of novel music scores. In order to achieve this goal, the bar length has to be established for proper measure splitting. The bar length can be manually set but also a system to perform this task automatically can be devised. Thus, tempo estimation is required in first place.

The tempo can be extracted easily by analyzing Musical Instrument Digital Interface (MIDI) metadata messages [42.42], if present. But this information can also be incorrectly stored. In order to develop a robust estimation scheme, an algorithm to estimate the tempo and time signature from MIDI files can be used. Note that the availability of correct tempo information is critical in order to relate the duration of the notes obtained by means of the analysis of Note On and Note Off messages [42.42] to musical figures.

Note that according to [42.43], the target parameters in this work are the basic ingredients for the composition of music: rhythm, pitch motives (melody) and harmony (which is considered at the score composition stage).

Now, we consider the specific estimation stages.

Temporal Estimations

The tempo and the time signature have to be estimated in order to correctly perform bar separation and properly split rhythmic patterns. Note that here we consider a rhythmic pattern to be equivalent to a complete measure from the input training data.

Tempo Estimation. The algorithm considered for tempo estimation is inspired by the work presented in [42.7]. However, in our scenario, the analyzed IOIs are directly extracted from the melody. Initially, the most repeated IOI value can be considered a candidate pulse, or tactus [42.44]. This pulse is related to tapping or dancing while listening to a piece of music [42.45]. However, some considerations must be taken into account:

- Resting periods are not explicitly extracted. MIDI files contain information about the notes solely (Note On and Note Off events [42.42]). However, resting periods can be indirectly extracted and must be used to properly estimate the tempo.
- The tactus extracted can be a multiple or a divisor of the actual tactus. By setting a valid tempo range, this value can be corrected.
- The tactus estimated will not be the exact one due to the discrete nature of the histogram. The value can be finely corrected in a postprocessing stage.

The objective of the fine adjustment of the tactus is to find the value that causes the lowest displacement from the constant beat and the input file onsets. This can be achieved by defining a specific model to interpolate the histogram of the IOIs.

Then, the tactus has to be associated with a certain rhythmic element to define the duration of the quarter note and for the estimation of the tempo. Since the range of valid tempos in music is large – from *Largo* ($40 \sim 60$ quarters per minute) to *Presto* ($180 \sim 200$ quarters per minute) [42.46] – the tempo range must be manually reduced in order to establish an accurate relation between durations and musical elements. A suitable hypothesis is that the tempo of the training data is *Moderato* ($76 \sim 108$ quarters per minute). Anyway, a mapping can always be defined by calculating the duration of each rhythm figure in the range selected.

As described in [42.47], the tempo estimation algorithm often estimates doubled or halved tempos. This is a normal behavior caused by the tempo concept itself [42.48]. The tempo is actually subjective, which means that some editors may use shorter rhythm figures reducing the selected tempo, while other can do the opposite, to represent the same performance speed.

Finally, observe that the duration of the metric figures is well known after the tempo is estimated. The duration of each measure can be obtained by multiplying the duration of the pulse by the number of pulses that fit in one bar. So, the next goal is estimate the bar duration. The approach for this purpose can be based on the evaluation of different bar split scenarios for several tentative lengths. Then, some features like the number of repeated bars, the number of bars and the number of split notes can be considered.

Time Signature Estimation. The estimation of the time signature can be based on the analysis of bar repetitions, which can be done using a multiresolution analysis scheme [42.49, 50] to obtain the bar length that best suits the input melody among a set of candidates.

The rhythm self-similarity matrix (RSSM), as described in [42.51], is useful for the purpose at hand. The input melodies can be split into the k candidate bar lengths in order to build the RSSM using the tactus as a unit. Note that the analysis system will create k RSSM matrices, one for each of the candidates. Using those

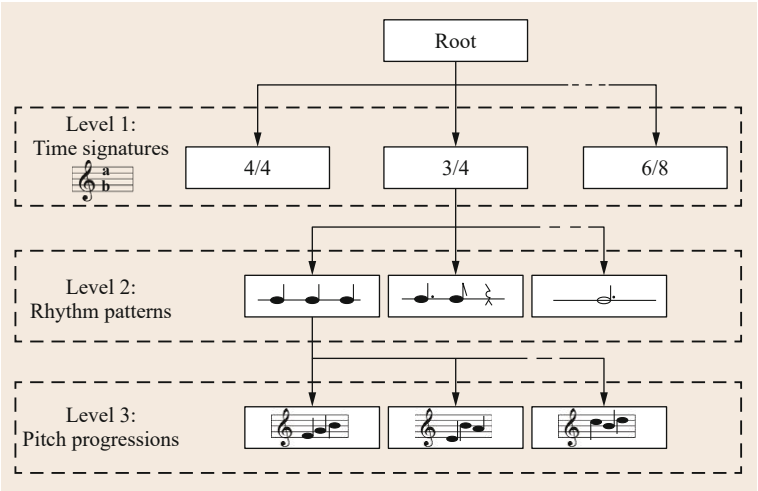

Fig. 42.3 Representation of the hierarchical database considered to store and organize music parameters for music composition based on pattern repetitions

RSSMs, the following descriptors can be extracted and considered in the estimation process:

- Number of repeated bars: the amount of different bars repeated along the split performed for a certain length candidate. The most repeated bar will, more probably, perform a proper separation.
- Number of repeated bar instances: the average number of instances per repeated bar. The larger this number, the more probable the separation will be.
- Number of ties between bars: the number of notes divided between two bars for the candidate length. The lower the number of ties between bars, the more probable the separation will be.
- Number of detected bars: the number of bar splits in the original stream. The number of bars tends to be a power of two.

Note that the number of repeated bars, bar instances and ties must be normalized by the total number of bars detected to give rise to comparable measures. In order to classify the time signature of the input melodies using these descriptors, different classification schemes can be considered, such as the J48 decision tree classifier [42.52], or another one based on sequential minimal optimization (SMO) [42.53], which are available in the Weka machine learning software suite [42.54].

Rhythm Patterns

Rhythm is probably the musical feature more closely related to the structure of a musical composition. The parameters obtained by the tempo estimation stage (see previous section) can be used to quantize the duration information extracted from the input MIDI file and relate the intervals to the corresponding figure duration.

Observe that splitting into measures is accomplished by applying thresholds to the accumulative sum of measure durations of the input.

If the accumulation of durations equals the threshold, the measure splitter gets the measure and stores it in the database since the measure is complete. If the accumulation of durations overpasses the threshold, then a tie between bars exists and the estimated time signature at the current point is assumed to be correct, although a note is between two bars. Also, the note that overpasses the measure duration must be split into two notes: one with the proper duration to complete the previous bar, and another one with the remaining duration that will be part of the following bar, to remove the tie.

The pitch contour of the rhythmic patterns obtained by the splitting scheme are stored (Fig. 42.3). Later, patterns with more contour versions will be selected with higher probability than others by the composition system. This choice is oriented to the replication of the probabilistic model of the rhythmic patterns in the melodies composed.

Pitch Progression

The pitch contour [42.46] is more important for the generation scheme than the notes themselves since, in order to maintain the personality and the style of the reused motives, the pitch contour must be preserved [42.55]. Note that the notes are specified by the MIDI messages.

Summing up, the actual notes are not necessary if a harmony corrector is used to adapt the melody to the chord progressions. Also, the use of variations instead of the unmodified pitch patterns provides flexibility so that the patterns can be adapted to the harmonies and, additionally, the output melody can be set up to any desired key signature.

42.3.2 Melody Generator

The melody generator will use the rhythmic and pitch information and the predefined chord progression stored in the database (Fig. 42.3) to create new melodies that replicate the style or complexity of the songs previously analyzed. The melody generation can be performed by means of the concatenation of rhythmic patterns according to composition rules defined by the analyzed music samples and by previously selected musical parameters (time signature, tempo for a chosen complexity level).

First of all, the initial tonality, the time signature, the number of bars and the dataset of parameters corresponding to a certain training level can be selected beforehand. Then, other specific parameters can be selected or modified: all these are presented in Table 42.1.

Then, some rules have been considered to be automatically applied in order to guide the pattern selection, to ensure the proper harmony adaptation and to guarantee the continuity of the pitch contour. In order to define the rules, *Schellenberg*'s simplification [42.56] of *Narmour*'s Realization-Expectation model [42.57] is perfectly suitable. A specific algorithm based on music theory concepts can be used for harmony adaptation at each measure [42.58]. Figure 42.4 shows a schematic representation of the stages of the melody generation algorithm.

In the next subsections, the steps performed by the melody generator proposed will be described in detail.

Pattern Selection

The items i the dataset that fulfill the time signature requirement (database level 1) chosen by the user beforehand will be selected. Then, among these patterns, stored in the database after the analysis stage, the ones required for the creation of the rhythmic structure will be selected. For example, if the melody structure is defined as A-B-B-A, then two rhythmic patters (from the database, level 2), will be acquired.

Table 42.1 Music generation: selectable parameters

Global level
• Initial tonality
• Time signature
• Number of bars
• Style database
Phrase level
• Predefined rhythmic pattern
• Predefined harmonic pattern
Measure level
• Tonality
• Chord
• Rhythmic pattern

After linking each measure in the structure to a particular rhythm pattern, a pitch contour is selected randomly among all the pitch version for each of the motives (from database, level 3).

Note that at this stage, the pitch progression selected may not be in accordance with the harmony set up. At a later stage, a chord transposition system should adapt the pitch curve to fulfill the given harmony progression keeping the continuity of the melodic curve.

Harmony Progression

A user can design a particular chord progression. However, note that the chord progression is a very important parameter for the musical success: there are combinations of chords that do not sound well together while others do [42.59]. So, in order to guide the selection of the chord progression, a set of harmonic progressions that sound well together can be defined [42.60].

The reason why some harmonic progressions sound well while others do not is related to the listener expectation [42.57], which is linked to the cultural environment and the preference of the listener for some chord transitions rather than others. The predefined progressions considered follow the Western music theory [42.60]. These progressions are I-ii-V-I, I-vii-I-V, I-I-IV-V or I-IV-V-I, among others.

Finally, in order to adapt the patterns selected in the previous stage, a melody transposition scheme based on music theory rules must be employed. This method will be described in next section.

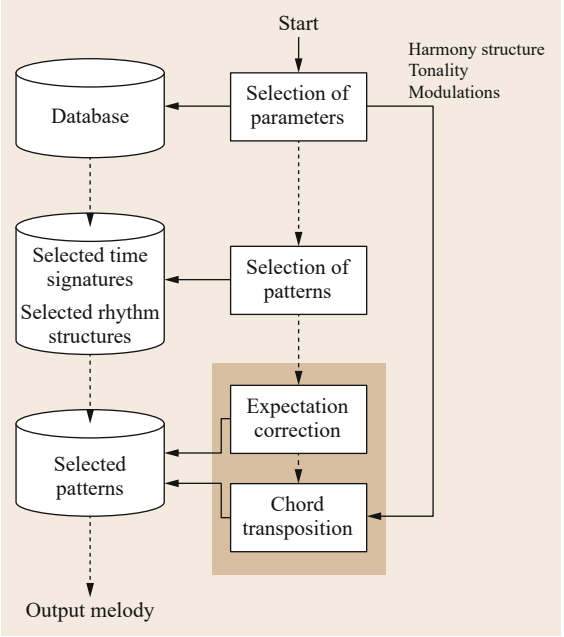

Fig. 42.4 Scheme of the melody generator

Chord Transposition

The chord transposition system must perform the proper changes to the sequence of notes to ensure that the harmony attained is the one selected and to guarantee the continuity of the melodic line according to the expectation model [42.56, 57]. This can be achieved by applying a musical harmony adaptation method based on level changing [42.58] together with additional constrains derived from the expectation model.

As the simple concatenation of patterns causes the appearance of transitions that do not sound natural, the idea to fix this issue is to generate a Narmour candidate [42.57] that properly follows the melodic line in the posterior measure. This candidate should fulfill the rules regarding the musical expectation.

The system analyses the last two notes of each measure to generate a new note. These two notes (called implication) are used to evaluate a third note (called realization), which will be the candidate note [42.56]. The following items are observed for the generation of the candidate notes [42.56]:

- Interval: A small interval [42.61] (less than a tritone) implies that the next note should follow the direction of the pitch progression. Otherwise, it would not achieve the expectation.
- Pitch jump: The pitch jump after a small interval should be similar to the previous one and in the same direction, according to the previous rule.
- Progression of the intervals:
  - If the implication interval is less than two semitones, then the third note should be back closer to the first note of the implication.
  - After a change in the direction or a large interval, the realization interval should be smaller than a tritone.

Recall that the position of the notes in the measures is key for the chord transposition stage. So, first, the chord notes, considered responsible of the harmony definition, and the nonchord notes, commonly called passing notes, are identified [42.59]. This process can be based on the analysis of the position of each note within each measure. The notes in downbeats will be considered chord notes, whilst those placed in upbeats will be considered nonchord notes.

Then, the chord transposition subsystem applies two different procedures to these two types of notes:

- Accented notes must belong to the chord
  - First chord note (or Narmour candidate [42.57]): This note is assigned to the closest pitch of the chord.
  - Secondary chord notes: Following the original pitch contour, secondary accented notes are moved to the closest pitch in the contour direction.
- Unaccented notes: The original interval between the previous note and the current note is replicated.

When the pitch and harmony adaptation processes are finished for every measure, the creation of a new melody is completed. Then, the performance on the melody by the user must be assessed.

42.4 Singing Assessment

In this section, we consider the problem of singing assessment for music learning. The descriptions will be based on the algorithm described in [42.62]. This algorithm evaluates the user's singing performance by comparing the processed audio against a reference melody.

In our case, the reference melody corresponds to the final output of the methods described in previous sections.

The main steps often required for the task at hand are illustrated in Fig. 42.5. These steps include the following global tasks: fundamental frequency (F_0) extraction and singing assessment based on F_0 alignment.

Next, we will briefly describe these steps following the approach selected, although other relevant schemes can be found in the literature [42.19, 25, 63].

42.4.1 F_0 Extraction

The Yin algorithm [42.29] has been found to be a good choice to extract the F_0 vector. This evolves from the idea of the autocorrelation method [42.64] to introduce relevant improvements. The modifications are based on the definition of the so-called cumulative mean normalized difference function $d'_t(\tau)$. This function peaks at the local period with lower deviations than the conventional autocorrelation function [42.29]. The cumulative mean normalized difference function is defined upon the squared difference function $d_t(\tau)$ given by

$$d_t(\tau) = \sum_{j=t}^{t+W} (x(j) - x(j+\tau))^2 \ , \qquad (42.1)$$

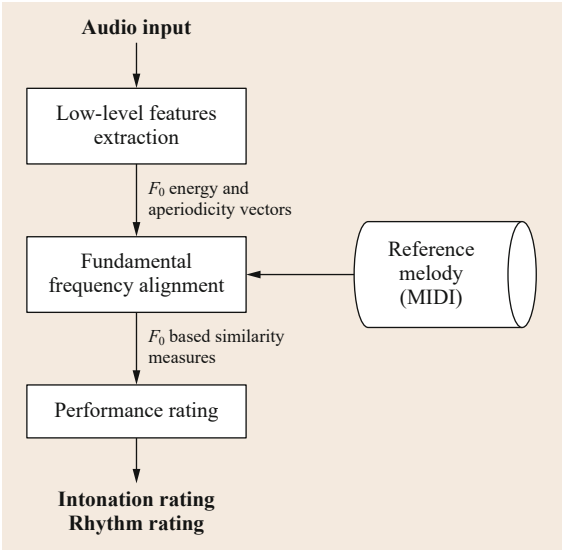

Fig. 42.5 A block diagram of the method for automatic singing assessment proposed in [42.62]

where $\tau \in [0, W)$ is an integer lag variable, W is the window size, $x(\tau)$ is the amplitude of the input signal x at time τ and t is the time index. Then, this function is normalized to give rise to the cumulative mean normalized difference function

$$d'_t(\tau) = \begin{cases} 1 & \tau = 0 \\ \dfrac{d_t(\tau)}{\frac{1}{\tau}\sum_{j=1}^{\tau} d_t(j)} & \text{otherwise} . \end{cases} \quad (42.2)$$

The Yin algorithm finds the local minimum in $d'_t(\tau)$ with the smallest τ'. Afterwards, a parabolic interpolation stage is performed using $d'_t(\tau')$, $d'_t(\tau'-1)$ and $d'_t(\tau'+1)$ to obtain an accurately estimated local minimum at τ_p. This value can be used to calculate the F_0 with $F_0 = f_s/\tau_p$, where f_s stands for the sampling rate.

The aperiodicity measure or voicing parameter is given by $ap = d'_t(\tau_p)$. This parameter is useful to identify voiced/unvoiced frames [42.62].

Note that the original Yin algorithm, implemented in Matlab, can be found in [42.65].

42.4.2 Assessment of Singing Voice

Once the F_0s of the user's performance and the reference melodies are extracted, they must be compared. A suitable method to align the functions for comparison is dynamic time warping (DTW) [42.66, 67]. This technique is useful for finding an optimal match between two sequences under certain restrictions. Note that the definition of the optimality criterion of the match strongly affects the performance of the alignment.

In [42.62], the cost matrix M for the DTW algorithm is defined as (other choices could be considered)

$$M_{ij} = \min\left\{(F_{0T}(i) - F_{0U}(j))^2, \alpha\right\} , \quad (42.3)$$

where $F_{0T}(i)$ is the F_0 of the target melody in the frame i, and $F_{0U}(j)$ represents the F_0 of the user's performance in the frame j. M_{ij} is the cost and α is a constant. Note that using this scheme, when the squared difference between F_0s becomes larger than α, the situation is considered to correspond to a spurious value and its contribution to the cost matrix is bounded.

The DTW algorithm uses the cost matrix to provide an optimal path $[i_k, j_k]$ for $k \in 1 \ldots K$, where K is the length of the path, matching the two input signals. Figure 42.6 illustrates the alignment performance.

In [42.68], a Matlab implementation of the DTW algorithm can be found.

DTW as a Similarity Measure

The path for the alignment between the user's performance and the reference melody conveys relevant information for singing evaluation. Actually, the DTW is suitable for assessing both the intonation and the rhythmic performance [42.62].

DTW to Assess Intonation. The cost matrix M provides information about the instantaneous deviation of the sung note with respect to the reference, as well as information about the overall F_0 deviation. Consequently, the total cost of the optimal alignment path found can be used as the similarity measure for intonation assessment. Then, the total intonation error (TIE) can be computed as

$$TIE = \sum_{k=1}^{K} M_{i_k j_k} , \quad (42.4)$$

where M is the cost matrix previously defined, and $[i_k, j_k]$, with $k \in 1 \ldots K$, represents each of the steps of the optimal path, K being the length of the path.

DTW to Assess Rhythm. DTW is also a powerful procedure for automatic rhythm assessment. The specific shape of the optimal path contains the necessary information about the rhythmic performance.

In the cost matrix of the DTW, a diagonal straight line represents a perfect rhythmic performance (no de-

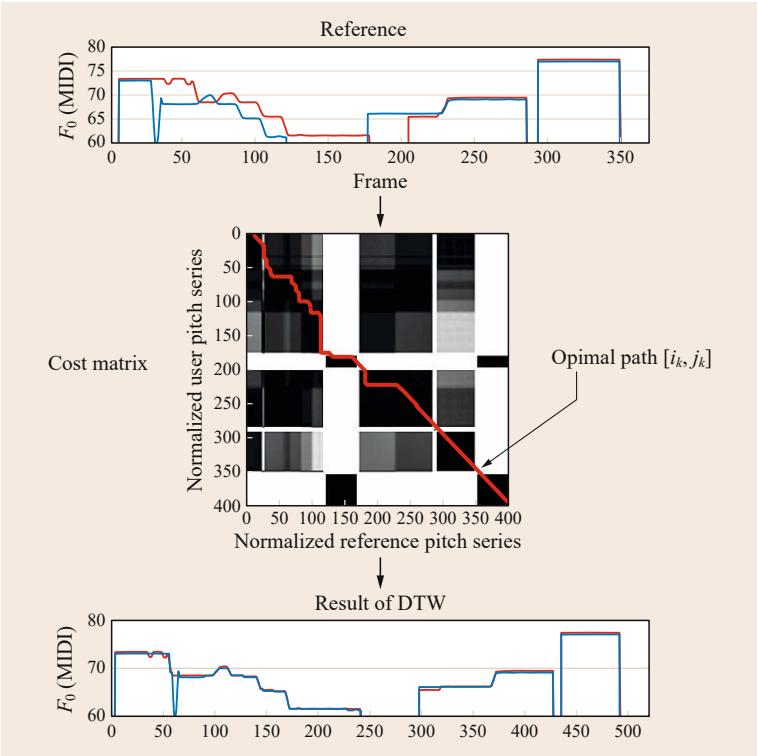

Fig. 42.6 F_0 alignment between a user's performance and the reference melody using dynamic time warping (DTW)

viation with respect to the target melody). A poor rhythmic performance would yield large deviations with respect to such a straight line. Figure 42.7 illustrates this idea.

The analysis of the deviations of the alignment path found with respect to the ideal path provides relevant rhythm assessment information. Specifically, a straight line with a slope different from the ideal one represents good rhythmic performance in a different tempo. On the other hand, the straightness of the path reveals the presence of erratic rhythmic errors. The straightness can be quantified by performing an ad hoc linear approximation to the path found, and then analyzing the error.

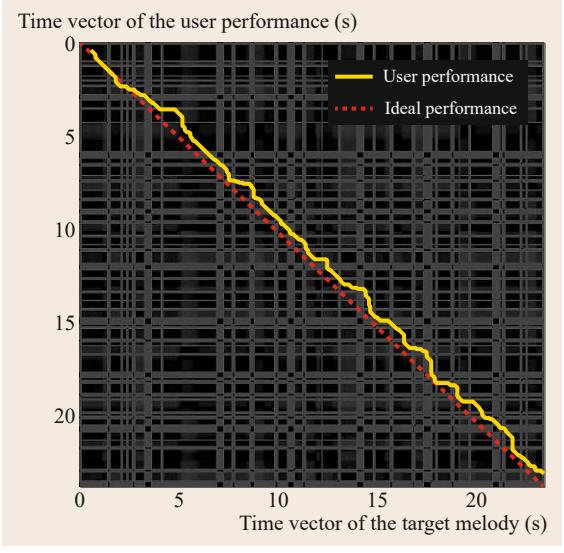

Fig. 42.7 Sample of the usage of DTW with F_0 signal for rhythm assessment. Rhythmically stable user's performance (*solid line*) and ideal rhythm performance (*dotted line*) ►

42.5 Summary

In this chapter, a complete approach to the development of computational tools for singing learning has been proposed.

Two main subsystems are required for the singing learning purpose: a module for the automatic generation of singing exercises with selectable complexity levels,

and a module for the automatic assessment of the user's singing performance.

A complete melody generator scheme, including the required analysis stages, has been presented. The generator described is able to automatically generate new melodies adapted to a certain music level selected beforehand.

An approach for the automatic assessment of singing voice has also been described. The method selected compares the F_0 of the user's performance against the reference F_0 of an automatically generated melody. The scheme provides an evaluation of both intonation and rhythm.

43. Computational Ethnomusicology: A Study of Flamenco and Arab-Andalusian Vocal Music

Nadine Kroher, Emilia Gómez, Amin Chaachoo, Mohamed Sordo, José-Miguel Díaz-Báñez, Francisco Gómez, Joaquin Mora

In this chapter we approach flamenco and Arab-Andalusian vocal music through the analysis of two representative pieces. We apply a hybrid methodology consisting of audio-signal processing to describe and contrast their melodic characteristics followed by musicological analysis. The use of such computational analysis tools complements a musicological-historical study with the aim of supporting the discovery and understanding of the specific characteristics of these musical traditions, their similarities and differences, while offering solutions to more general music information retrieval (MIR) research challenges.

43.1 Motivation

Over the last decades, the music information retrieval (MIR) community has earnestly striven towards the development of technologies for the automatic description of signals from musical phenomena such as melody, harmony, dynamics, or instrumentation. These technologies have been exploited in the context of numerous applications such as music identification, retrieval and recommendation. However, while the number of applications has been plentiful and covering a broad spectrum of needs, in the majority of cases they are limited to mainstream popular music from the so-called Western tradition [43.1].

Fortunately, a genuine interest in applying those techniques to varied repertoire, including traditional, folk and ethnic music [43.2] has awakened recently. The task of adapting existing technologies is not clear-cut and many challenges are posed because of the particular musical features of the given tradition, which may be markedly different from the Western one.

The main goal of this chapter is to illustrate the potential of music content description techniques for the analysis of traditional music. For this study, we focused on two well-established music traditions, flamenco and Arab-Andalusian music, which are studied through a computer-assisted analysis of a selected set of pieces in audio format. These traditions are an important part of the musical heritage of Andalusia and the North of Africa. Given the main role of the singing voice in those traditions, our study pays close attention to its melodic aspects.

Through the analysis of two representative pieces, a flamenco *martinete* and an Arab-Andalusian *inshád*, we illustrate some commonalities and divergences in these traditions and present evidence on how existing technologies allow us to formalize expert knowledge and complement traditional analysis methodologies by discovering relationships that might otherwise have been unnoticed. Moreover, this study implements a method for the computer-assisted analysis of traditional music, which can provide means to formulate, test out, and confirm research hypotheses that are not always evident from a perceptual and musicological analysis.

43.1.1 Computational Music Analysis

Regarding the issue of how to computationally model and study the musical phenomenon, two different trends shape the existing research in music information re-

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_43

trieval (MIR) [43.3], namely, the symbolic approach and the signal description approach. On one side, the symbolic description disregards any audio signal analysis in order to concentrate just on abstract representations of musical concepts, such as notes, durations, beats, rhythm, melody patterns, harmony, or structural relationships. This type of analyses use scores, Musical Instrument Digital Interface (MIDI) files or other symbolic representations of music as input data and, in most of the cases, assumes a listener who has been educated on some formal music tradition (by learning to play an instrument and by being exposed to this type of music). On the other side, the audio-content approach, which is the path pursued here, uses the audio signal as the basis for the description and processing of music.

Since the beginning of MIR, most models and technologies have been developed for mainstream popular music in the so-called *Western* tradition. In parallel to that extensive and rich body of research, over the last few years an increasing interest in applying available techniques to the study of traditional, folk or ethnic music has developed. As mentioned in [43.4], the name of *computational ethnomusicology* could be at least as old as 34 years [43.5]. In [43.5], two mathematicians and an engineer provided an interesting discussion about the role of computers in five areas of research in ethnomusicology: collection, administration, notation, selection and systematization, and scientific treatment of music data. They state that computers might be essential tools for managing three groups of data: melodies (the study involves 10 000 melodies), recordings and social context. Although these principles and usages of computers are still valid today, computational models have evolved to the extent that they can be employed to efficiently collect field data or simulate complex social interactions.

The term computational ethnomusicology was recently redefined by *Tzanetakis* et al. [43.6] as the *design, development and usage of computer tools that have the potential to assist in ethnomusicological research*. Under this view there is a main discipline, ethnomusicology, that takes advantage of advances made in supportive disciplines such as computer science, music cognition or cultural studies, and applies them – after the appropriate tuning – to its particular tasks. Even though this could be the most accepted and practiced view, *Gómez* et al. [43.4] argue that this is a restrictive definition of a discipline as a tool provider. According to them,

> *computer models can be theories or hypotheses (not just tools as a spreadsheet or a statistical package can be) about processes and problems studied by traditional ethnomusicologists. When we approach computational ethnomusicology this way, we adopt a new mental framework that helps to restructure problems and perceive the relationships between their constitutive elements under a different perspective.*

With the present study we aspire to help overcome such procedural views of computation and strive for a broad and fertile conception of the discipline.

State-of-the-art techniques for the description of music audio signals allow the automatic computation of features related to different musical facets such as melody, harmony, rhythm, and instrumentation [43.7]. These features have been used to compute similarity distances and classify musical pieces according to, e.g., artist, genre, or mood. In this way, current systems can, for instance, locate different versions of the same song with a high accuracy rate [43.8]. Although computational techniques have been proven to be of great interest when applied to different musical repertoires, it is apparent that we need to develop culture-specific methods to understand and model different music repertoires. Existing literature has addressed repertoires from a variety of music traditions, e.g., Turkish makam music [43.9], Hungarian *siratok*, Torah cantillation, 10th century St Gallen plainchant and Koran recitation [43.10], music from Central Africa [43.11] and Indian classical music [43.12], as well as the automatic detection and classification of non-Western music genres [43.13].

For the case of flamenco, first approaches to computational analysis and description have been mainly carried out by the Computational Analysis of Flamenco Music (COFLA) [43.14] research group, which has focused on rhythmic properties [43.15], melodic similarity [43.16, 17], and pattern matching [43.18, 19]. *Wu* [43.20] approached computational modeling of the complex rhythmical structures of *bulerías*. Considering the extensive use of stylistic ornamentation in the singing interpretation in the music traditions under study, adjustments of existing technologies are necessary. Resulting computational tools can support and complement traditional musicological studies and thus provide a novel approach that permits advancements in rigorous understanding, diffusion and preservation of these musical traditions.

43.2 Background

43.2.1 Flamenco

Flamenco is an oral tradition with roots as diverse as the cultural influences of its area of origin, Andalusia (a region in southern Spain). In the course of history, immigrants with a great variety of cultural backgrounds arrived at its harbors and settled in the surrounding cities. Over the centuries, the area and, of course, its music have been influenced by the ancient Tartessian culture as well as Phoenician and Roman colonizations, notwithstanding later settlements by the Visigoths, the Arabs, the Jews, the Christians, and to a large extent gypsies, who decisively contributed to shape its form as we know it today. The reader is referred to the books of *Blas-Vega* and *Ríos-Ruiz* [43.21], *Navarro* and *Ropero* [43.22], and *Gamboa* [43.23] for a comprehensive study of styles, musical forms, and history of flamenco.

Flamenco music germinated from and was nourished mainly by the singing tradition [43.23]. Accordingly, the role of the singer soon became dominant and fundamental. In the flamenco jargon, singing is called *cante*, and songs are termed *cantes*. The flamenco singing voice can be characterized as unstable in pitch, timbre and dynamics [43.24]. Furthermore, the typical voice quality is described as matte, containing few high-frequency harmonics, and usually lacking the singer's formant. Melodic movements are composed of conjunct degrees, a high degree of complex, microtonal ornamentation and melisma [43.16]. Flamenco singing is usually accompanied by the guitar. Other forms of accompaniment may include clapping, stamping of feet, or percussion instruments. The origin and evolution of the more than fifty different flamenco styles (*palos*) [43.21] and variants have been studied from different disciplines, including ethnomusicology, literature and anthropology, and different theories have been proposed [43.21, 23, 25]. The most widespread [43.25] claims a period of isolation in which Andalusian gypsies kept their musical tradition from the outside world and performed only at intimate family reunions. However, this theory lacks reliable documentation and recent research has suggested that the growing popularity of singing performances put on at theaters in Andalusian cities could be the origin of this music as we know it today.

43.2.2 Arab-Andalusian Music

The Arab-Andalusian music (or simply, Andalusian music) is a musical tradition that can be traced back to the 12th century in Al-Andalus, to the Muslims and Christians living in the Moorish Spain [43.26]. Andalusian music is the result of many influences, including Middle-East Arabic classical music, the Hispanic music traditions of the Iberian peninsula, and other classical traditions such as the Gregorian and Byzantine. The Andalusian tradition is maintained in quite a few north African regions [43.27, 28], mainly in Morocco, Algeria, and Tunisia.

Andalusian music is organized around the concept of *nawba* [43.27, 28], a collection of melodies belonging to the same *tab'* (roughly, a melodic mode). The melodic structure is modal in essence, a factor that is critical for an appropriate description of the pitch relationships as music unfolds over time. Beyond the definition of scale or a set of pitches, a particular *tab'* [43.28] is linked to specific emotions or states of mind and is consequently associated with certain social occasions and circumstances.

Apart from the clear dominance of the singing voice, the *oud* is the most prominent instrument in Andalusian music. The original *oud* is a lute-related instrument, whose four strings are described by ancient music treatises as bringers of temperament (mood), senses (color, touch), spiritual or energetic states, and other metaphorical human constructs [43.28]. These relationships are actually used as methodological tools in current music training, and they presumably play an important role during performance and listening engagement. Other instruments in the Andalusian music tradition include *rbab, derbuga, qanun, tar, kamanya, and nay*. Despite the close connection between the musical instruments and the emotions or spirituality, the singing voice represents the key element. Andalusian music is furthermore characterized by the use of sung poems (*san'as*) [43.29]. The instruments are considered as accompaniments or bridges between sung verses or hemistichs. The poems (*muwashshahas* or *zĂl'jels*) are taken from Arabic classical poetry. However, their meter and rhymes have been evolved and adapted to the local sociocultural background [43.26].

As in the case of flamenco, the Andalusian music has been preserved and kept alive as an oral tradition. The modern study of the Andalusian music theory started in the colonial period (20th century), but most of these studies did not consider the plurality and the diverse influences of Andalusian music.

In this comparative analysis of flamenco and Arab-Andalusian music we consider both as independent music traditions. Even though both share a geographic

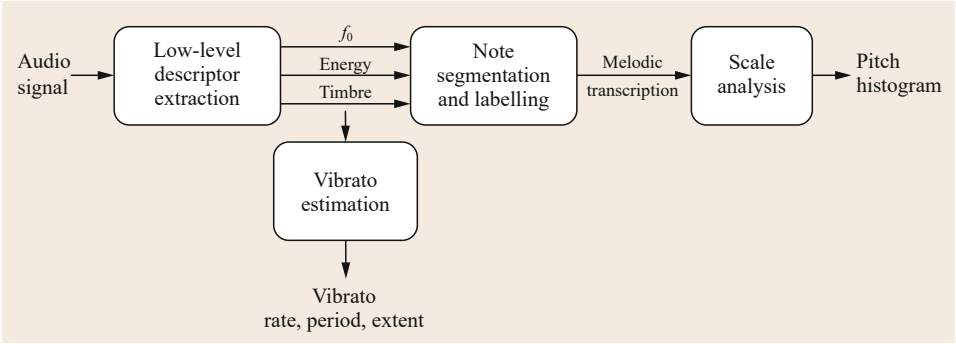

Fig. 43.1 Block diagram for melodic characterization

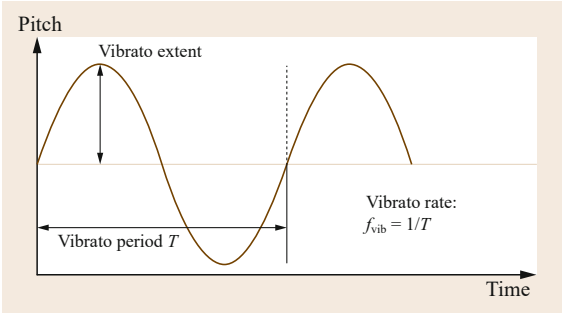

Fig. 43.2 Vibrato rate, period and extent

location of origin, they posses individual characteristics regarding aesthetics, musical structure and communicative intention. Nevertheless, some common variables can be easily found by simply listening to examples of both styles: melismatic ornamentation, importance of vocal vibrato, and even similar melodic patterns.

43.2.3 Music Content Description

In a first step towards retrieving musical content from a piece of audio, physical properties are extracted directly or in a mathematically derived way from the signal without incorporating further high-level musical and contextual knowledge. In order to obtain a higher level of abstraction and prove comprehensive content descriptors (i. e., instrumentation, genre, or melodic transcription), such low-level descriptors need to be combined with content-based generalizations about the data. For the analysis of the pieces under study we mainly focus on properties related to the vocal melody and consider state-of-the-art methods according to the steps shown in Fig. 43.1.

Low-Level Descriptors

The most relevant low-level descriptors required to obtain melodic descriptors are fundamental frequency, energy and timbre-related spectral features [43.30]. The fundamental frequency (f_0) is closely related to its perceptual equivalent, the pitch, and in most scenarios the former corresponds to the latter. Changes in timbre (spectral content) and energy are correlated to note onsets and offsets and therefore give complementary information when segmenting the pitch contour into single note events. A great variety of algorithms for extracting the fundamental frequency from monophonic audio signal have been proposed in the past. For a detailed overview the reader is referred to [43.31]. In the present study we estimated the fundamental frequency by computing the spectrum of the signal and analyzing the magnitude correlation in the frequency domain [43.30], thus exploiting the regular distance between fundamental frequency and overtones.

Vibrato Descriptors

Vocal vibrato can be characterized as an oscillation of the fundamental frequency within a range of 4–8 Hz and an extent of less than one semitone (Fig. 43.2). We estimate the local vibrato rate and extent from the fundamental frequency [43.17]. The contour is treated as a time series and high-pass filtered in order to obtain a zero-centered signal in which only fast pitch fluctuation is preserved. If vibrato is present, the spectrum of the preprocessed contour shows a peak in the considered frequency range. The instantaneous vibrato rate corresponds to the peak frequency and the vibrato extent can be estimated as the magnitude of the pitch fluctuation in the current frame. We furthermore extract the vibrato amount as the percentage of voiced frames in which vibrato is detected.

Melodic Contour Analysis

In order to provide a symbolic representation for melodic analysis, we transform the fundamental frequency contour into a sequence of single notes, described by their energy, pitch and duration, as explained in *Gómez* and *Bonada* [43.30]. After estimating a global tuning frequency, the fundamental frequency contour is

segmented into notes by maximizing a likelihood function along the analyzed excerpt. In this step, the typical pitch range of a singer as well as limitations for note durations are considered when finding the optimal path for the pitch progression. In a later step, successive short notes are consolidated if pitch, energy and timbre descriptors indicate a single note instead of consecutive onsets. From the resulting symbolic note representation we can extract statistical descriptors of the melodic content, as, i. e., pitch range, pitch fluctuation or average note duration.

Scale Analysis

Pitch histograms have been widely used to characterize the pitch content distribution of music in different traditions [43.11, 32]. In order to analyze the tonality of the considered pieces, a pitch histogram is computed from the note transcription, displaying the occurrence of distinct pitches, weighted by their duration. Since tonal centers and pitches belonging to the underlying scale tend to appear more frequently, such pitch histograms are used to extract and analyze the tonality of a piece of music.

43.3 Case Study

43.3.1 The Flamenco Martinete

The *martinete* is a traditional flamenco singing style without guitar accompaniment, characterized by a distinct melodic skeleton. It forms part of the subgenre of the *tonás* (from Spanish *tonadas* – *singable* or *melodic fragment*), a group of a cappella styles, which are thought be the origin of a number of flamenco styles [43.25]. According to [43.33], the *martinete* has its origins in Arab chants that were heard and adapted by gypsies. Flamenco experts distinguish between a number of substyles, corresponding to their creator or geographic origin (i. e., *martinete* from *Triana, Jerez*, and *Los Puertos*), and whether lyrics are repeated (*natural* without repetition and *redoblao* with repetition). Similar styles are *debla*, which shares musical elements with *martinete redoblao*, *carcelera* and *saeta*, which in some cases are interpreted by using *martinete's* distinct melodic progression. In 1952 *Antonio el Bailarín* was the first to dance to a *martinete*, using the characteristic *siguiriya* rhythm. Furthermore, in order to pay tribute to the assertion that the style has been sung by workers in blacksmith's shops, *martinetes* are sometimes accompanied by mallet strokes on metal surfaces.

General Characteristics

Characterized by a slow tempo, solemn performance, free rhythmic interpretation and a large amount of melismatic ornamentation, songs belonging to the style have a common melodic skeleton based on the major scale. While the major mode is dominant throughout, the third degree may be occasionally lowered by a semitone, converting the scale into minor mode. The four eight-syllable verses are arranged in an A-B-A-C form, where the first and the third sections share a similar melodic contour. These two sections are separated into two segments by a rest. The first section contains a characteristic melodic sequence that clearly identifies the style: a jump from the subtonic or the dominant to the tonic followed by a raise to the subdominant by conjunct degrees.

Martinete by Singer Tomás Pavón

In the present study we focused on the example of a *martinete* performance by the renowned singer Tomás Pavón, which belongs to the substyle of *martinetes* by *Juan Pelao*, also referred to as *origin martinete* (*martinete de origen*).

Figure 43.3 shows a manually annotated representation of the melodic contour of the piece, where verses are marked by numbers. Figure 43.4 provides a manual

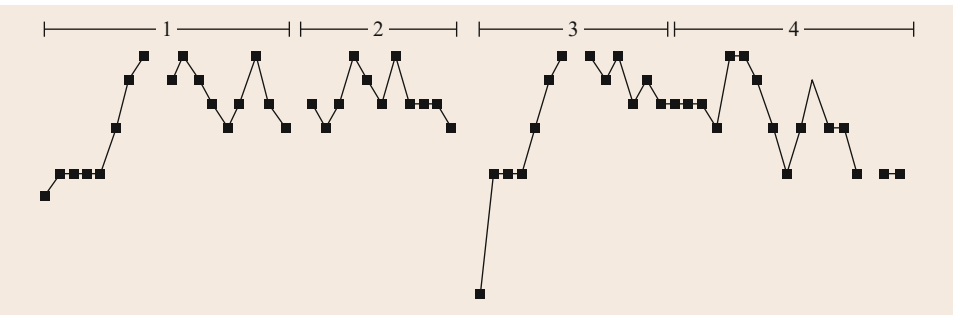

Fig. 43.3 Symbolic representation of the melodic contour of a *martinete* by singer Tomás Pavón

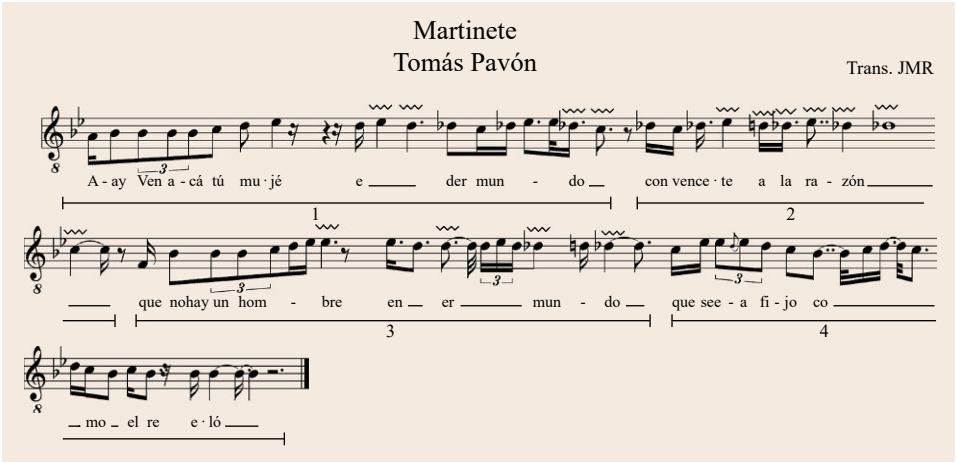

Fig. 43.4 Transcription in Western Music notation of a *martinete* by singer Tomás Pavón

Table 43.1 Relevant pitch values for the four verses of the *martinete* by singer Tomás Pavón

Verse	First note	Recitative note	Last note	Direction
1	A4	Eb5	C5	Rising
2	D5	Eb5	C5	Horizontal
3	F4	Eb5	Db5	Rising
4	C5	C5	Bb4	Falling

transcription of the piece in Western notation and Table 43.1 provides some features of the different verses of the piece. The melodic contour is based on the B-flat major scale and shows the style-specific note sequences described in the previous subsection. In the first half of the first verse, the tonic is reached from the subtonic, followed by three subsequent degree steps to the subdominant. In the first half of the third verse, the melodic contour is repeated, whereas the tonic is reached from the dominant. The recitative note in each movement is prolonged and subject to strong melismatic ornamentation. Furthermore, note that the first and second verses are separated by silences, while the third and fourth are fused together.

Tomás Pavón's interpretation is rich in melismatic ornamentations, which cause a stronger prolongation of some syllables than in most other performances. Trills and double relishes become denser with increasing scale degree, while chromatic ornamentations are bound to the third scale degree. Frequently, such ornamentations take on rhythmic patterns of triplets and quintuplets. The melisma are performed rapidly and with a precise breath management. While the tuning varies during the performance, the transcription in Western music notation (Fig. 43.4) refers to note values quantized to the equal-tempered scale. Since the song is performed in free rhythm, a separation into bars is furthermore omitted, while traditional symbolism is used to describe note durations. In order to simplify reading, some ornamentation details have been taken out. Figure 43.5 shows these details for a small excerpt.

43.3.2 The Arab-Andalusian Inshád

Arab-Andalusian music is strongly modal and, similarly to Gregorian chant, based on particular melodic cells known as *centones*. The use of *centones* is quite characteristic of Christian music in the Middle Ages (in the Byzantine tradition they are sometimes referred to as *schemata*). Rather than creating new *centones*, composers of those times made creative use of the existing ones. Furthermore a mode is defined by its pitch range, a tonal center around which the melody gravitates, important scale degrees that provide the mode's characteristic flavor and a set of *centones* on which melodic phrases end.

The *inshád* is a sung poem of two verses. Forming part of the Arab-Andalusian musical heritage, the melodic progression is based on set motives that are

Fig. 43.5 Ornamentation details of an excerpt of a *martinete* by singer Tomás Pavón

Fig. 43.6 Example melodic phrase of the *San'a "Sallu ya 'ibad"* of *Basit Raml al-Maya*

spontaneously ornamented [43.26]. Below we describe the main characteristics of the analyzed piece.

General Characteristics

The *inshád* has a series of particular musical characteristics [43.26]. Its melodies are integrated in the modal system of Arab-Andalusian music. The most common intervals are a (major or minor) second, followed by minor third and major third. Most of the melodic phrases end with a long note. The latter is a common characteristic found in different forms in Arab-Andalusian music corpora [43.34]. Figure 43.6 shows a melodic phrase of the *San'a "Sallu ya 'ibad"* of *Basit Raml al-Maya* (*Basit* is the name of the rhythmic structure and *Raml al-Maya* is the name of the *nawba*).

Even though the meter of the *inshád* is free, this freedom is not absolute, but rather rational. Indeed, the notes of the *inshád* are not tied to a rhythmic pulse or an exact execution time. Yet they have to be subject to a temporal hierarchy of notes and complete phrases, rationally approximate but intuitively guided: The importance of a note in a phrase implies an extension of its duration compared to the other notes within the phrase. Furthermore, the duration of the rests between (blocks of) melodic phrases depends on the global cadence of the *inshád*. This cadence depends on the general ambiance of the concert as well as the typical tendencies of orchestra and singer.

Melodic Improvisation in the Inshád

The melodic improvisation in Arab-Andalusian music can be of two types: ornamentation of existing melodies or creation of new melodies, such as *mawwals* and *istijbárs*. In a performance of an *inshád*, the improvisation can only occur as an ornamentation of the its base melody.

Ornamentation is a key feature in Arab-Andalusian music, given the limitation on a set of fixed melodies. Hence, it represents an important tool for musicians to express their individual interpretation and performance character. As a result, individual performances of an *inshád* vary regarding the amount and complexity of ornamentation. There are however some constraints: the musical mode, an intuitive phrase duration, the aesthetic traits and the emotional context of the performance need to be preserved (e.g., an ornamentation related to a sad emotion should be avoided in a wedding performance). Even though the melodic content is limited to the mode, singers can include notes from so-called *neighbor modes*: as explained in [43.26], two musical modes are considered to be neighbors if their scale sequences differ by an alteration of a single note.

Al-Sika Mode

The *Al-Sika* mode with its *centones* is shown in Fig. 43.7. In contrast to Western scales, the tonal center does not correspond to the first scale degree, but to the note E, the third degree. The first (C) and fifth degree (G) are fundamental notes with higher melodic importance. Furthermore the scale is subdivided into four units of consecutive notes with a common intervallic structure (*al-Dayl*).

The ethos (the character or emotion) associated with the *Al-Sika* mode is a complaint of a resigned person

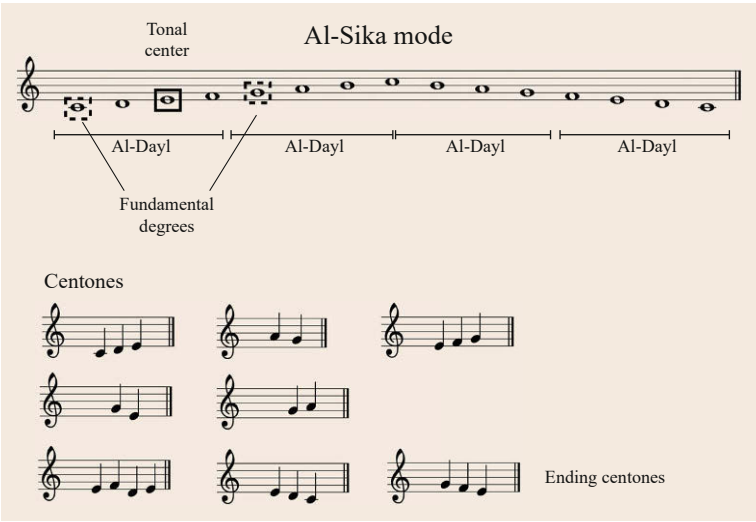

Fig. 43.7 Summary of the main characteristics of the Al-Sika mode

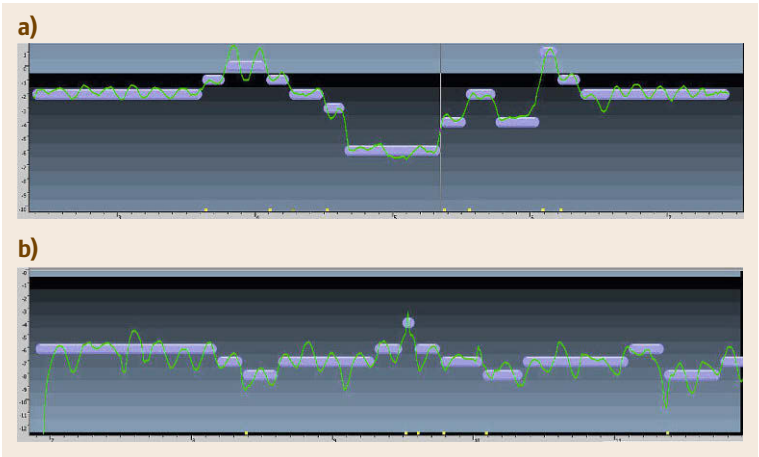

Fig. 43.8a,b Fundamental frequency contour and note transcription of a phrase; **(a)** inshád; **(b)** martinete

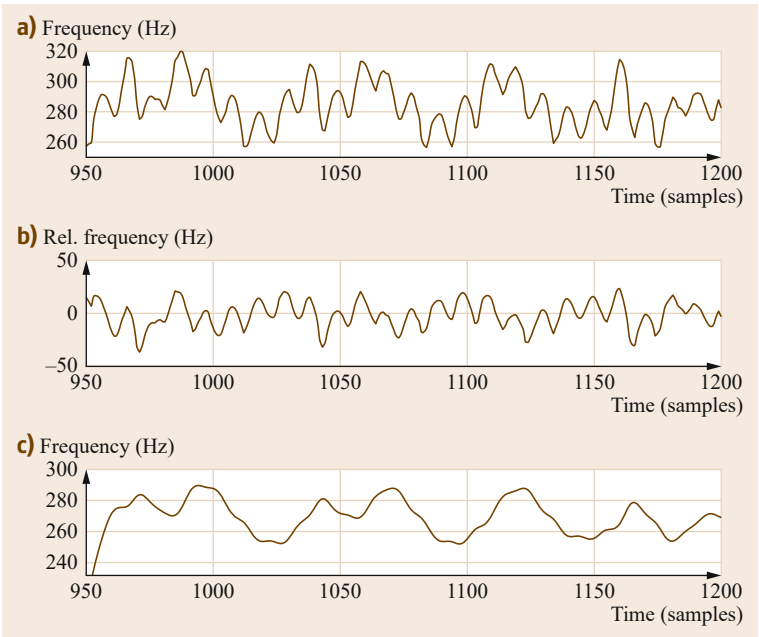

Fig. 43.9a–c Martinete excerpt; fundamental frequency contour; **(a)** unfiltered; **(b)** vibrato; **(c)** slow pitch modulation

who is watching her loved one moving away. The resignation appears in phrases such as E-F-G-E or E-F-D-E, and the distance of the loved one shows up in the alteration of F to F# in the phrase E-F-G (which becomes E-F#-G).

Inshád in Al-Sika Mode by Zohra Abbetiw

The present study focuses on the analysis of an *inshád* performance in *Al-Sika* mode by Zohra Abettiw, a female singer from the school of Tetouan (north Morocco). She is accompanied by the Orchestra of the Tetouan Conservatory, led by Mohammed Ben Larbi Temsamani. The audio piece is a recording of the Moroccan national radio and television and it dates back to the 1960s. The melody ranges from B_3 to B_4, if we consider the ornamentation notes as part of the melody, that is, the interpretation as a whole. The studied *inshád* consists of three blocks. The first and the third blocks contain three phrases. The first phrase is a typical phrase in *Al-Sika* mode and acts as the presentation of the *inshád*. The second phrase ends with on the note C, where the substitution of an F with an F# symbolizes the feeling of distance to the loved one. Finally, the third phrase is similar to the second phrase, but it connects with the last interval, which corresponds to the final *centon* (E-F-D-E). On the other hand, the second block is the shortest, containing only one isolated

Table 43.2 Comparison of statistical note and vibrato descriptors for the considered pieces

Descriptor	Martinete	Inshád
Average vibrato rate (Hz)	6.19	5.91
Average vibrato extent (cents)	75.47	62.02
Vibrato amount (%)	41	64
Lowest pitch (MIDI pitch)	53	59
Highest pitch (MIDI pitch)	64	71
Mean pitch (MIDI pitch)	60.83	65.03
Pitch fluctuation (MIDI pitch)	2.11	3.17
Pitch range (MIDI pitch)	11	12
Average note duration (s)	0.34	0.42
Note duration fluctuation (s)	0.24	0.43
Onset rate (notes/s)	2.52	1.61

phrase, which is again similar to the second phrase of the first block.

43.3.3 Computational Analysis

This section contrasts previous manual analyses with computational description tools. We compare fundamental frequency envelopes and symbolic note representations and compute statistical descriptors related to pitch content and vibrato. We analyze pitch histograms in relation to the tonal concepts introduced in the previous section.

Melodic Contours

We first compare automatically computed fundamental frequency envelopes and melodic contours of both pieces, as illustrated in Fig. 43.8. We observe that notes possess more ornamentation in the *martinete* than in the *inshád* performance. The fundamental frequency contour of the *martinete* excerpt can be modeled by an overlay of two periodic pitch fluctuations: the high frequency voice vibrato and a slow periodic melisma. When filtering the fundamental frequency envelope at suitable cutoff frequencies, both periodic pitch fluctuations can be visualized (Fig. 43.9). By analyzing the energy trajectory of both excerpts, we furthermore observe that the fast pitch fluctuation is accompanied by a simultaneous dynamic modulation (Figs. 43.10 and 43.12). The fundamental frequency contour of the *inshád* piece shows glissandi in note transitions and vibrato during longer notes, but we do not observe melismatic ornamentation (Fig. 43.11).

Statistical Descriptors

From both automatic transcriptions, we extract statistical features related to the pitch content and vibrato, which are presented in Table 43.2. In both pieces we observe an extensive use of vibrato, as shown by the *vibrato amount* descriptor. The corresponding average frequency and extent reflect the singer's individual characteristics. The pitch range of both pieces is comparable. The pitch content of the *inshád*, sung by a female singer, is located in a higher register, with a higher average pitch. The comparatively high onset rate calculated for the *martinete* originates from the large amount of melismatic ornamentation and the low pitch fluctuation relates to the insistence on the recitative notes, while the pitch content of the *inshád* appears to be wider spread.

Pitch Histograms

By analyzing the temporal note predominances in the automatic transcriptions, we obtain pitch class histograms, illustrated in Fig. 43.13. All occurring pitches are wrapped in a single octave and displayed relative to their tonic. The tonal center (E) and the fundamen-

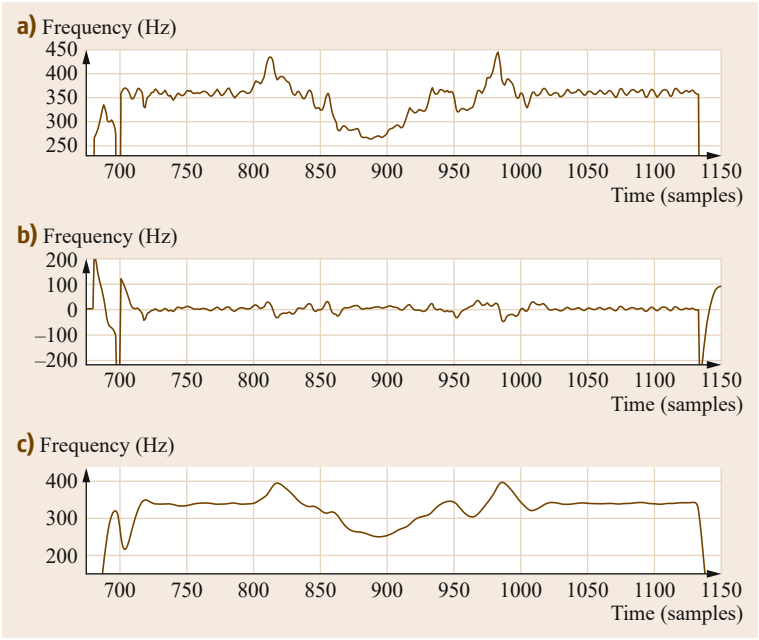

Fig. 43.11a–c Inshád excerpt; fundamental frequency contour; **(a)** unfiltered; **(b)** vibrato; **(c)** slow pitch modulation

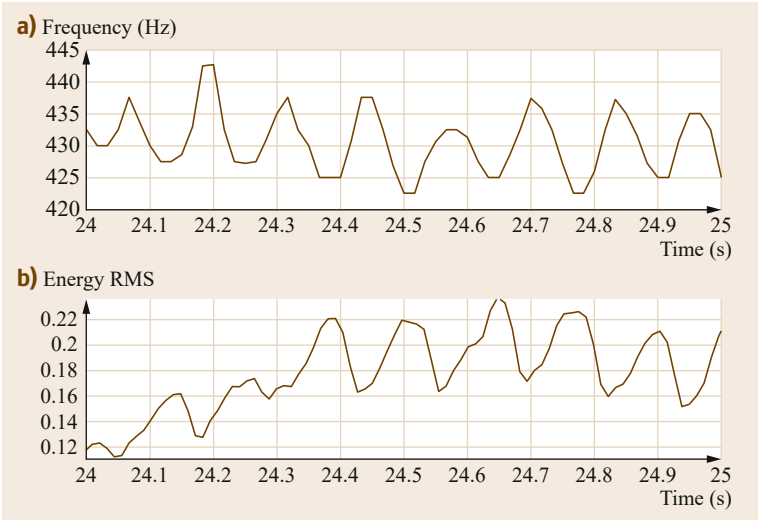

Fig. 43.12a,b Inshád excerpt; **(a)** fundamental frequency contour; **(b)** energy trajectory

tal scale degrees (C and G) of the *Al-Sika* mode in the Andalusian piece appear with a significantly higher frequency throughout the contour. Also the modulation from F to F# can be observed. The pitch content of the *martinete* is concentrated in the first six chromatic scale degrees. It can be seen that the total duration of occurrence of the tonic is lower than for the fourth, fifth and sixth degree, which are extensively used in melismatic ornamentations around the recitative notes. Consequently, the pitch content is mainly concentrated between the tonic and the subdominant and includes an elevated occurrence of notes that do not belong to the underlying scale. In contrast, the *inshád* shows a wider-spread distribution of all pitch classes over the octave, strongly weighted by the importance of the corresponding scale degrees.

43.4 Conclusion and Future Perspectives

As we stated at the outset, our intention in carrying out this piece of research is to show how to use computational tools in a meaningful manner, beyond mere consideration of them as powerful or sophisticated tools. In this study, we have presented a methodology for the analysis of vocal music of two complex, rich music traditions, flamenco and Arab-Andalusian music. We adopted the audio approach because we consider it more appropriate for the repertoires under study, given the complex ornamentations and the absence of score. We have studied vocal music and a symbolic approach would have missed many musical phenomena of importance, such as vibrato or microtonality. Also, this approach allows automatic computational analysis of large corpora, as it can easily be deduced from the description of our methodology.

However, the proposed methodology does not ignore the musicological aspects nor concentrates on physical features of the audio files. To the contrary, this work is the fruit of the collaboration of experts on flamenco and Arab-Andalusian music and computer scientists, thus showing that, because music is a complex and multidimensional phenomenon, its analysis should a be carried out from variety of standpoints and with various tools.

In particular, we have presented a methodology for the analysis of music recordings that combines manual and automatic descriptions of music recordings by using state-of-the-art techniques. Through our computational analyses, we detected similarities and differences on the two analyzed pieces, *martinete* and *inshád*, in terms of ornamentation, melodic line, scale, and vibrato. Although these properties refer to specific pieces, some of the traits are representative of flamenco and Arab-Andalusian music traditions. In the future, we intend to carry out a more extensive analysis that will include a large number of pieces of each music tradition.

Our methodology can be applied to other pieces and traditions, but proper adaptation should be carried out. As a matter of fact, this adaptation should be based on

the theoretical foundations of the tradition under study. Our endeavor is to provide novel tools and methodologies for the analysis and description of traditional music that may complement traditional approaches.

43.5 Complementary Material

The link http://mtg.upf.edu/flamenco-arabandalusian contains additional material to foster reproducibility of the presented study:

- Audio files
- Manual transcriptions
- Automatic transcriptions and descriptions
- Multimedia examples from both music traditions.

Acknowledgments. This research was partly funded by the Spanish Ministry of Economy and Competitiveness (grant TIN2012-36650), the Junta de Andalucía (grant P09-TIC-4840), the FEDER funds of the European Union and the PhD fellowship program of the Department of Information and Communication Technology (DTIC), Universitat Pompeu Fabra.

44. The Relation Between Music Technology and Music Industry

Alexander Lerch

The music industry has changed drastically over the last century and most of its changes and transformations have been technology-driven. Music technology – encompassing musical instruments, sound generators, studio equipment and software, perceptual audio coding algorithms, and reproduction software and devices – has shaped the way music is produced, performed, distributed, and consumed. The evolution of music technology enabled studios and hobbyist producers to produce music at a technical quality unthinkable decades ago and have affordable access to new effects as well as production techniques. Artists explore nontraditional ways of sound generation and sound modification to create previously unheard effects, soundscapes, or even to conceive new musical styles. The consumer has immediate access to a vast diversity of songs and styles and is able to listen to individualized playlists virtually everywhere and at any time. The most disruptive technological innovations during the past 130 years have probably been:

1. The possibility to record and distribute recordings on a large scale through the gramophone.
2. The introduction of vinyl disks enabling high-quality sound reproduction.
3. The compact cassette enabling individualized playlists, music sharing with friends and mobile listening.
4. Digital audio technology enabling high quality professional-grade studio equipment at low prices.
5. Perceptual audio coding in combination with online distribution, streaming, and file sharing.

This text will describe these technological innovations and their impact on artists, engineers, and listeners.

The development of the music industry has always been closely related to the creation of new music technology. Many changes in the industry can be directly related to technological innovation. It can be argued that technology shaped the music industry as much as the industry shaped technological evolution.

During the 19th century, the distribution of music was practically limited to sheet-music; music could only be consumed live in concert halls and at private concerts. The invention of recording devices such as the phonograph [44.1], the graphophone [44.2], and the gramophone [44.3] in the late 19th century changed that radically: the possibility to record and reproduce a live performance not only allowed publishers to mass-produce and distribute records, but eventually enabled the consumer to listen to a recording anywhere and anytime. Additional technologies such as radio broadcasting and, much later, mobile playing devices and internet streaming enforced this development: music is now omnipresent in our daily lives.

After the music industry changed from being dominated by sheet-music publishers to a new industry with a focus on recording performances and the mass production and distribution of media, it adapted and reinvented itself several times over the last century. The landscape of today's music industry includes musicians, record labels, rights holders, distributors, recording studios, manufacturers of instruments, and manufacturers of production and reproduction equipment and software. The impact of technological evolution on how

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_44

music is produced, recorded, and distributed is easily identifiable from a modern perspective, but on closer inspection it also becomes apparent how technology changed the way music is consumed and, within certain limits, influenced music performance styles and music composition as well.

This influence is not only identifiable in retrospect – many technological innovations led to a lively discussion in the music world after they were introduced. Just to give two examples, the conductor *Furtwängler* commented on radio broadcasting [44.4]:

> *The sapless and insubstantial rehash that broadcast listeners hear will only be interpreted as an adequate alternative for the concert by those who do not know the real concert anymore (translated from German by the author: Den vitaminlosen, saft- und kraftlosen Aufguss, den die Hörer des Rundfunks von einem Konzert erhalten, können wirklich nur diejenigen für vollwertigen Ersatz des Konzertes halten, die nicht mehr wissen, was ein wirkliches Konzert ist.)*

while the composer Babbitt noted [44.5]:

> *I can't believe that people really prefer to go to the concert hall under intellectually trying, socially trying, physically trying conditions, unable to repeat something they have missed, when they can sit at home under the most comfortable and stimulating circumstances and hear it as they want to hear it.*

Table 44.1 lists the approximate release dates for selected technological innovations as mentioned later in this text. The two columns of the table categorize the technology into equipment for recording, music production, and music performance (left) and technology for music distribution and consumption (right).

The remainder of this text is structured as follows: the following section will describe the interaction of music technology with both the performance and the recording of music, and the impact of the technological evolution on the recording studio sector. Section 44.2 discusses the creative uses of technology. The influence of technology on the distribution and the consumption of music will be reviewed in Sect. 44.3.

Table 44.1 Approximate dates of technological innovation in the music industry

Year	Production	Consumption
1878	Phonograph (Edison)	
1885	Graphophone (Bell and Tainter)	
1887	Gramophone (Berliner)	
1920	Condenser microphone (Wente)	
1923		Radio broadcasting
1928	Neumann CMV3 condenser microphone Theremin	
1930	Trautonium	
1933		Stereophony
1935	Hammond organ	
1941	High-quality tape recording (AEG)	
1948		12″ 33-1/3 rpm LP (Columbia)
1949		7″ 45 rpm single (RCA Victor)
1957	Ampex 8-track recorder	
1959	Fender Rhodes Piano	
1963		Philips compact cassette
1976		Dolby Stereo
1978	Lexicon L224 Reverb 3M digital multitrack	
1979	NED Synclavier	Sony Walkman
1980	Sony DAE-1100	
1981	Sony PCM-3324 digital multitrack	
1983	Yamaha DX-7 MIDI	
1985	CSound	CD (Sony, Philips)
1987	DAT	
1988	Harddisk Editing (Sonic Solution) Akai MPC and S1000	
1990		MP3
1991	Alesis ADAT	Sony MiniDisc

Table 44.1 (continued)

Year	Production	Consumption
1993	TASCAM DA-88	ITU 5.1 Multichannel
1995		Real-Audio Streaming
1997	Antares Auto-tune	DVD
1998		MP3-Player
1999		File Sharing (Napster) SACD
2000		DVD-Audio
2001		iPod (Apple)
2003		iTunes Music Store (Apple)

44.1 Recording and Performance

The recording process attempts to capture a music performance and its characteristics in order to reproduce it later. However, it does not capture all details of a performance; elements such as the communication by body language, gestures, and facial expression will be missing from the recording. Furthermore, the experience of performing for a recording can be significantly different from a live performance. The suspense of performing in front of an audience is missing, and no interaction with the audience is possible. There is also the recording process itself that may impact the performance: the musicians can perform a piece of music, listen to the recorded result, and discuss and possibly adapt their performance. The pianist *Glenn Gould* describes the advantages of this process [44.6]:

> *By taking advantage of the post-taping afterthought, however, one can very often transcend the limitations that performance imposes upon the imagination.*

The production team may also influence the performance by pointing out technical necessities and by making suggestions on how to better convey musical thoughts over the medium.

Since the introduction of multitrack recording machines, each instrument or instrument group can be recorded separately on its own track. After the first analogue multitrack machines were released in the 1950s (e.g., *Ampex* 8-track), the number of tracks increased over the decades; digital multitrack tape machines were released in the late 1970s and early 1980s with a number of tracks between 24 and 32, followed by the cassette-based recorders *Alesis ADAT* and *Tascam DA-88* in the 1990s. Both the ADAT and the DA-88 allowed one to sync several machines up to an overall limit of 128 simultaneous tracks. Modern digital audio workstations (DAWs) have no restriction with respect to the maximum number of tracks. In the context of classical music, multitrack recordings are primarily used to allow for postprocessing of the recording by adjusting the level and equalization of individual tracks. In the case of popular music, however, multitrack recording not only offered enhanced postproduction options but it transformed the way music is recorded: instead of recording all musicians of a band simultaneously, the sound engineers could record individual instruments at different times and possibly different places. This process is not applicable to all styles of music, but its implications for the performance are noteworthy; not only have the musicians lost the communication with the audience, but they are not even able to communicate with each other during the recording session. Musicians who have never met can *perform together* by sending the recording to a different studio and record the next musician at a different time and a different place.

It has also been argued that the process of recording and the public availability of recordings can influence long-term performance strategies and trends. For example, *Mark Katz* points out that the increased use of vibrato at the begin of the twentieth century coincides with the increasing availability of the gramophone. He makes a compelling argument that this change in performance style was motivated and triggered by the growing popularity of the gramophone [44.7]. Katz lists three reasons for the violinists to increase their vibrato usage for a recording:

1. It allowed the violin to be more perceptible on early recordings with limited dynamic range and poor transfer characteristics.
2. It helped to obscure imperfect intonation which is more likely to be noticeable on a recording than in a live setting.
3. It might enhance the artist's presence in order to compensate for the missing visual cues in a concert situation.

The so-called crooning is another example of the inter-relation of technology and performance styles.

Crooning was a popular singing style in the 1930s to the 1950s that created a personal atmosphere by singing at a low volume. The vocals could only carry over the accompanying band or orchestra by means of amplification of the microphone signal. Singers such as Bing Crosby and Frank Sinatra used this technique to create intimacy between audience and singer.

44.1.1 Recording Perfection

Technological innovations and improvements increased the sonic quality of recording and reproduction equipment continuously throughout the 20th century. The most notable quality improvements were probably a) the transition from an acoustic to an electric way of recording by means of the condenser (also: capacitor) microphone (1920s: [44.8]), b) the possibility to make high-quality recordings on tape (1940s), and c) the introduction of digital means for recording, processing, editing, storing, and distributing music (1970s–1990s).

These general improvements in audio quality are an unsurprising and foreseeable technological evolution. However, it was less foreseeable how technological possibilities would influence the musical content itself. It has been observed that the level of perfection of recorded music performances has been continuously increasing over the last century [44.9]. The main reason is probably that a recording, unlike a live performance, can be listened to repeatedly and is preserved for a long time. Even a minor imperfection or performance nuance, barely noteworthy in a live setting, can become an annoying artifact. The technical flawlessness of a studio recording may, in some ways, compensate for the missing live concert experience.

Editing (or *splicing*) a recording is an aspect of the postproduction process that originated in the 1940s and 1950s. While in early recording sessions the artist had to perform the whole piece for the recording process and repeat this until satisfaction was obtained, technological development opened up new ways of dealing with nonoptimal recordings. After the introduction of the first tape machines it was soon discovered that the tape could be split and joined together. This allowed for merging two or more recordings of the same piece of music; a section with a small mistake could easily be replaced with another recording of this section from the same recording session. The advent of digital processing allowed an unprecedented level of editing; *Weinzierl* and *Franke* presented evidence that the amount of edit points increased by a factor of two to three with the introduction of digital editing stations such as the *Sony DAE-1100* and digital audio workstations (DAWs) [44.10]. It is a valid assumption that modern productions make even more extensive use of the possibilities of splicing and joining of two or more recordings at virtually any position; hundreds of edit points can be expected in such a modern production. Note that the editing process not only involves removing errors and mistakes from the recording – the editor essentially has the power to select and merge takes according to his own artistic taste. This choice does not necessarily reflect the musical intentions of the artists, although it is common for the artists to give final approval of an edited recording.

The modern postproduction process offers more options to change a recording. Traditionally, these modifications were restricted to changing the sound quality by using equalization or adding artificial reverberation and (passively or actively) modifying the dynamic variation or the level relationships between instruments. Newer digital tools, however, allow more drastic changes of the music content. For instance, technologies such as time-stretching (changing the tempo without changing the pitch) and pitch-shifting (changing the pitch without changing the tempo) allow detailed modifications of the (micro-)tempo and the pitch in order to correct or modify intonation and timing. The final, published recording thus evolves more and more from the *plain* reproduction of one recording studio performance to a new performance with a level of technical perfection hard to match in a live context.

44.1.2 Recording Authenticity

Throughout the last century the music industry put significant effort into marketing records as a realistic medium which is indistinguishable from the live concert experience [44.11]. However, listeners realized early on that playing recorded music does in fact not result in the same experience as a live concert. In the early days of recording, one important factor was clearly the quality of the recording and reproduction systems. To give an example, the dynamic range of the recording devices was limited which meant that instrumentalists had to minimize the dynamic range of their performance or continuously change the distance from the recording device to adjust for the correct level. The quality-related restrictions such as insufficient dynamic range, added noise, and added distortion disappeared with improved recording technology and better storage media. However, while research in virtual acoustics led to recording and reproduction methods that enabled a listening experience that was practically indistinguishable from a live setting [44.12], the standard consumer reproduction technologies (e.g., stereo, 5.1) are unable to reproduce this concert experience.

Since the consumer's normal listening environment is fundamentally different from a live concert setting, it

is doubtful that even an accurate physical reproduction of the sound field would be perceived by the listener as realistic. Therefore, the sound engineer's goal is usually not to create a realistic reproduction, but a recording that is *perceived* as realistic and thus implies realism. This has been referred to as the *concept of artificial realism* [44.13].

It has also been argued that, because of limitations in the listening environment, the recording is not even supposed to be as realistic as possible. To give an example, the dynamic range of symphonic recordings is usually reduced to allow a comfortable listening experience – to reproduce the whole dynamic range of an orchestra would result in the listener constantly adjusting the playback level. The musically informed adjustment of the level of single instruments and instrument groups by the sound engineer may compensate for the missing visual component and probably allows for a better, more transparent listening experience.

Similar to the discussion of realism in classical music, there has been a debate about authenticity in popular music as well [44.14]. The controversy is about the use of new technologies to produce or postprocess recordings and the utilization of new effects and sounds versus a *plain* recording made with as few technological gadgets as possible. *Alex Ross* comments on this discussion [44.15]:

> *Yet frills-free, low-fi recording has no special claim on musical truth; indeed, it easily becomes another phonograph effect, the effect of no effect.*

44.1.3 Changes in the Recording Studio Sector

The changes in the recording studio sector are well aligned with technological innovation. Leyshon summarizes the different stages of historical development [44.16]: during the 1930s and 1940s, studios were built by the major labels with custom-designed and unique equipment. The introduction of the tape machine in the 1940s made the recording process less expensive and triggered the establishment of new, privately owned recording studios in the 1950s. Digital audio technology disrupted the recording studio market twice: first, with the introduction of digital studio hardware for recording and processing offering a sonic quality and functionality at the same or a higher level than comparable analogue hardware at a fraction of the price. Second, with software applications offering to replace most of the studio hardware (except microphones and speakers) at affordable prices. Essentially, computer software is able to replace the tape machine, patch bay, mixing console, sound generators and synthesizers, and external audio effects. Although analogue studio equipment continues to be used for its special sound characteristics, virtually every modern music production will use software; for some genres, music may be produced exclusively by using software.

There is a general trend for high-quality audio technology, previously only available to specialists at high prices to become more easily available and affordable to nonprofessionals and hobbyists. The price drop is not only observable between hardware and software, but also in the software market itself. To give one example, the sales price of *Apple's* DAW Logic Pro dropped from $999 to $499 and then to today's price of $199 between 2004 and 2011. Similar price developments can be observed for professional-grade audio plugins. This democratizes the recording market by decoupling audio quality from the budget invested into the studio equipment.

For the music (software) industry, however, this presents a problem due to decreasing revenue. As a result, new distribution models are being evaluated. Current trends, possibly influenced by the rise of the mobile app market, include consumer versions of software targeted at professionals at low prices and profit generation through sales of additional content such as audio loops. Software-as-a-Service solutions are not yet popular in the consumer market, but are starting to gain traction in the business-to-business market with companies such as *EchoNest* (now part of Spotify), *Gracenote*, and *sonicAPI.com*.

44.2 Music Creation

The creative interaction of musicians and composers with technology is a fascinating topic. New technologies have always inspired composers and musicians to explore new ways of creating sound and music, either by using new or modified musical instruments, by integrating new technology into their work, or by *misusing* gear to create new sounds and new musical concepts.

44.2.1 Instruments

The development of music instruments is often closely related to technology; to give two historic examples, the mechanical systems of wind instruments allowed a broader pitch range and easier intonation, and improved piano mechanics increased volume and expressive control of the instrument. Both changes were

welcomed by composers and musicians alike and were accepted quickly. In the twentieth century, electric and electronic instruments added to the well-established pool of traditional instruments. Some of them, despite a certain fame, were never really accepted by large numbers of performers; well-known examples from the 1920s are Trautwein's *Trautonium* and Theremin's instrument (later simply referred to as *Theremin*). These two instruments have been used in art music, popular music, and film music, however, they still remain more or less unknown to nonmusicians.

Other instruments, however, have been seminal to certain genres. The genre of rock music is hard to conceive without the (distorted) electric guitar, and synthesizers certainly contributed to shaping the sound of pop music. Instruments such as the *Hammond* organ, the *Rhodes* piano, and synthesizers such as the ones invented by *Moog* expanded the dimensions of sound and enabled musicians to generate new, never-heard-before sounds. With growing popularity, these new instruments created new markets and a new instrument manufacturer landscape. As in other areas, the introduction of digital technology was the next major step in instrument design. The famous *Yamaha DX-7* synthesizer, for instance, allowed exploration of the unknown sound spaces of FM synthesis. In addition to sound synthesis, digital audio allowed sampling (see Sect. 44.2.4); the introduction of *Akai's S-1000* and *MPC* is seen as a milestone in popular music production and sound design.

Meanwhile, performers and composers of electro-acoustic music moved on to other, non-mainstream tools. Examples of these tools are the audio programming languages *CSound* and *SuperCollider* [44.17], and solutions such as *Max/MSP* [44.18] or *PD* [44.19], software that allows the rapid design and prototyping of real-time audio processing and synthesis systems with a visual programming language.

There is academic and commercial interest in developing new software tools and new devices for sound synthesis such as virtual instrument plugins; the interested reader is referred to events such as the *International Conference on New Interfaces for Musical Expression* (NIME) [44.20] and the *Margaret Guthman Musical Instrument Competition* [44.21]. However, new instruments with new interfaces that are used by a larger group of musicians are not easy to find. One prominent example of a more recently introduced musical interface is the *reacTable* [44.22], an instrument which was featured by the artist Björk on her 2007 tour.

Playback media have also been used as instruments or as part of a performance. Wolpe, for instance, experimented with gramophones on the stage. He remembers a concert in Berlin in the early 1920s in a lecture [44.23]:

> *I had eight gramophones, record players, at my disposal. And these were lovely record players because one could regulate their speed. Here you have only certain speeds – seventy-four and so on – but there you could play a Beethoven symphony very, very slow, and very quick at the same time that you could mix it with a popular tune.*

However, despite these efforts and related experiments by Hindemith at the time, the active use of turntables as musical instruments did not establish itself until the rise of the DJ in the 1980s. DJs can use the turntable to create new sounds and sound effects by means of mixing the sound of two vinyl discs dynamically and modifying the playback speed and the playback direction in fast patterns (scratching). Effectively, they use the turntable as a musical instrument. Another recording and playback medium has been more successful in electro-acoustic music: the tape machine. Starting in the early 1950s, composers such as Cage, Varèse, and Stockhausen actively used tapes and tape machines in their compositions and performances. The creative use of the tape machine was not restricted to electro-acoustic music: The Beatles also experimented with tape loops, for example, in their song *Tomorrow Never Knows* on the studio album *Revolver*, enabling them to create a soundscape not reproducible in a live performance.

44.2.2 MIDI

It was not only new instruments or devices reused as musical instruments that had an impact on the creation of music. The MIDI protocol, introduced in the 1980s and eventually supported by a large number of manufacturers, allowed musicians to connect two or more keyboards and sound generators and to slave an arbitrary number of synthesizers in order to play them simultaneously, to switch instantaneously between the instruments without changing the control keyboard itself, or to send or store configuration information from or to devices [44.24]. The introduction of MIDI, combined with the advances in computer hardware and software, resulted in the rapidly growing popularity of the so-called sequencer. A sequencer could record, edit, store, and reproduce a performance and corresponding data in MIDI. It also allowed prototyping and evaluation of the arrangement of complete songs in a small home-recording set-up or playback of an additional synthesizer track during a live performance. A sequencer can be either a hardware or a software product. Over the last two decades, especially soft-

ware sequencers gained new features – last but not least the ability to record and edit multitrack audio data – so rapidly that software-based sequencers became the most common tool to work with MIDI and audio in the studio. Today they are usually referred to as digital audio workstations (DAW). There are variants of DAW software (for example, *Ableton Live*) and DJ software (for example, *Serato Scratch Live* or *Native Instrument's Traktor DJ*) which try to redefine the role of the computer as a mere recording, editing, and playback device to an instrument that can be interacted with in a live performance.

44.2.3 Audio Effects

While in the production of classical music audio effects such as equalization and artificial reverberation are mainly used to increase the realism and the pleasantness of the listening experience, the creative potential of audio effects in popular music has been explored extensively. Dynamics processing, modulated effects, delay and reverberation, distortion, etc. became standard tools to work on the sound of individual tracks or on the complete mix. Digital technology not only made these effects more affordable but also allowed unprecedented quality (artificial reverberation), flexibility (digital amp simulation), and not-heard-before effects (pitch-shifting). Pitch-shifting, for example, can be used to correct the intonation of a (vocal) performance, but it can also be used as a sound effect. One example is the so-called auto-tune effect, initially conceived as a real-time vocal intonation correction tool. By setting the parameters of this auto-tune effect to very aggressive settings instead of the recommended settings, a very audible effect is created. The robotic character of singer Cher in her song *Believe* stems from using an auto-tune effect, and the artist T-Pain is frequently associated with this effect as well. Pitch-shifting can also be used for auto-harmonization (i. e., for the generation of additional voices from a single-voiced input in order to create a choir-effect), or to transform musical phrases into something impossible to perform.

44.2.4 Sampling

With digital recording and storage, the phenomenon called *sampling* appeared. In digital sampling, an artist records a segment of a song or sound, modifies, edits, and transforms it, and then reuses it (and possibly other recordings) by incorporating it into a new work. Musical quotations are well known in the music history, however, sampling allows what *Katz* refers to as *performative quotation* [44.7]; not only does the quote feature the same melodic, harmonic, and rhythmic content, but it also has the same timbre and can be, in fact, a bit-accurate copy of the original recording. Hip hop and electronic music are examples of genres with intensive use of sampling. Sampling is legally controversial, but also enabled an interesting way of producing music; since the composer works directly with sounds to produce the recording, there is no performer as intermediary between the abstract musical ideas and the sound creation. *Tara Rodgers* notes [44.25]:

> *Electronic music culture is at least in conversation, if not inextricably entwined, with the legacy of modernist notions of authorship and authenticity. But electronic musicians destabilize these notions by exposing the fluidity of boundaries between human- and machine-generated music, as well as the cultural angst over the dissolution of these boundaries.*

44.2.5 Inspiration and Restriction

From the examples presented above, it is clear how technology can shape new instruments and tools and how technology can been (mis-)used to explore new realms of musical expression. But technology can also serve as a source of inspiration; the composer Steve Reich, for instance, describes how he discovered the phase-shifting effect for his work *It's Gonna Rain* by accident while experimenting with two tape recorders playing two nearly identical loops, resulting in the loops going in and out of sync slowly [44.26]. He used the same effect later for nontape works as well.

However, apart from the role of music technology as both artistic inspiration and as a provider of new ways to create new works or new sounds, technology can also restrict creative processes. The composer *Stravinsky*, for example, wrote in his autobiography on the topic of making records of some of his music in America in the 1920s [44.27]:

> *This suggested the idea that I should compose something whose length should be determined by the capacity of the record. I should in that way avoid all the trouble of cutting and adapting. And that is how my* Sérénade en LA pour Piano *came to be written.*

When *RCA Victor* introduced the vinyl single format in addition to the vinyl LP, artists were forced to a song length of three minutes for their songs. It is unclear whether the format was introduced because most of the songs at that time had this length, or if the company thought that songs of this length would market better. Either way, the introduction of this format did have an undeniable impact on standard song lengths and possibly also on how music is marketed and distributed.

44.3 Music Distribution and Consumption

In the previous sections we considered the impact of technology on composer and performer, but technology has also transformed our listening habits. In times before recording was possible, we could only listen to live performances and had to share our experience with others in the audience. The gramophone, and later the radio, revolutionized that; without the need for a specific concert venue, recordings could be listened to at home, at convenient times, and both in a group or as an individual. And not only could recordings be listened to anytime, they could also be listened to repeatedly. Being able to reproduce the same recorded performance as often as desired allowed listeners to subject the recording to an analysis of both musical ideas and the performance in unprecedented detail.

With respect to end-user media, technological innovation during the first half of the twentieth century focused on improving the sound quality. Vinyl discs, both the LP and the single, offered a significant quality improvement over shellac, and the introduction of stereophony provided the listener with an unheard-of sound field envelopment compared to monophonic recordings [44.28].

The introduction of the Compact Cassette (*Philips*) initiated another substantial change in the way music is consumed; it not only allowed sharing of music with friends but also compilation of song collections on the medium and creation of customized playlists. *Sony's* Walkman, a portable device for playing Compact Cassettes reached high popularity in the 1980s. It enabled listeners to consume music of their choice with headphones in any environment, for example, while working out or while traveling. All these changes might be interpreted as a logical continuation of the listening habit trend we observed earlier: make music accessible anytime, everywhere, and transform the act of listening to music to a potentially more private, intimate, experience.

The impact of digital (audio) technology on the distribution has been dramatic and not unopposed as can be seen from the formation of groups such as *Musicians Against Digital (MAD)* [44.29]. The Compact Disc (CD), presented by *Sony* and *Philips*, had several advantages over the vinyl disc: it is a more compact, one-sided medium, its quality does not deteriorate with the number of playbacks, and it arguably offers higher general audio quality than vinyl. The CD also allowed the music industry to generate new revenue by re-releasing previous recordings for this new medium. It stores stereo audio signals at a sample rate of 44.1 kHz and with a word length of 16 bit per sample. On the one hand, these specific values were chosen due to technical practicalities. On the other hand, they result in an audio bandwidth of approximately 20 kHz, corresponding to the upper limit of hearing for the average young adult, and a dynamic range of roughly 90 dB, providing sufficient signal-to-noise ratio for most use cases. The resulting audio quality appears to be more than sufficient for the requirements of the average consumer, as later industry attempts to introduce higher quality and multichannel audio media such as the Super Audio CD (SACD) and the DVD-A were not met with success.

The MP3 (short for MPEG-1 Layer 3) audio format and similar formats disrupted both the distribution of music and the consumers' listening habits on various levels at the turn of the millennium [44.30]. MP3 allows storage or transmission of digital audio data at a fraction (typically around a tenth) of the original data rate while attempting to minimize perceptual differences between the original and encoded audio signal by using models of human sound perception [44.31]. The audio data is thus modified, but in most cases these changes are only noticeable at low bit rates. In combination with the growing popularity of the internet in the 1990s, the importance of the MP3 file format cannot be underestimated. Not only could listeners now have instant access to their whole music library on mobile audio players such as *Apple's* iPod, they could also access music on web sites, online music stores, peer-to-peer file sharing networks such as *Napster*, and online radio stations through streaming.

Both the rise of the internet and the introduction of perceptual audio coding techniques such as MP3 enabled the user to take habits shaped by the Compact Cassette to a different level. The coded digital files can be copied without quality loss and stored on various devices, and the network to exchange and find music extended from a circle of friends to potentially millions of listeners through forums and peer-to-peer networks. Not only is the personal music collection with you all the time, but every type of music is instantly available everywhere either by streaming audio from web radios, from a cloud storage service, or from other online services.

These technologies also changed how music is purchased by listeners. Instead of buying a physical album in a store, the consumer downloads or streams music files online. Instead of having the notion of *owning* and collecting the music, it is apparently of greater importance to the listeners to have access to any music anytime and anywhere. This behavior has several implications:

- *Access to a vast database of musical styles*. The discovery of new artists and unfamiliar musical styles is no longer restricted to suggestions by lo-

cal friends, the local record store, radio stations, and magazines. Listeners can be exposed to music they might have never come across outside the internet.
- *Quasi-instant access to all music*. If the user is interested in listening to a song, she can do so immediately.
- *Decline of the album-based distribution behavior*. Despite the vinyl single format, traditional marketing and distribution was mostly focused on the album (LP and CD); online distribution, however, is nowadays song-based. The listeners tend to listen to individual songs in uncontrolled order and do not necessarily recognize the album as a holistic work of art anymore.
- *Change in music buying behavior*. The big music labels did not anticipate the transformation of the music distribution channels; the exchange of music files over peer-to-peer networks such as Napster resulted in a decline of record sales, and the industry's reaction with lawsuits and the introduction of digital rights management (DRM) alienated the consumers. *Leyshon* argues, however, that it was not only the music downloaded for free that resulted in the decline of sales but also the growing popularity of other media such as DVDs and computer games that caught the attention and the money of young consumers [44.32].

As of the year 2000, eighty percent of the music industry (licensing and distribution) was controlled by five (now four) companies: *BMG Entertainment* and *Sony Music*, *Warner Music Group*, *EMI Recorded Music*, and the *Universal Music Group* [44.33]. As *Fox* pointed out, this agglomeration resulted in difficulties for small record companies to survive, artists having only limited control over the distribution of their music, fewer releases of new recordings due to high levels of industry concentration, and music consumers being restricted to obtaining consumers to obtain music only through industry-approved and controlled channels [44.34]. Each of these points was subject to change eventually. Smaller labels took advantage of new distribution models, artists experimented with a direct connection with their fans through social media and direct distribution models, and new companies such as *Apple*, *Google*, *Pandora*, and *Spotify* entered the music distribution market. The amount of legally obtained music, however, is probably still lower than the amount of music downloads that are illegal. There are also indications of a growing expectation amongst users that music should be freely available [44.16]. The overall volume of music sales has declined since the year 2000 (compare *RIAA Year-end Shipment Statistics*, [44.35]), but recent numbers concerning increasing digital sales and licensing income fuel hopes in the industry about a trend reversal [44.36].

As the introduction of digital recording equipment with affordable prices has democratized the recording market (see Sect. 44.1.3), *Hracs* argues that the technological change eroding the power of the major record labels will ultimately lead to a democratization of the production and distribution of music [44.37].

44.4 Conclusion

Technological innovation transformed the way music is performed, recorded, produced, distributed, and consumed. It expanded creative artistic possibilities, supported the creation of new musical styles, and changed the consumers' listening habits. Music technology can be categorized as serving one or more of the following purposes:

1. Enhance the technical and perceptual quality of recording and reproduction.
2. Provide new tools to create music, synthesize sound, process audio, and access music.
3. Improve music distribution by optimizing existing distribution channels or explore new channels.
4. Provide established functionality at lower cost or higher robustness.

The music industry is a diverse industry, consisting of record labels and rights holders, distributors, recording studios, instrument manufacturers, and manufacturers of production and reproduction equipment. Each of the industry branches has been changed radically by music technology during the past 130 years and will continue to change, regardless of the technological innovation being initiated by the industry or reacted upon. What these changes will be, however, is difficult to predict. It is clear that the manufacturing industry will continue to work on new ways to create and modify sound and on new or improved interfaces for creating music. Apart from that, the following trends with the potential to shape parts of the music industry can be observed today:

- The distribution of music shifts from selling albums and songs to licensing rights to subscription services. It appears to be increasingly important to the consumers to access music rather than own it.

- The traditional distribution channels will be threatened by community-based services for sharing music and audio files such as *Soundcloud* or direct-to-fan solutions which allow musicians and independent music labels to sell music and merchandise by bypassing major record labels.
- The borders between professional music production and hobbyists blur. On the one hand, the cost of music production equipment declines; on the other modern tools can perform tasks automatically that previously were understood as craftsmanship. DJ tools, for instance, are able to create mash-ups automatically by beat-matching two or more songs, a process that required practiced skill when performing on vinyl.
- New and improved tools for editing and morphing sounds will be able to improve the *perfection* of recordings. It will be increasingly difficult to differentiate between an unedited and a heavily modified or even synthesized song.
- Online collaboration platforms for the distributed creation of music already exist but have not been overwhelmingly successful in the past. Their approaches and business models, however, are constantly being evaluated and re-thought so that successful services might be launched anytime.
- The potential of using music technology for music education has not been explored in-depth yet. Computer-assisted instruction systems to teach score reading and intonation, to assist vocal and ear training, and to actively support learning a musical instrument effectively and possibly in a game-like environment are only just starting to become more popular.
- The way we find and explore new music will continue to change with the improvement of music recommendation systems, automatic playlist generation algorithms, and general music similarity measures.
- Object-based audio has the potential to completely transform music listening: in contrast to a channel-based system such as stereo or 5.1, object-based audio transmits individual sound elements accompanied by metadata describing how the element should be reproduced. Object-based audio systems are thus independent of the reproduction system configuration and potentially allow an unprecedented interaction between the listener and the mix.

The last century has shown a remarkable evolution in all areas of music technology, and we can expect the future to bring as many exciting changes. However, instead of being overwhelmed by these changes, it is good to keep in mind that, ultimately, music technology serves only one purpose: to explore new or improved ways to create and to access music.

45. Enabling Interactive and Interoperable Semantic Music Applications

Jesús Corral García, Panos Kudumakis, Isabel Barbancho, Lorenzo J. Tardón, Mark Sandler

New interactive music services have emerged, but many of them use proprietary file formats. In order to enable interoperability among these services, the International Organization for Standardization (ISO)/International Electrotechnical Commission (IEC) Moving Picture Experts Group (MPEG) issued a new standard, the so-called MPEG-A: Interactive Music Application Format (IM AF).

The purpose of this chapter is to review the IM AF standard and its features, and also to provide a detailed description of the design and implementation of an IM AF codec and its integration into a popular open source analysis, annotation and visualization audio tool known as Sonic Visualiser. This is followed by a discussion highlighting the benefits of their combined features, such as automatic chords or melody extraction time-aligned with the song's lyrics. Furthermore, this integration provides the semantic music research community with a testbed enabling further development and comparison of new Sonic Visualiser plug-ins, e.g., from singing voice-to-text conversion with automatic lyrics highlighting for karaoke applications, to source separation-based music instrument extraction from a mixed song.

The music industry has been experiencing remarkable changes over the past two decades, especially since the popularization of the MP3 standard and the use of the Internet by a large portion of the population. However, such changes are mostly related to more efficient distribution of music content rather than the way users are interacting with the music itself. Despite the widespread use of touchscreen smart phones and tablets that enable interactivity, users of formats like MP3, FLAC or AAC can still only interact with the music they listen to to a limited extent. To address this, interactive music services are emerging to enhance the listener's experience [45.1, 2]. In recent years there have been various interactive services marketed as iKlax [45.3], MOGG [45.4] or MT9 [45.5].

However, such interactive services use their own proprietary formats. In order to ensure interoperability between different interactive music players and interactive songs, a standardized file format is required.

This shortcoming has been overcome by the ISO/IEC Moving Picture Experts Group (MPEG), which has recently released a standard, known as MPEG-A: Interactive Music Application Format (IM AF) [45.6, 7]. This is a multitrack format, so it contains individual audio tracks for different musical instruments. It allows the user to change the mix of the song by changing the volume of each instrument separately.

The novelty of this format over other multitrack formats lies in the ability to add multimedia content to enrich the user experience. For example, it is possible to include text synchronized with audio, which represents the lyrics or the chords of the song.

It may also contain images related to the album or the song. The producer has the ability to define rules to prevent the song becoming unrecognizable. In addition different presets of the song (e.g., a karaoke or rhythmic version) can also be defined.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_45

Table 45.1 shows a comparison of the characteristics of iKlax, MT9, MOGG and IM AF formats.

This chapter introduces the benefits of adding IM AF support to Sonic Visualiser [45.8]. Sonic Visualiser [45.9] is an open-source application designed to assist semantic audio and signal processing researchers looking at what lies inside an audio file. It has been selected among other music analysis and annotation tools because of its widespread use (10 000 active users in December 2013). An essential strength of Sonic Visualiser is its ability to support third-party plug-ins. The native plug-in format is called VAMP, which enables developers to implement algorithms for extracting descriptive information from audio data. In this context, with respect to IM AF, we will make use of VAMP plug-ins specifically designed for chords [45.10] and melody pitch [45.11].

This chapter is structured as follows: the IM AF standard is described in Sect. 45.1; in Sect. 45.2 the implementation aspects of the IM AF encoder are discussed; Sect. 45.3 introduces a discussion on how Sonic Visualiser with IM AF support can be used with respect to the aforementioned plug-ins; and future developments and conclusions are given in Sect. 45.4.

45.1 IM AF Standard

An IM AF file consists of:

- Multiple audio tracks that represent the different parts of a song (instruments and/or voices)
- Groups of audio tracks that define a hierarchical structure of audio tracks (e.g., all the guitars of a song can be gathered in the same group)
- Presets that contain predefined information about the mixing of multiple audio tracks (for example, a karaoke version of the song or a version with only the rhythmic base)
- Rules that introduce specific data related to the interaction with the user (definition of allowable actions concerning the audio tracks, group selection and volume control)
- Additional multimedia information to enrich the user interaction (text synchronized with audio to represent the lyrics of a song, images related to the song, album or artist)
- Metadata to describe the song, album or artist.

The IM AF standard supports compression of the audio tracks in various formats including PCM, MP3, AAC, and SAOC [45.12]. It also supports the JPEG file format for still pictures [45.13], the 3GPP timed text for lyrics [45.14] and the MPEG-7 Multimedia Description Scheme for metadata [45.15]. The framework of the IM AF file is based on the MPEG-4 ISO Based Media File Format (ISO-BMFF) standard [45.16].

Table 45.2 shows all the supported components in IM AF format.

IM AF files consist of a set of objects, called boxes (Fig. 45.1), which contain all data in the file. We can classify them into two types: general boxes (which may contain other boxes inside them), and FullBoxes, which just contain data (no other boxes allowed inside them).

The File Type Box *ftyp* box should appear at the beginning of the file, as it defines the type of file, declaring the brand compatibility (Table 45.3). The brand is related to the maximum number of audio tracks that can be decoded simultaneously depending on the processing capabilities of the device that will play the IM AF file.

Brands starting with *im0* are intended for mobile phones and portable audio players, while brands start-

Table 45.3 IM AF brands

Brands	Audio AAC	MP3	SAOC	PCM	Max. number of simultaneously decoded audio tracks	Max. sampling frequency/bits	Profile/level	Application
im01	•	•			4	48 kHz/16 bits	AAC/level 2	Mobile
im02	•	•			6	48 kHz/16 bits	AAC/level 2	Mobile
im03	•	•			8	48 kHz/16 bits	AAC/level 2	Mobile
im04	•	•	•		2	48 kHz/16 bits	AAC/level 2 SAOC baseline/2	Mobile
im11	•	•		•	16	48 kHz/16 bits	AAC/level 2	Normal
im12	•	•	•		2	48 kHz/16 bits	AAC/level 2 SAOC baseline/3	Normal
im21	•			•	32	96 kHz/24 bits	AAC/level 5	High-end

ing with *im1* are intended for general music services. *im21* is the brand for high-end processing applications for professional users [45.2].

The multimedia content (audio, text, images) is stored within the Media Data Box *mdat*.

The information needed for decoding the multimedia content is stored in the Movie Box *moov*. This box can contain one or more Track Boxes *trak*. Each Track Box contains the description of one type of media (audio or text) and it may include a URL indicating where the media content is stored. Thus, IM AF files can be very light in terms of storage requirements. The information on the groups, presets and rules are stored in the Group Container Box *grco*, Preset Container Box *prco* and Rule Container Box *ruco* respectively.

The Metadata Box *meta* includes metadata, such as simple background information for a song (title, singer, album, etc.).

45.2 Implementation of the IM AF Encoder

The encoder is responsible for creating the IM AF files. It has been implemented in C programming language and does not use external libraries. In this way, we can ensure that it can be compiled on any platform. The following sections explain the implementation of the encoder. For further details see [45.17]. Each section addresses a different functionality of the encoder.

45.2.1 Audio Tracks

The File Type Box *ftyp* appears at the beginning of the file and defines the characteristics of the audio tracks contained in the IM AF file. We have implemented the brand *im02*, which allows up to six simultaneous tracks of audio. Thus the IM AF file created can be easily re-

produced in any kind of device without requiring high processing capabilities. The total size of this box is 24 bits.

The next step is to extract the audio samples of each of the MP3 files and store them in the Media Data Box *mdat*. The encoder searches the header of the first frame of the MP3 file, skipping any ID3 tags, and stores the samples byte by byte. Note that the audio tracks are stored one after another in the IM AF file. The player will need information in order to extract these audio tracks contained in the IM AF file. This information is stored in the Sample Table Box *stbl*.

An IM AF file stores a Track Box *trak* for each audio track, containing several tables with the information necessary for the player to play the media data. Those tables are saved in boxes inside the Sample Table Box *stbl*.

The Sample Description Box *stsd* stores the technical specifications of an audio track. It contains information on the type of encoding used, bit rate, sample rate and specific information for decoding. The encoder we developed sets a sample rate of 44 100 Hz and a bit rate of 128 kbps.

The Sample Size Box *stsz* stores the number of frames of the audio track and a table with the number of bytes in each frame. In the case of MP3 files with a constant bit rate of 128 kbps, the frames may be 417 or 418 bytes. The IM AF encoder reads byte by byte the MP3 file, searching all possible headers. When there is a known header, the algorithm counts the number of bytes to find the next header known. Thus, the number of frames and their size are calculated.

The Sample Table Box *stts* contains a table that stores for each entry two values: the number of contiguous frames that have the same length, and the duration of these frames (in milliseconds).

Frames are grouped into chunks. The Sample to Chunk Box *stsc* defines a table that includes the number of frames of each chunk and the number of chunks that have the same number of frames. For constant bit rate MP3s, this table includes only one entry, because all the frames are equally sized.

The Sample Size Box *stsz* stores the number of MP3 frames once more and a table giving the size (in bytes) of each of these audio frames.

Finally, the Chunk Offset Box *stco* indicates the position of the first frame of the audio track in the Media Data Container Box *mdat* of the IM AF file.

Figure 45.2 illustrates the process explained above.

45.2.2 3GPP Timed Text

Another feature of IM AF is that it allows timed text, which may represent the lyrics of the song for karaoke applications. The format of the text track is defined in 3GPP TS 26.245 standard [45.14]. IM AF files store character strings to be displayed, text modifiers that describe how the text should be shown, and temporal information in order to display the text in perfect sync with the music.

Strings and text modifiers are stored in the Media Data Box *mdat*, and information to display the text in sync with the audio is stored in the boxes as *stts*, *stsc*,

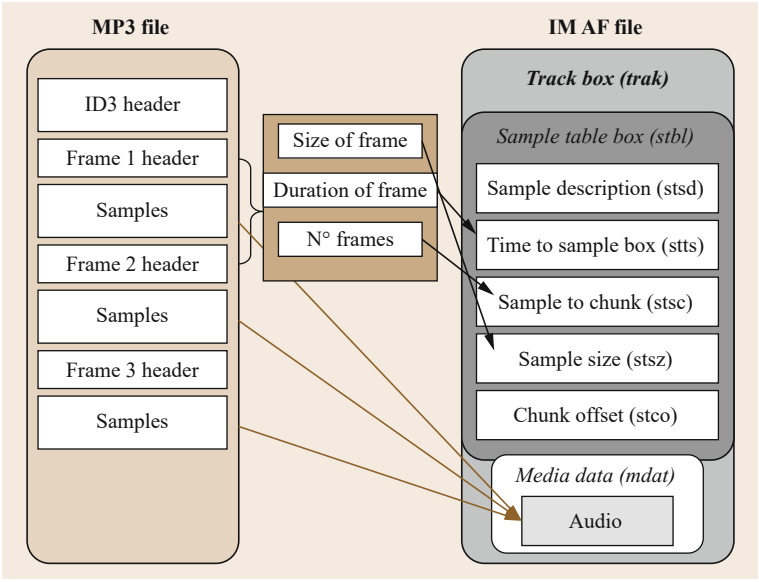

Fig. 45.2 Audio samples and associated data transfer from MP3 to IM AF

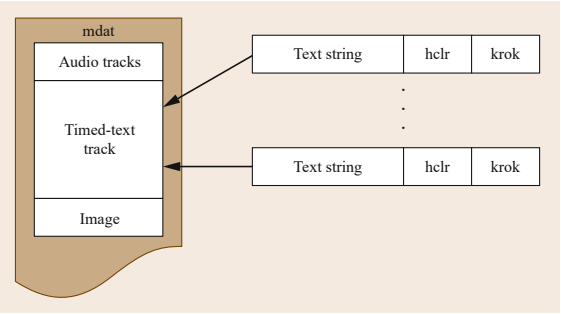

Fig. 45.3 Lyrics encoding

and *stco*. The box *stsd* stores the way in which the text is to be displayed.

Text strings are stored in an external text file with the following syntax,

[start time] Text String [end time] .

The instant of time (in seconds) in which the text string is displayed appears before the text string. The instant of time (in seconds) at which the string is no longer displayed on the screen is stored after the text string.

The encoder seeks every text string inside the text file and it copies them in the *mdat* box of an IM AF file. After a text string is stored, the encoder writes the text modifier boxes. The first modifier box is the Text Highlight Color Box *hclr*, which specifies the highlight color (expressed as hexadecimal RGB color) of the text. The second modifier box is the Text Karaoke Box *krok*. This box specifies the highlighting color start/end time of words in a phrase (Fig. 45.3).

Storage of timing information is similar to audio tracks, as the same boxes are used (*stts*, *stsc*, *stsz* and *stco*, as shown in Fig. 45.2). Duration for every string is saved in the *stts* box (sample delta = duration of interval ∗ timescale). In *stsz* the size of every string is stored including the modifiers. Another important box is *tx3g*, contained inside Sample Description Box (*stsd*), which defines font type and size, horizontal and vertical justification or background color.

45.2.3 Metadata

There are two types of metadata included in the IM AF file:

- Metadata for the song and track
- Metadata for the album.

Table 45.4 shows the boxes containing the various types of metadata.

The *meta* box has two distinct functions: it stores the descriptive metadata (see Table 45.5) and provides information about the JPEG picture included in the IM AF file by locating its length (in bytes) and its offset within the file.

Table 45.4 Levels of metadata in IM AF

Metadata	Location
Track level	Trak/meta box
Song level	Moov/meta box
Album level	Meta box for file

Table 45.5 Descriptive metadata in IM AF

Description	Level		
	Album	Song	Track
Title	●	●	●
Singer	●	●	–
Composer	–	●	–
Lyricist	–	●	–
Performing musician	–	–	●
Genre	●	●	–
File date	●	●	●
CD track number of the song	–	●	–
Production	●	●	–
Publisher	●	●	–
Copyright information	●	●	–
ISRC (International Standard Recording Code)	–	●	–
Image	●	●	–
URL Site address related to the music and the artist (e.g., album homepage, music video)	●	●	–

The container for metadata information is the Meta Box *meta*. This box includes a Handler Box *hdlr* indicating the structure of the contents. The handler type is set to *mp7t*.

The descriptive metadata is located in the XML Box *xml* in XML format. The IM AF encoder simply includes such information in the resulting file by writing the string value. For now, this value can only be changed in the source code.

45.2.4 JPEG Still Pictures

Another feature of the IM AF interactive player is that it can display images while a song is played, by supporting the JPEG file format for still pictures [45.13]. Images can be associated, e.g., to music album's cover and/or artist's photos.

In the box *mdat* the entire content of a JPEG file is stored, while the box *meta* contains the size of the picture and the picture offset within *mdat*.

The first step performed by the encoder is to calculate the size of the image. This task is performed by the getImageSize() function. The image size is used to cal-

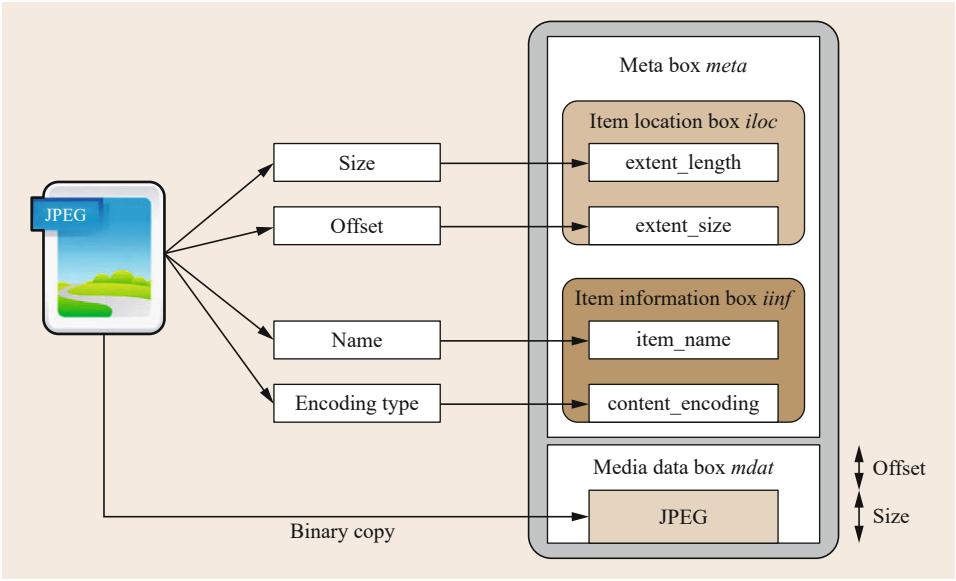

Fig. 45.4 JPEG inclusion process in IM AF

culate the size of the box *mdat*, which is the sum of the size of the audio tracks, the track size of text and the size of the image.

The Item Location Box *iloc* stores the image's size and its offset in *mdat*, in particular into the *extent-length* and *extent-offset* values. The Item Information Box *iinf* contains the picture's name (*item-name*) and its encoding type (*content-encoding*).

The insertImage() function inserts the image in the IM AF file within the box *mdat*.

Figure 45.4 shows the JPEG picture insertion process in an IM AF file during encoding.

45.2.5 Groups

For the creation of groups, two boxes are used: Group Container Box *grco* and Group Box *grup*. The Group Box is located inside the Group Container Box.

The groupcontainer() function is responsible for creating these boxes and returns the size of the Group Container Box.

The Group Container Box stores the number of groups that have been defined inside the IM AF file. The encoder currently allows you to create one group, although the code can be modified easily to allow the creation of multiple groups.

The Group Box contains all other information necessary to define a group. The name assigned to the group is stored in the variable *groupname*. An array stores the identifiers of the audio tracks that make up the group. The variable *group-activation-mode* contains a flag that defines the way the elements of a group shall be activated when a group is switched on. The encoder assigns the value 1 to the variable. This means that the decoder plays all audio tracks contained in the group. The variable *group-reference-volume* specifies the volume gain applied on this group when it is switched on. The variable *flags* stores the value 0x02, so the group information contained in the Group Box is able to display on the player, but it is not able to be edited by the user.

45.2.6 Presets

The IM AF standard defines some default presets. Despite the availability of 11 presets, only six of them are implemented in the reference software. Table 45.6 shows the available presets.

There are two categories of presets: static (fixed volume in each audio track) and dynamic (volume of the tracks can vary over time). There are two boxes involved in presets: Preset Container Box *prco* and Preset Box *prst*. The Preset Box is contained inside the Preset Container Box. The function presetcontainer() creates the presets and returns the size of *prco* box. A switch-case structure selects the implementation, with *preset-type* value as the switching variable. The static presets require the definition of the playback volume gain for each audio track or object, by setting the *preset-volume-element*. The presets that involve objects require the definition of the *output-channel-type*, that is, the number of channels of each included audio track. The encoder sets this value to 1 for stereo tracks.

There is only one working dynamic preset, *Dynamic track approximated volume preset*. This preset is used

Table 45.6 Presets defined in IM AF standard and their availability in reference software

Preset type	Availability	Description
0	✓	Static track volume preset
1	✓	Static object volume preset
2	✓	Dynamic track volume preset
3	✓	Dynamic object volume preset
4	✓	Dynamic track approximated volume preset
5	✗	Dynamic object approximated volume preset
6	–	Value reserved
7	–	Value reserved
8	✓	Static track volume preset with EQ
9	✗	Static object volume preset with EQ
10	✗	Dynamic track volume preset with EQ
11	✗	Dynamic object volume preset with EQ
12	✗	Dynamic track approximated volume preset with EQ
13	✗	Dynamic object approximated volume preset with EQ

to create a fade-in or fade-out effect. The variables *start-sample-number* and *duration-update* indicate the sample where the volume change takes place and the number of samples that it occurs for respectively.

45.2.7 Rules

The function rulescontainer() is responsible for creating rules. It defines the structure of the Rule Container Box *ruco*, which hosts a Selection Rule Box *rusc* and a Mixing Rule Box *rumx*.

Two switch-case structures are responsible for creating the desired Selection and Mixing rules.

Tables 45.7 and 45.8 show the parameters needed by the encoder to create each of the rules.

The *element-ID* is an integer that represents the ID of the element involved in a selection rule. In the case of the Min/Max rule, it must be the same ID as the group. In order to represent the ID of the element on which the rule is applied the encoder uses the *key-element-ID*. The *rule description* is a character string that allows a rule to be named.

Table 45.7 Parameters in Selection Rules

Selection rules						
	Mixing rule type	Element ID	Key element ID	Min num elements	Max num elements	Rule description
Min/Max	0	Group ID	–	✓	✓	✓
Exclusion	1	✓	✓	–	–	✓
Not mute	2	✓	–	–	–	✓
Implication	3	✓	✓	–	–	✓

Table 45.8 Parameters in Mixing Rules

Mixing rules						
	Selection rule type	Element ID	Key element ID	Min volume	Max volume	Rule description
Equivalence	0	✓	✓	–	–	✓
Upper	1	✓	✓	–	–	✓
Lower	2	✓	✓	–	–	✓
Limit	3	✓	–	✓	✓	✓

45.3 IM AF in Sonic Visualiser

Sonic Visualiser (SV) is an application for viewing and analyzing the content of audio files. This open-source software was developed at the Centre for Digital Music at Queen Mary, University of London. The IM AF codec has been fully integrated into Sonic Visualiser. Figure 45.5 shows the interface of the encoder in Sonic Visualiser. The source code as well as executables for both Windows and Mac OS/X of Sonic Visualiser with IM AF support are available through the http://soundsoftware.ac.uk repository [45.18].

The integration of the IM AF codec in SV allows the user to create IM AF files in a quick, convenient and reliable way.

Furthermore, importing an IM AF file into SV opens up and display at once both individual music tracks and mixed versions (presets) of a song. This is a huge relief for SV users that otherwise would have to search their folders and import all of the music audio tracks one by one. That is, SV with IM AF support can be used by music producers as an archival

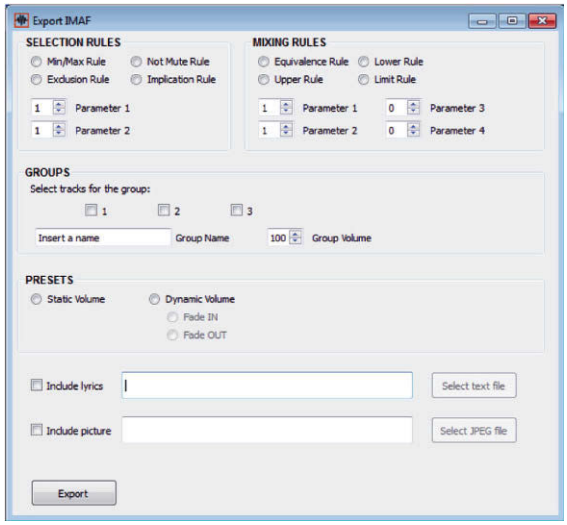

Fig. 45.5 IM AF encoder interface in Sonic Visualiser

tool for saving and importing their music projects at once, thus increasing their time efficiency and productivity.

Furthermore, SV with IM AF support has been converted from an audio analysis and visualization tool to a multimedia editing suite (e.g., multitrack audio, lyrics, pictures, etc.).

Including text synchronized with audio in IM AF offers great potential for the format to be used in conjunction with some SV plug-ins. The possibility of extracting the chords of a song by using the Chordino [45.10] plug-in and presenting them in perfect sync with the song's lyrics can be of great help to those musicians who wish to practice the songs of their favorite artists and improve their musical or vocals skills.

It is equally possible to extract the melody of a song by using the Melodia [45.11] plug-in and display it perfectly aligned with the lyrics.

In order to facilitate interaction with the audio tracks, a panel with gain knobs to control the volume of each of the audio tracks is also included. Subsequent versions of our IM AF codec will allow users to record their own mixes of songs in real time using these gain knobs and share them on social networks.

In the following section some use case scenarios are presented together with instructions on how to use the IM AF codec in Sonic Visualiser. The first subsection is devoted to the steps necessary to create an IM AF file in Sonic Visualiser with certain characteristics. The following two subsections describe the steps required to extract the chords and the melody of a certain musical instrument of an IM AF song.

45.3.1 Creation of an IM AF File

We will show the steps to create an IM AF song with multiple audio tracks, two rules, a fade-in effect, a timed-text track and a picture. A similar process can be used for any combination of features that may be needed:

1. Download and run Sonic Visualiser.
2. File → Open...
3. Select an audio track.
4. To include more audio tracks: File → Import More Audio...
5. Select an audio track. Repeat steps 4) and 5) until you have opened all the desired audio tracks.
6. File → Export IMAF File... At this point the interface of the IM AF encoder pops up.
7. Select *Implication Rule* and choose Track A = 1 and Track B = 2. Thus if Track B is active then track A will also be active. If track A is inactive the track B will also be inactive.
8. Select *Limit Rule*, choose Track A = 1, Min Volume = 10, Max Volume = 20. The minimum volume level of Track A will be 10, and the maximum volume level will be 20.
9. Select *Dynamic Volume* and *Fade IN*. A fade-in effect is a gradual increase in the volume level of an audio track from silence at the beginning.
10. Select *Include lyrics* and press *Select text file*. Choose the text file. The syntax used to create the text file must be the same as shown in Sect. 45.2.2.
11. Select *Include picture* and press *Select JPEG file*. Choose the image file.
12. Press *Export*.
13. Select the name of the IM AF file and the folder. Press *Save*.
14. If the file has been created properly you will see the next message: *IMAF file successfully created!*

45.3.2 Chord Extraction Time-Aligned with Lyrics

One of the possibilities offered by the integration of the IM AF codec in Sonic Visualiser is the potential to extract the chords of a song and present them as text synchronized with the audio (Fig. 45.6). We will use a Sonic Visualiser plug-in for chord extraction, known as Chordino [45.10]:

1. Run Sonic Visualiser.
2. File → Import IMAF File...
3. Select an IM AF file.
4. You will see the waveforms of the audio tracks, a pane with the lyrics and a panel with the gain knobs of the different tracks.

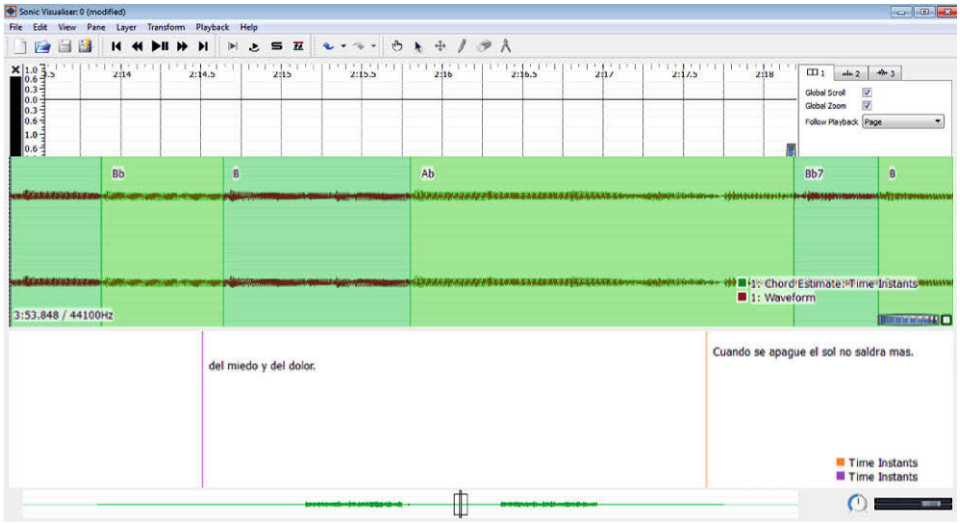

Fig. 45.6 Lyrics aligned in time with chords in Sonic Visualiser with IM AF support

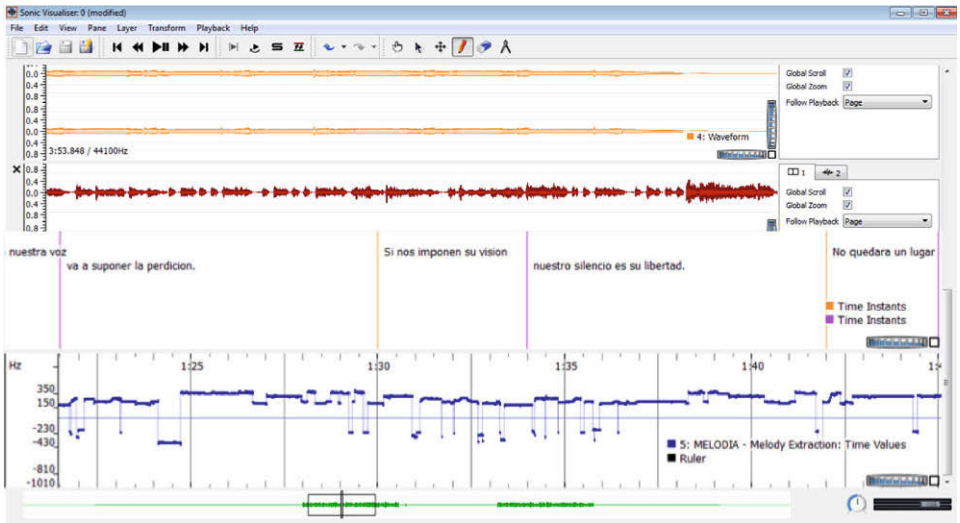

Fig. 45.7 Lyrics aligned in time with melody pitch in Sonic Visualiser with IM AF support

5. Transform → Analysis by Plugin Name → Chordino → Chord Estimate... Select the audio track to apply the Plugin in *Input Material*. Press *Accept*.

45.3.3 Melody Extraction Time-Aligned with Lyrics

Another interesting application of SV is the extraction of the melody pitch of a song. Using the VAMP plug-in called Melodia [45.11], an algorithm for melody pitch estimation, it is possible to gain a more efficient pitch extraction from only the vocal track, rather than the mixed song. Furthermore, the melody pitch is now presented aligned in time with the song's lyrics (Fig. 45.7):

1. Run Sonic Visualiser.
2. File → Import IMAF File...
3. Select an IM AF file.
4. You will see the waveforms of the audio tracks, a pane with the lyrics and a panel with the gain knobs of the different tracks.
5. Pane → Add New Pane.
6. Transform → Analysis by Plugin Name → MELODIA → Melody Extraction... Select the audio track to apply the Plugin in *Input Material*. Press *Accept*.

45.4 Future Developments and Conclusions

The integration of IM AF in Sonic Visualiser opens up new possibilities for researchers in the area of signal processing, offering a testbed for the development of new plug-ins such as:

- On extracting the lyrics from the vocal track (singing to text) [45.19] and automatic highlighting of lyrics, thus relieving IM AF creators from having to insert the lyrics and their time-stamps for highlighting. In particular, the latter task is very tedious, so a plug-in to make this process happen automatically would be extremely useful for karaoke fans.
- On source separation for extracting music instruments from a mix-down song version [45.20].

As has been already mentioned, it would be interesting to enable users to record each tracks' volume while disc-jockeying in Sonic Visualiser and share their own presets with their friends using social networks (e.g., Facebook). Due to the flexibility of the IM AF format, the file does not have to contain the audio tracks themselves but only their URL. In that way the tracks can be recalled from a server. As a result, it enables efficient exchange and sharing of IM AF files, which may include only the mixing parameters.

Furthermore, an alternative cross-platform and cross-browser HTML5 IM AF player [45.21] has also been developed for users that would only like to listen to their friends' mixes with no need to download Sonic Visualiser.

This chapter described the design and implementation of an IM AF codec and its integration in SV as well as highlighting the benefits of their combined features with some use case scenarios.

46. Digital Sensing of Musical Instruments

Peter Driessen, George Tzanetakis

Acoustic musical instruments enable very rich and subtle control when used by experienced musicians. Musicology has traditionally focused on analysis of scores and more recently audio recordings. However, most music from around the world is not notated, and many nuances of music performance are hard to recover from audio recordings. In this chapter, we describe hyperinstruments, i. e., acoustic instruments that are augmented with digital sensors for capturing performance information and in some cases offering additional playing possibilities. Direct sensors are integrated onto the physical instrument, possibly requiring modifications. Indirect sensors such as cameras and microphones can be used to analyze performer gestures without requiring modifications to the instrument. We describe some representative case studies of hyperinstruments from our own research as well as some representative case studies of the types of musicological analysis one can perform using this approach, such as performer identification, microtiming analysis, and transcription. Until recently, hyperinstruments were mostly used for electroacoustic music creation, but we believe they have a lot of potential in systematic musicological applications involving music performance analysis.

46.1 Digital Music Instruments

Traditional musical instruments are some of the most fascinating artifacts created by human beings throughout history and across cultures. The complexity and richness of control afforded by acoustic musical instruments (such as a cello or saxophone) to professional musicians is impressive and takes a lifetime of practice to develop. Musicology has traditionally focused on musical scores as the primary representation used to analyze music, despite the fact that the majority of music throughout history has not been notated. In addition to musical scores, more recently audio recordings in conjunction with signal processing techniques such as spectrography have also been used in musicology and especially computational ethnomusicology [46.1]. An audio recording captures information about the end result of making music but makes it hard to analyze the actual process or cultural aspects of making music.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_46

Over the past 20 years, there has been increasing interest in developing new interfaces for musical expression using actuators, computers, and sensors. The main venue for this type of work is the New Interfaces for Musical Expression (NIME) conference [46.2], http://www.nime.org/archive/. Some of these new instruments are completely novel contraptions, while others either draw inspiration from or digitally augment existing acoustic instruments. The term *hyperinstrument* [46.3] has been used to refer to an acoustic musical instrument that can be played conventionally but has also been augmented with various sensors to transmit information about what is being played. The commonest use of hyperinstruments has been in the context of live electroacoustic music performance, where they combine the wide variety of control possibilities of digital instruments such as Musical Instrument Digital Interface (MIDI) keyboards with the expressive richness of acoustic instruments. A less explored, but more interesting from a musicological perspective, application of hyperinstruments is performance analysis. The best-known example is the use of acoustic pianos fitted with a robotic sensing and actuation system on the keys to capture the exact details of the player's actions and replicate them. Such systems allow the exact nuances of a particular piano performer to be captured so that, when played back on the same acoustic piano with mechanical actuation, they will sound identical to the original performance. The captured information can be used to analyze specific characteristics of the music performance, such as how the timing of different sections varies among different performers [46.4, 5].

46.2 Elements of a Hyperinstrument

In this section, we describe the elements of a hyperinstrument in a general way that is common to all such instruments. A hyperinstrument may be defined as an acoustic musical instrument that can be played in the conventional way for that instrument but has also been augmented with sensors to transmit information about what is being played and, in some cases, actuators that create sound.

At this point, some readers may prefer to skip this section and read ahead to the example instrument and application case studies of specific hyperinstruments. These readers can return later to this section, which provides a systematic but somewhat abstract description of the elements of a hyperinstrument and its performance modes.

In this section, we first describe the elements of a conventional acoustic instrument, followed by the additional elements that are needed for a hyperinstrument. The hyperinstrument can include direct and indirect (surrogate) sensors and elements for sonic and visual display, and a computer means of interpreting the sensor data and generating appropriate signals to directly or indirectly control the display elements. The hyperinstrument also has performance modes using both event-based and continuous control and playing scenarios for very slow, slow, and fast playing. In the following subsections, each of these hyperinstrument elements and the performance modes are described.

46.3 Acoustic Instrument

A hyperinstrument includes first the elements of a conventional acoustic instrument (string [46.6], wind [46.7, 8], brass [46.9], percussion [46.10], keyboard [46.11]):

- The physical acoustic instrument per se, including physical elements made from raw materials such as wood, brass, gut (for strings), and membranes (for percussion). This physical object (instrument) includes two further essential design elements
- A sensor (or interface) that accepts a gestural input from a human performer to actuate and control some of the physical elements
- An acoustic structure using these physical elements that can produce sound when actuated (moved).

These two design elements may rely on the same physical element; For example, a guitar string or drum membrane is an interface that accepts a pluck or tap gesture from a finger and also comprises an acoustic structure that produces sound.

These two design elements may also use different physical elements. A woodwind or brass instrument accepts the airflow and embouchure tension gestures from the player on the mouthpiece that actuate the reed or the vibration of the lips that produces the sound.

For some instruments, the sensor accepts gestural input directly from the performer's body (hands or mouth). For other instruments, the sensor (or interface) is a separate component (bow for some string instruments, stick or mallet for some percussion instruments, piano action mechanism) that accepts gestural inputs from the performer. For these instruments, the gestural input from the performer only indirectly actuates the physical element that produces the sound.

For most acoustic instruments, the acoustic structure also includes an acoustic amplification mechanism (partially enclosed volume or resonant cavity) by which the sound arising from the human gesture is amplified, for example, guitar or violin body, drum shell, main body of woodwind or brass instrument, or piano soundboard.

For some acoustic instruments, the amplification mechanism may include a separate interface that accepts gestural inputs from the hands to depress keys or valves that modify the resonance properties of the enclosed volume, thus changing the pitch. This interface may be designed to accept discrete inputs (key or valve up or down) but may create idiosyncratic sounds when not fully up or down.

46.4 Hyperinstrument

In addition to the above elements of a conventional acoustic instrument, a hyperinstrument includes one or more additional elements:

- Electronic and/or mechanical sensors that detect the gestural input of the human performer and change their electrical properties or emit an electronic signal in accordance with that input, including integrated sensors such as a Wii remote or tablet (referred to as *direct* sensors)
- A means of converting the sensor output to a form readable by computer
- A computer program or other means to interpret the sensor data and then map this data to control signals needed to control the following elements:
- Elements that create a sonic and visual display to supplement the performer's own display:
  - Mechanical machinery such as motors and actuators that can actuate the physical elements on the instrument or on a second separate (robotic) instrument
  - Electrical transducers such as loudspeakers, video screens, and projectors that can reproduce sound, music, images, and video
  - A computer program that uses the interpreted sensor data to cause the mechanical and/or electrical elements to change in some way to create both sound and a visual display.

A hyperinstrument may be inspired by but built without any of the elements of a conventional acoustic instrument. In this case, we may label it as a new interface for musical expression. In this chapter, we focus on the idea of a conventional instrument that is augmented as described above.

In the following subsections, we describe each of these elements in turn.

46.5 Direct Sensors

A direct sensor is added to a conventional acoustic instrument to make a hyperinstrument. Direct sensors accept gestural input from the performer and change an electronic property in a way that is related to that input. Direct sensors may be classified along several dimensions:

- Gestural input source: fingers, hands, feet, head, arms, legs, torso, or other
- Nature of gestural input that creates the sensor response: impact, pressure, position, velocity, or acceleration
- Sensor electronic properties in response to input:
  - Passive analog (change in resistance, capacitance, and/or inductance)
  - Active analog (change in output voltage or current)
  - Active digital (change in output data stream), where the data stream may be in MIDI or open sound control (OSC) format [46.12] but also in video format if the sensor is a digital camera
  - Integrated (smartphone with touchscreen and multiple embedded sensors, motion capture

system with cameras, markers, and software).
- Discrete amplitude or continuous amplitude sensor output in one, two, or three dimensions
- Discrete time event-based (sequence of asynchronous time-stamped events) output or continuous time sensor output (or sequence of numbers at constant sample rate) in one or more dimensions
- With or without tactile feedback.

These sensors require a means of converting the sensor output signal to a form readable by computer. This may be an analog electronic circuit that detects changes in resistance, capacitance, inductance, voltage or current, followed by an analog to digital converter (ADC), or a digital circuit that reads the output data stream. A commonly employed means for both cases is an Arduino or similar electronic prototyping platform. The integrated sensors include an internal computer that reads the data.

The resulting computer-readable sensor data may be represented or interpreted as a waveform (signal) showing amplitude versus time for each dimension. This sensor data has five important characteristics:

- Amplitude dynamic range (maximum signal to noise ratio)
- Amplitude precision
- Time resolution
- Time precision
- Latency (delay).

The amplitude dynamic range of a sensor with continuous output is the (logarithm of the) ratio between the strongest and weakest output signal. The dynamic range is equivalent to the maximum signal to noise ratio, where the weakest signal is barely perceptible above the noise. Ideally, the dynamic range is sufficient to allow the performer to fully utilize the dynamic range available in the aforementioned mechanical machinery and electrical transducers that create the sound and visual display. In the best case, the dynamic range will match that of the relevant human perceptual system: 140 dB or 14 orders of magnitude for the auditory system, or 5 orders of magnitude static and 9 orders with adaption for the human visual system. The amplitude precision will determine the number of distinguishable amplitude levels within the dynamic range limits. If the gestural input is position, then the amplitude resolution and precision correspond to the spatial resolution and precision.

The time resolution of an analog sensor is determined by the ADC sampling rate. For digital sensors, the time resolution may be inherent in the design (e.g., the frame rate of a camera). The time resolution should ideally be sufficiently high to resolve rapid gestures (up to 160 km/h or 44 m/s for the hand in baseball and cricket, higher for drumstick tip), as well as subtle variations in gesture. In other words, the sampling rate must be at least double the highest spatial frequency in the gesture. The time precision determines the number of distinguishable time intervals. Time precision may also be affected by jitter in the sampling clock. Latency or delay may be caused by hysteresis in the sensor or delayed response to tactile feedback. Additional latency may be caused by the means of converting sensor data to computer-readable form, e.g., memory buffers.

In this section, we consider some examples of direct sensors:

- Switch
- Force-sensitive resistor
- Accelerometer
- Integrated position sensor
- Camera
- Radio drum
- Sound plane.

46.5.1 Switch

A switch is perhaps the simplest sensor, accepting input from any part of the performer's body that can push or touch it. It responds to pressure (light or heavy) or touch, and changes its resistance from infinity (open circuit) to zero (closed circuit). It is a discrete sensor in one dimension with only two possible states (on or off), and may have tactile feedback (mechanical switch) or not (touch or heat sensitive). The switch may be a simple pushbutton, or one key on an organ or harpsichord or qwerty keyboard. Multiple switches may be considered as having outputs in multiple dimensions.

46.5.2 Force-Sensitive Resistor

A force-sensitive resistor is well described by its name. The input source is typically a finger. It responds to pressure (force) by changing its resistance continuously over a range of values. It may or may not have tactile feedback, depending on the surface on which it is mounted.

46.5.3 Accelerometer

An accelerometer responds to the rate of change of velocity in one, two or three dimensions from any gestural input source. Typically, the output voltage changes in

step with the acceleration, has a continuous output in one dimension, and no tactile feedback.

46.5.4 Contact Microphone

A contact microphone or piezo senses audio vibrations through solid objects. When mounted on the tip of a drumstick, it detects the instant of a strike when the stick vibrates. The piezo responds to an impact and has no output otherwise, producing an active analog output. The output at the moment of impact is continuous in amplitude but discrete in time and has tactile feedback.

46.5.5 Integrated Inertial Sensor

An integrated inertial sensor comprising an accelerometer, gyroscope, and magnetometer accepts any gestural input source, responds to changes in position, has multiple electronic signal outputs, and has continuous output in three dimensions with no tactile feedback. These sensors are also used in inertial motion capture systems.

46.5.6 Camera

A camera accepts any gestural input source (the entire body), responds to position, is an active digital sensor (makes changes to the output video data stream), is a continuous sensor in two dimensions (although a third dimension can be inferred), and has no tactile feedback. The Microsoft Kinect is a specialized camera that uses structured light to infer a third (depth) dimension. An optical motion capture system is another specialized camera system that detects markers on the body.

46.5.7 Key or Valve Position Sensor

A trumpet valve or piano key position sensor accepts gestural input from the fingers and responds to the position of the key or valve, ranging from fully up to fully down. In the case of a trumpet valve position sensor, the optical sensor is active analog (measuring the time delay of an infrared laser pulse reflected inside the valve chamber). The sensor is continuous in one dimension for each valve. In the case of a piano key position sensor, an optical sensor may be used also, in contrast to the traditional velocity-sensitive piano key that measures the time delay between two positions, almost fully up and almost fully down. The valve or key provides tactile feedback that can be adjusted via the amount of spring tension (for trumpet valves) or the mechanical design of the action (for piano keys).

46.6 Indirect or Surrogate Sensors

Some hyperinstruments may also include sensors that do not accept gestural input from the performer (referred to as *indirect* sensors):

- Auditory sensors (microphones, vibration sensors) that detect the sound emanated by the instrument
- Sensors that observe the environment and its parameters and generate data, including temperature, air pressure, light sources and their intensities, air motion speed and direction
- Sensors that detect audience interaction, i. e., movement, gestures, expressions, and sounds; these may be simple infrared or ultrasound motion sensors, or cameras
- A computer program to interpret the sensor data, causing the mechanical and/or electrical elements to change in some way.

An indirect sensor does not accept gestural inputs. Instead, it senses some attribute of the environment, including sound and vibration emanated by the performer's acoustic instrument, as well as environmental (weather) parameters. As for direct sensors, the sensor data has five important characteristics:

- Amplitude dynamic range (maximum signal to noise ratio)
- Amplitude precision
- Time resolution
- Time precision
- Latency (delay).

A surrogate sensor uses a direct sensor to train a machine learning model that can then be used with an indirect sensor [46.13].

46.6.1 Microphone

A microphone is a very useful indirect sensor in that its output can be interpreted by a computer program to identify specific characteristics of the acoustic instrument sound, such as pitch, spectrum (related to timbre), loudness (related to sound pressure level and timbre), dynamics (attack and release times), and rhythmic patterns. The microphone as a system includes

a preamplifier, and an ADC so that the data can be read by computer. The computer software uses digital signal processing techniques taken from the literature of music information retrieval. The microphone sensor is a surrogate sensor in that it can detect pitch without using the gestural data from the performer's fingers depressing keys, valves or strings on a fingerboard. As a surrogate sensor, the microphone can also detect loudness without directly sensing the gestural data from the performer's airflow or piano key velocity.

46.6.2 Eddy-Current Sensor

An eddy-current sensor detects the vibrations in a metal bar of a vibraphone via a pickup coil placed close to but not touching it. The bar moves closer and further away from the coil, thus changing its inductance. The coil is tuned with a capacitor to make an *RLC* resonant circuit (bandpass filter) at a frequency near 1 MHz. A signal is injected offset from this resonant frequency on the slope (skirt) of the bandpass filter. Changes in the resonant frequency then cause changes in the amplitude of the injected signal. A separate eddy-current sensor is placed underneath each bar of the vibraphone and can pick up the vibrations of each bar independently without crosstalk from other nearby vibrating bars.

The eddy-current sensor is listed in this section as an indirect sensor, since it does not respond directly to gestural input. It may be viewed as a surrogate sensor for the bar itself, which is a direct sensor of an acoustic instrument as defined above, similar to the guitar string or drum membrane. However, it does respond when a bar is struck, just as a guitar string responds to a pluck from a finger, and thus may also be viewed as a direct sensor that responds to the hand gesture via the mallet, responds to the velocity of the mallet, is active analog with continuous amplitude output in one dimension, and offers tactile feedback to the hand via the mallet only at the moment of time when struck but not other times.

46.7 Instrument Case Studies

In this section, we describe some representative case studies of digital sensing of acoustic musical instruments drawn from our own research, as we have more detailed information about these compared with systems developed by other groups and they illustrate different design considerations.

46.7.1 E-Sitar

The sitar is a 19-stringed, pumpkin-shelled, traditional north Indian instrument. Its bulbous gourd (Fig. 46.1), cut flat on the top, is joined to a long-necked hollowed concave stem that extends three feet long and three inches wide. The sitar contains seven strings on the upper bridge, and 12 sympathetic strings below. All strings can be tuned using tuning pegs. The upper strings include rhythm and drone strings, known as chikari. Melodies, which are primarily performed on the uppermost string and occasionally the second copper string, induce sympathetic resonances in the 12 strings below. The sitar can have up to 22 movable frets, tuned to the notes of a raga (the melodic mode, scale, order, and rules of a particular piece of Indian classical music) [46.14].

It is important to understand the traditional playing style of the sitar to comprehend how the controller captures its hand gestures. The controller design has been informed by the needs and constraints of the long tradition and practice of sitar playing. The sitar player uses his left index finger and middle finger to press the string to the fret to play the desired swara (note). The frets are elliptically curved so the string can be pulled downward, to bend to a higher note. This is how a performer incorporates the use of shruti (microtones), which is an essential characteristic of traditional classical Indian music. On the right index finger, a sitar player wears a ring-like plectrum, known as a *mizrab*. The thumb of the right hand remains securely on the edge of the dand (neck) as the entire right hand gets pulled up and down over the seven main strings, letting the *mizrab* strum the desired melody. An upward stroke is known as Dha, and a downward stroke is known as Ra [46.14]. These two

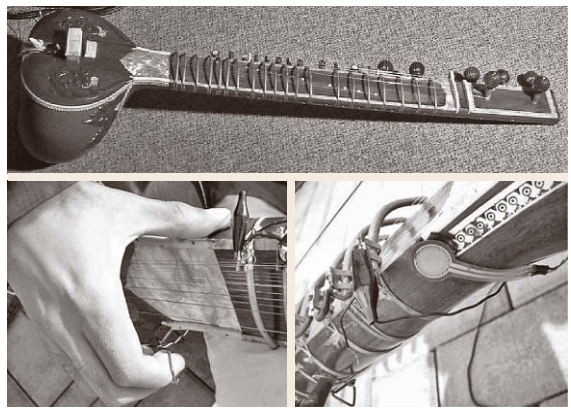

Fig. 46.1 E-Sitar and thumb sensor

main gestures are captured using sensors, and audio-based analysis is then used to model the following:

1. Pitch/fret position
2. *Mizrab* stroke direction.

The E-Sitar [46.15] was built with the goal of capturing a variety of gestural input data. A variety of different sensors, such as fret detection using a network of resistors, are used, combined with an Atmel AVR ATMega16 microcontroller for data acquisition. Fret detection is achieved using a network of resistors attached in series to each fret on the E-Sitar. A voltage is applied to the string, and a connection is established when the string is pressed down onto a fret. This results in a unique voltage based on the amount of resistance in series up to that fret. The voltage is then calculated and transmitted using the MIDI protocol.

The direct sensor used to deduce the direction of a *mizrab* stroke is a force-sensing resistor (FSR), which is placed directly under the thumb of the right hand (Fig. 46.1). The thumb never moves from this position while playing, but the force applied varies based on the *mizrab* stroke direction. A *Dha* stroke (upward stroke) produces more pressure on the thumb than a *Ra* stroke (downward stroke). A continuous stream of data is sent from the FSR via MIDI, because this data is rhythmical in time and can be used compositionally for more than just deducing the pluck direction.

46.7.2 EROSS

One of the problems with many hyperinstruments is that they require extensive modifications to the actual acoustic instrument in order to install the sensing apparatus. The Easily Removable, wireless Optical Sensor System (EROSS) [46.16] can be used with with any conventional piston valve acoustic trumpet (Fig. 46.2). Optical sensors are used to track the displacement of the three trumpet valves continuously. These values are transmitted wirelessly to a host computer system. The hardware has been designed to be reconfigurable by using three-dimensional (3-D) printing to form the housing, with dimensions that can be adjusted for any particular model of trumpet.

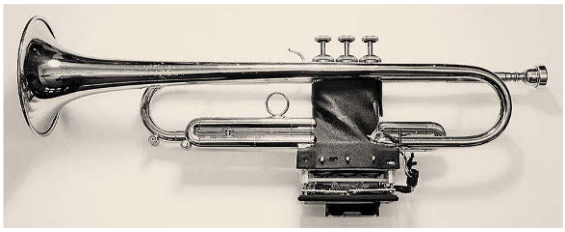

Fig. 46.2 EROSS mounted on a trumpet

46.7.3 Radio Drum

The radio drum (Fig. 46.3) [46.10, 17] is essentially a three-dimensional sensor that detects the *xyz* position of a drumstick tip above a planar surface with high temporal accuracy. The radio drum responds to gestural input from the hands indirectly via the drumsticks. The nature of the gestural input is the position of the drumstick tip. The radio drum response to this input is an active analog sensor with six continuous analog signal waveform outputs, one for each dimension for each of two sticks. The radio drum provides tactile feedback only when striking or dragging along the surface but not when moving the sticks above the surface. The amplitude dynamic range is about 30 dB, while the time resolution is determined by the ADC sampling rate.

Fig. 46.3 Radio drum

46.8 Application Case Studies

In this section, we describe some examples of how data acquired through digital sensing can be used for different types of music performance analysis. These case studies illustrate the potential of digital sensing of musical instruments for musicological research that would be difficult or even impossible to carry out based on scores or audio recordings.

46.8.1 Sitar Transcription

Automatic music transcription is a well-researched area [46.18] and is typically based on analyzing an audio recording. The novelty of this work is that it looks beyond the audio data by using sensors to avoid octave errors and problems caused by polyphonic transcription. In addition, it does not share the bias of most research that focuses only on Western music. The sitar is a fretted stringed instrument from north India. Unlike many Western fretted stringed instruments (classical guitar, viola de gamba, etc.) sitar performers pull (or bend) their strings to produce higher pitches. In normal performance, the bending of a string will produce notes as much as a fifth higher than the same fret position played without bending. In addition to simply showing which notes are audible, the system also provides information about how to produce such notes. A musician working from an audio recording (or transcription of an audio recording) alone will need to determine which fret they should begin pulling from. This can be challenging for a skilled performer, let alone a beginner. By representing the fret information on sheet music, sitar musicians may overcome these problems. The E-Sitar was the hyperinstrument used for these experiments. Automatic pitch detection using an autocorrelation-based approach was utilized with adaptive constraints (minimum and maximum pitch) based on the sensor fret data from the E-Sitar. To compensate for noisy fret data, median filtering in time was applied. To obtain an accurate final result, pitch information from the audio signal chain is fused with onset and pitch boundaries calculated from the fret signal chain. The fret provides convenient lower and upper bounds on the pitch: a note cannot be lower than the fret, nor higher than a fifth (i. e., seven MIDI notes) above the fret. Using the note boundaries derived from the fret data, the median value of the pitches (inside the boundaries supplied by the fret data) are found. These are represented by the vertical lines in Fig. 46.4, and are the note pitches in the final output.

46.8.2 Microtiming in Afro-Cuban Music

Using a percussion sensing apparatus such as the radio drum, it is possible to extract onsets of rhythmic events in rhythmically complicated music such as Afro-Cuban music based on the *clave* pattern. A special domain-specific beat-tracking technique called rotation-aware dynamic programming has been developed for this challenging scenario [46.19]. The output of either direct sensing or beat tracking based on the indirect audio signal provides the time locations of clave *notes*. A performance typically consists of about 625–1000 such clave notes. Simply plotting each point along a linear time axis would either require excessive width, or would make the figure too small to see anything; this motivates bar wrapping. Conceptually, one starts by

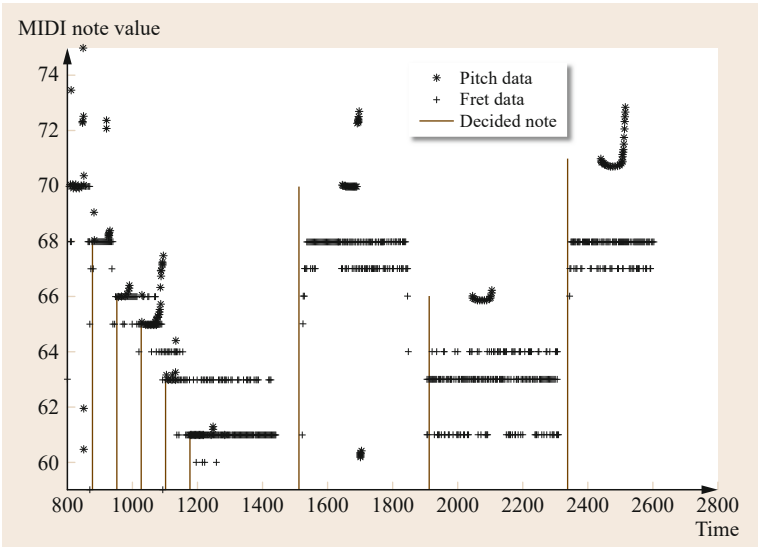

Fig. 46.4 Fret data, audio pitches, and the resulting detected notes. The final three notes were pulled

marking each event time on a linear time axis. If one imagines this time axis as a strip of magnetic tape holding our recording, then metaphorically we cut the tape just before each downbeat, so that we have 200 short pieces of tape, which we then stack vertically, so that time reads from left to right along each row, then down to the next row, like text in languages such as English. Each of these strips is then stretched horizontally to fill the figure width, adding a tempo curve along the right side to show the original duration of each bar. Figure 46.5 depicts the times of our detected onsets for for a music recording of afro-cuban music with this technique. The straight lines show the theoretical clave locations. Close inspection of this figure reveals that the fifth clave note is consistently slightly later than its theoretical location. This would be hard to notice without precise estimation of the tempo curve.

46.8.3 Performance Analysis of Kazakh Dombra

Wright [46.20] used a computer to compare the spectral content and note timings for two recorded performances of a composition for the Kazakh dombra, a long-necked, fretted, two-stringed plucked lute. He implemented a simple custom beat-tracking algorithm optimized for the extremely short-term tempo changes of this style: given hand-marked note onset times for both performances, it produces continuous curves showing local tempo as a function of time, as shown in Fig. 46.6. Comparison of these curves indicates that both performers varied the tempo in much the same way at specific points in the composition (supporting the idea that specific tempo modulations are an intrinsic part of this musical style and this particular piece), while also showing stylistic differences between the two musicians; For example, though both performances tended to have bumps in the tempo curve (i. e., brief changes in local tempo followed by a return to the original speed) at the same places in the piece, the younger musician tended to spend more time at the second tempo before returning to the first, while the older musician tended to return more quickly to the original tempo. This difference is very apparent for the sudden slowing down near the 45-second point in Fig. 46.6.

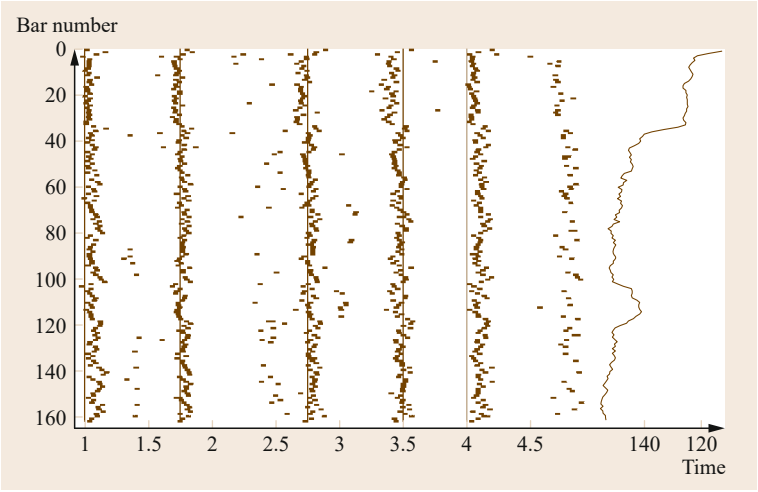

Fig. 46.5 Display of micro-timing in afro-cuban clave showing automatically detected onsets and theoretical clave locations by *straight lines*, normalizing tempo variations

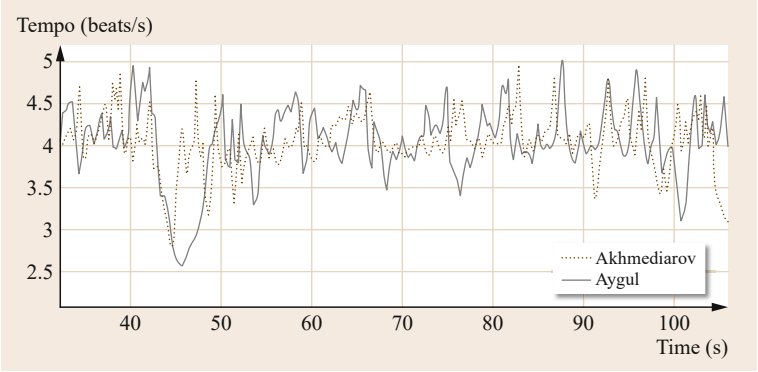

Fig. 46.6 Instantaneous tempo curves of two performances of a composition for the Kazakh dombra (time-stretched for alignment, as they have different durations)

46.8.4 Multimodal Musician Recognition

An interesting analysis task that trained humans are able to do is to recognize a particular musician from the sound of their playing, even if they are performing the same piece. Using a combination of sensor data from the E-Sitar as well as audio features, it has been shown that accurate automatic identification of the musician playing is possible [46.9, 21]. The sensor data and audio features are used to train machine learning classifiers for the performer identification. Three datasets corresponding to exercises, a composition, and an improvisation were used for the identification. Table 46.1 presents the classification accuracy results for different classifiers and datasets (MLP is a multilayer perceptron, sequential minimal optimization (SMO) is a linear support vector machine, and NB is a naive Bayes classifier).

Table 46.1 Classification accuracy for musician identification

	Exercise	Practice	Improv.	Combined
MLP	100	100	100	100
SMO	97	100	93	86
NB	85	100	94	67

46.9 Conclusions

Digital sensing technology can be used in several ways to extract performance information from musical instruments. They can be classified into direct sensing methods, in which sensors are attached to the instrument, and indirect sensing, in which sensors external to the instrument such as cameras and microphones are utilized. Some representative examples of particular hyperinstruments and a high-level overview of their corresponding sensing apparatus were also presented. The last section of the chapter describes some application case studies that illustrate the potential of digital sensing for various types of analysis such as microtiming, performer identification, and transcription. Digital sensing of musical instruments is a relatively new research area and has mostly focused on music creation rather than analysis, so its use in musicology is still in its infancy. We believe that such technologies have great potential for extraction and analysis of interesting music performance information for the enormous diversity of musical instruments from around the world.

Part G

Music Ethnology

Part G Music Ethnology

Ed. by Rolf Bader

During its foundation in modern times, around the year 1900, systematic musicology was termed comparative musicology: comparing music from all over the world to find universals in music. Comparative studies arose in many disciplines during the 19th century, e.g., in archeology, where Julius Braun founded a comparative archaeology study around 1850 comparing the ancient Egyptian, Assyrian and Greek cultures. To compare music from around the world, a recording device was needed, which Edison invented in 1877. The Edison phonograph recorded music through a large horn on wax cylinders. Carl Stumpf and his assistant Erich von Hornbostel recorded a Thai *phi pha* orchestra playing in the Berlin Tiergarten in 1900 and therefore started the first phonogram archive in Berlin. From there on musicologists, archeologists or other world travelers were encouraged by the archive to record music on these cylinders and send them to Berlin.

Right from the start comparative musicology combined musical acoustics and music psychology with music ethnology. The instrument classification of Horbostel/Sachs published in 1914, and still valid today, sorts instruments according to their driving mechanism: a physical parameter rather than a place of origin. The classification lists an enormous number of instruments from all over the world, as does the Sachs Real-Lexikon of musical instruments from 1913.

Still, not all researchers in the field were interested in comparing the music traditions of the world and finding universals; some were interested in documenting single music cultures. Jaap Kunst (1891–1960) started collecting music during his free weekends as a colonial official in Bandung, Java by taking a boat to nearby islands in the Indonesian archipelago, walking into the villages and playing his violin, therefore encouraging the natives to show and play their instruments. After sending many wax cylinders to Berlin and publishing his work he was made the first fully paid ethnomusicologist in modern times. Therefore, after World War II next to comparative musicology the field of ethnomusicology, which recorded and documented single musical cultures without comparing them or looking for universals, was strong, especially in the US.

Comparative musicology was also misused by musicologists who argued that collecting music from around the world should be done to prove the superiority of the Western music tradition. These attempts were strong in Nazi Germany and were counteracted by close interaction between the German *Gesellschaft für Vergleichende Musikwissenschaft* and the *American Society of Comparative Musicology*, with a double membership to bring comparative musicologists out of Germany in times of danger. Charles Seeger, the father of Pete Seeger, the folk musician and political activist, was president of both societies in the 1930s and 1940s.

Still, music ethnology has a much longer history. During the 3rd and 2nd century BC in China there was an institute collecting and preserving the musical traditions of China, which had more than 800 researchers. This tradition in China continues to this day and large encyclopedias of the ethnic music traditions of China and neighboring countries exist. India is another example with a long and huge tradition of ethnomusicological research. However, these traditions are merely case studies and do not compare traditions.

During the 1980s and 1990s many case studies were conducted. The field also started discussing music in different contexts, including gender studies, cultural studies or the like. Still it was found that many publications might discuss the social or political context of the music but no longer the music itself. Indeed many publications were not authored by musicologists but conducted in related fields like political studies, cultural studies or anthropology.

During the last ten to fifteen years there has been a renewed interest in comparing melodies, tonal systems, textures or rhythms and discussing music itself with a broad background of technical and musicological knowledge. These are now subsumed under terms like computational ethnomusicology, analytical ethnomusicology or again comparative musicology. Music of the world is studied using musical acoustics, neuromusicology, gene expressions, and complex computational techniques, along with the invention of new phonogram archive standards. Related fields like popular music studies or music theory also try to study musical traditions in a systematic way.

The present section tries to give some insight into ongoing research directions in modern ethnomusicology. The papers provide insight into new trends and research paradigms, and with through many examples they show links between ethnomusicology and systematic musicology, or showcase exemplary research structures. It cannot be comprehensive in terms of giving an overview of musical traditions in the world or a history of world music, which has already been excellently done, e.g., in the *Garland Encyclopedia of World Music*. Also the computational part is left to Part F of this volume on Music and Media.

Jukka Louhivuori gives an overview of the relation between systematic musicology and Ethnomusicology in Chap. 47. He addresses the historical background of ethnology based on colonial interests as a collection of

case studies and the development of comparative musicology as an interest in general rules and relations in music concerning melodies, tonal systems, musical instruments, rhythms and other musical features. He gives many examples of modern methods in the field, like the use of multidimensional scaling techniques, implementation-realization models or methods of music information retrieval.

Comparing the American with the European tradition, *Leslie Tilley* in Chap. 48 discusses concepts, methods and views of ethnomusicology. Starting from Frances Densmore and Cunningham Fletcher investigating native American Indian music, and the Hornbostel/Stumpf/Sachs/Abraham European comparative musicology tradition, she goes on to discuss the post-World War II cultural relativistic approaches of Merriam, Hood and Blacking. From there, she gives many examples of the continuous analytical approaches of Kolinski starting from the 1960s, Alan Lomax and Victor Grauers' cantomerics project, and modern fields like analytical ethnomusicology co-initiated by Michael Tenzer, computational ethnomusicology, or studies in music and genetics.

As an example of music analysis at work, in Chap. 49 *Simha Arom* gives an overview of the structure of sub-Saharan music. After listing several general features of music-making in context, musical features like tonal systems, timbre, rhythms and polyphonic structures are listed and described. The analysis includes many musical styles, as referenced in the paper, supporting the findings and exemplifying the comparison of musical traditions within a geographic region.

Another analysis example of the music in a geographic region is given by *Håkan Lundström* in Chap. 50 about music of the *zomi*, the hill people of Southeast Asia. Despite the huge diversity of tribes like the *Lisu, Hmong, Kammu, Karen* etc. in Laos, Thailand, Vietnam or Yunnan, their music is subsumed under musical features like timbre related to the musical instrument material, singing styles associated with tonal languages or ensemble playing related to social and ritual habits.

An overview of music archeology is given by *Ricardo Eichmann* in Chap. 51. After discussing the historical roots of the discipline from the 19th century to the present he gives an overview about important excavations of musical instruments starting from flutes that are 40 000 years old, or of harps and flutes in ancient Sumeria, Mesopotamia or Egypt. As the music itself is not preserved the main focus of analysis is tonal systems derived, e.g., from flute tone hole spacing or from instrument geometry developments.

In Chap. 52 *David Borgo* gives insight into modern theories on music improvisation appearing in nearly all music cultures around the world. He discusses improvisation as a cognitive task, from creativity to pattern concatenation; time perception and time hierarchy; and the relation between composition and improvisation or the reasons for improvising at all. The modern term *free improvisation* as found in a Western music based on free jazz and contemporary classical music is considered.

As an example of the relation of music, musicology and politics, *Anthony Seeger* in Chap. 53 gives an overview of the history of American protest songs. Important musicians like Woody Guthrie, Pete Seeger and Bob Dylan are discussed in the context of political and industrial development and movement in the US. The influence of musicologists like Charles Seeger and Alan Lomax in the foundation and distribution of that movement is described.

47. Interaction Between Systematic Musicology and Research on Traditional Music

Jukka Louhivuori

The origin of systematic musicology is strongly linked to the studies of music cultures of non-Western origin. From the methodological point of view, folk music research applied systematic methods to collect and analyze data. Anthropology of music and later ethnomusicology had a different focus: musical phenomena should be interpreted in their cultural context. The cognitive approach was the third paradigm change in the field of systematic musicology, which again changed both methodology as well the point of view of research topics. In cross-cultural music cognition, as well as in cognitive ethnomusicology, previous approaches in systematic musicology, ethnomusicology, and cognitive science of music are combined: systematic analysis of data related to human cognition interpreted in a cultural context.

47.1 Background

From the very early stages of systematic musicology, researchers have been influenced by *folk music*, later more often called traditional music. (In the early stages of systematic musicology the term *folk music* was often used, but later the term was replaced with the term *traditional*, which does not take a stance on the social position of the people whose musical culture is under study.) Western musicology has been dominated by historical musicology, which typically concentrates on studies of European art music tradition. The music of countrymen (hunters, fishermen, farmers) was not in the core of interest until around the second half of 19th century.

The growing interest of Western musicologists in music cultures of non-Western origins (Africa, South America, Asia, Near and Far East) was closely related to colonialism. (*Jean de Léry* [47.1] was probably the first Western person who wrote about non-Western music cultures, in this case Brazil.) Connections with previously unknown (music) cultures increased interest in habits and cultures of the people living in colonial states. The first step was to collect instruments, costumes, music, dance and artifacts of other cultural activities.

New findings, such as musical instruments, playing/singing styles, scales, rhythms, harmonies and other musical behavior not known before, and new data collecting methods and equipment (phonograms, photographs and films) increased interest in and knowledge about folk/traditional music and music of non-Western origins. New equipment made it possible to analyze data in detail, which unveiled new musical phenomena.

New findings had a strong influence on the development of systematic musicology from the point of view of research topics, methodologies and theories about music. Early studies of folk/traditional/ethnic music did not take very seriously connections of musical behavior with the social and cultural context of musical behavior. Thus, the core of an ethnomusicological approach was missing from the first steps of folk/traditional music research done by systematic musicologists.

In the following text the interaction between folk/traditional, ethnomusicology and systematic musicology will be discussed. An overview of the historical background will be given, and the development of major research topics and methodologies will be described, as well as the most recent developments.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_47

47.2 Folk/Traditional Music Research

As an example of early influences of folk/traditional music in systematic musicology are the findings of previously unknown scales and intonation systems. These forced music researchers to develop new theories about music and new conceptual tools to analyze music. In order to precisely describe interval sizes and intonation in scales *A.J. Ellis* (1814–1890) invented a system of cents, which is today still largely used in systematic musicology (Fig. 47.1) [47.2]. *Carl Stumpf* was interested in non-Western music cultures and his findings had a strong influence on theories about music [47.3, 4]. Later, *Erich von Hornbostel* (1877–1935) studied African instruments [47.5], and based on the findings he developed together with *Curt Sachs* a hierarchical classification system of instruments [47.6].

In addition to colonialism, nationalism had a strong impact on the field. Romanticism and – in some cases – political changes had an influence on researchers representing new nations or nations dreaming of independency. In Finland Ilmari Krohn (1867–1960) began to collect folk music systematically at the end of 19th century. His aim was to develop a system by which melody variants could be categorized into logical (lexical) order [47.8, 9].

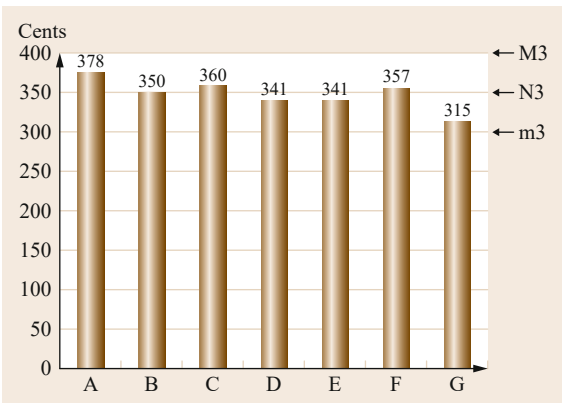

Fig. 47.1 Comparison of intonation differences in cents in Lutheran hymns in an African context. Neutral thirds and other intonation systems not used in classical Western art music tradition were difficult for early systematic musicologist to recognize. A common interpretation was (and still is for those not familiar with different intonations) to interpret the use of neutral thirds as *out of tune singing*. Invention of cents by *Ellis* [47.2] gave a precise method to measure previously unknown scales and intonations. The figure above describes intonation of thirds by seven Pedi singers in Limpopo province, South Africa. Six of the seven singers used neutral third instead of major or minor third (M3 = equal-tempered major third, 400 cents; N3 = equal-tempered neutral third, 350 cents; m3 = equal-tempered minor third, 300 cents) (after [47.7])

The systematic work by Krohn inspired other music researchers in Europe and a lively discussion started about which would be the best way to categorize folk melodies. Krohn soon understood the difficulties of the task, which resulted from the fact that folk melodies existed in thousands of variations. People sung and played music differently from one village to another, and from one performance to another. This finding caused theoretical discussions about similarity, variations, and melody families. *Oswald Koller*, Bela Bartók and many other researchers and composers participated in this theoretical discussion and searched for the *best method* to categorize folk music [47.10–12].

Krohn based his system on the cadence structure of melodies. He looked for stable positions of melodies and found out that the most invariant structural parts of melodies were cadences at the end of phrases [47.9]. Theoretical discussion on classification of folk/traditional music continued for decades and is still active [47.13–20].

The quick development of music technology has made it possible to record and store music easily, which has caused new problems related to music archives and databases. Transcription of music turned out to be a very slow process. A need to develop automatic transcription methods and to apply computer technology to statistical analysis of music was obvious [47.21–23].

The development of computer technology inspired researchers to invent new coding systems for the needs of music archives and researchers. Digitalization impacted on origination of new formats (MIDI, WAV, etc.) to store folk/traditional music. (See for example ESSEN collection, which contains about 10 000 Chinese and German folksongs [47.24, 25]. The collection of Finnish Folk Tunes, containing about 12 000 folk melodies, was published on the Internet in MIDI format in 2004 [47.26].) Recently the number of databases containing almost any kind of music is growing rapidly [47.27–30]. Today musical databases store millions of melodies and – in some cases – also contextual data. As an example, the Garland Encyclopedia of World Music Online is an online resource for music researchers interested in studying ethnic music cultures including both audio, video and text material [47.31].

Automatic transcription has appeared to be a very complex task and even today automatic music transcription contains many theoretical and practical problems, which need to be solved [47.32–34].

The size of databases has in turn caused the need to develop methods that might be helpful in musical

data mining (music information retrieval, MIR) [47.35–38].

From the point of view of systematic musicology, folk/traditional music and music of non-Western origins offers challenges for the researchers of our times. In addition to automatic transcription, the *traditional* theoretical topic about similarity is still under lively discussion [47.39–42].

The question of melodic similarity is closely related to the topics typical to music psychology (perception, cognition etc.). Because of the interest of systematic musicology in folk/traditional music, research topics moved naturally towards approaches and methodologies typical to cognitive sciences. Perhaps it is not incorrect to argue that interest in folk/traditional music and music of non-Western origins was the key factor in the paradigm change in systematic musicology in 1990s towards new approaches, such as comparative, cross-cultural and cognitive musicology.

47.3 Comparative Musicology

Systematic musicology as a term appeared in *Adler*'s writings in which he divided musicology into two fields: historical and systematic musicology [47.43]. Systematic musicology included:

1. Investigation and founding of laws in harmony, rhythm, and melody
2. Aesthetics of tonal art
3. Musical pedagogics and didactics
4. *Musicology* (examination and comparison for ethnographic purposes).

Thus, in this first definition of systematic musicology *examination and comparison for ethnographic purposes* was mentioned. Later the term comparative musicology appeared in the writings of researchers belonging to so call Berlin School [47.44–46].

If the study of folk/traditional music had a strong impact on the development of archiving music, analysis (categorization), analytical tools and methods, increasing data from non-Western cultures increased interest on comparative approaches.

A well-known systematic attempt to look at musical cultures from a global perspective was the research done by Alan Lomax. He analyzed thousands of songs and singing styles collected from different parts of the world. The aim was to categorize musical styles in a global perspective. Different from typical approaches in systematic musicology in which scales, rhythmic patters, melodic structure etc. are in the core of analysis, Lomax took into account social and cultural factors like group cohesion, orchestral cohesion, and features of voice production (vocal quality, breathiness etc.). He came to the conclusion that music cultures of the world can be categorized into eight major groups: Eurasian, Siberian-Amerindian, Pigmy, sub-Saharan African, Australian, Melanesian, and Polynesian [47.47–49].

Research by Allan Lomax differed from previous studies in systematic musicology especially because he took into account social and cultural factors. By doing this he came closer to approaches typical to ethnomusicology. Work by Lomax can be seen as a link between systematic folk/traditional music research and ethnomusicology.

47.4 Cognitive Approaches – Cross-Cultural Music Cognition and Cognitive Ethnomusicology

Typical to the early stages of systematic musicology was the interest in music psychology, especially Gestalt Theory [47.3, 50]. Later research oriented more towards *mechanical* classification of music, and automatic transcription methods (Fig. 47.2a–d) especially for the needs of music archives. The problem of categorization appeared to be much more complex than researchers had thought. It became clear that in order to solve the problem of similarity, categorization, classification etc., the cognitive mechanism of music perception, learning and production should be understood.

Linguist theories [47.51–53] inspired music researchers to apply cognitive and generative theories to the study of music. One of the first attempts was the study by *Sundberg* and *Lindblom* in which they developed a generative model that generated Swedish folk song variations [47.54, 55]. Later *Lehrdahl* and *Jackendoff* introduced the generative theory of tonal music [47.56]. Generative approaches developed by linguists and adapted by musicologists had a strong influence on the development of systematic musicology and in the growing inter-

est in the cognitive background of musical behavior.

Cognitive psychology – as with many other disciplines – has been a strongly Western-oriented field of science. What guarantees that theories developed and tested only in Western contexts are valid among other cultural contexts? Cross-cultural comparisons are needed to test the universal character of theories. Cross-cultural approaches aim to look at cognitive processes from a global perspective. How do people perceive music and what is the role of culture in perception? Methodologies of cognitive science were applied to studies of music cultures around the world. Cross-cultural music perception and cognition aimed to test existing theories in new cultural contexts [47.57–74].

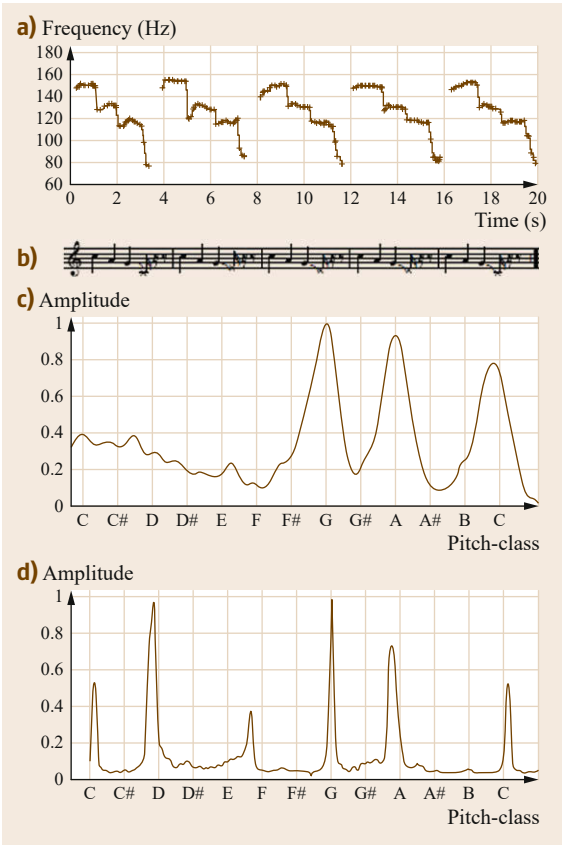

Fig. 47.2a–d Different representations used in the analysis of the singing of a Pedi traditional healer in South Africa [47.57, p. 240]. A quite common practice in traditional music contexts is the gradual rising of the pitch. This is one of the problems for automatic transcription. In the above example, the basic motive is repeated and the pitch rises gradually towards the end of the song. Recording solo performances during rituals is a difficult task. In this example the traditional healer followed the ritual from the video in a studio setting. He joined in with the singing heard from the video. By recording the singing of the traditional healer in the studio, it was possible to capture one improvised version of the song typical to Pedi traditional healers' rituals. **(a)** Pitch shift in Hz, **(b)** traditional notation, **(c)** frequency of pitches transposed to same octave, **(d)** absolute frequency of pitches

Cognitive approaches applied to folk/traditional and non-Western music research changed the direction of systematic musicology towards a more psychological (cognitive psychology) orientation. By this change the interest turned the field of systematic musicology closer to the approaches in the earlier stages of the field.

This cognitive turn had a strong impact on analytical methods. Modern statistical methods (computational methods, multidimensional scaling, see Fig. 47.3), computational modeling (self organizing maps, SOM), brain scanning (electroencephalogram, functional magnetic resonance imaging), and many others were applied to the methodological repertoire applied by researchers in systematic musicology [47.17, 20, 75–77].

Physical modeling of musical instruments has been a popular research topic in systematic musicology. In addition to computational modeling of Western instruments, computational modeling was applied also to the study of instruments used in folk/traditional music and instruments of non-Western origin [47.78–81]. An interesting and important development has been to create transcription methods, which take into account the way the sound is produced by the musicians [47.82].

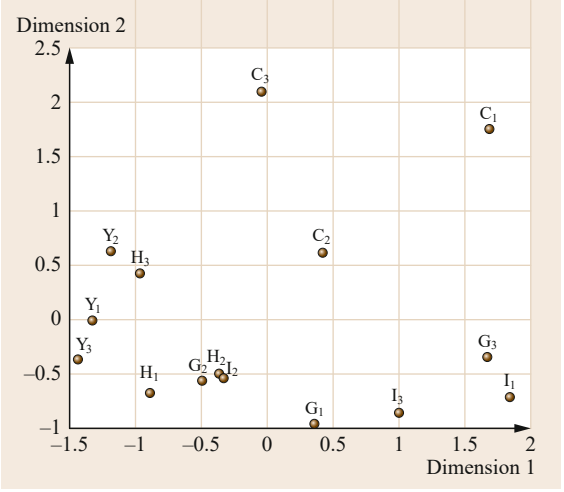

Fig. 47.3 Multidimensional scaling applied to categorization of folk music styles of Greek (C), Hungarian (H), German (G), Irish (I) and Sami people (Y) (after [47.75, p. 3])

47.5 Anthropology of Music – Ethnomusicology – Cultural Musicology

The terms *ethnic*, *folk*, and *traditional* used in this article have appeared to be problematic from many points of view. The term *ethnic* refers to something that is *far* (mostly geographically), *folk* refers to social position of the group of people under study (countrymen, fishermen, farmers, etc.), and *traditional* can refer as well to traditional classical music as other musical genres. The Society for Ethnomusicology describes ethnomusicology as the study of music in its cultural context:

> *Ethnomusicologists approach music as a social process in order to understand not only what music is but why it is: what music means to its practitioners and audiences, and how those meanings are conveyed.* [47.83]

The use of the term ethnomusicology is relative young; it was first introduced by *Jaap Kunst* in 1950 [47.84]. In the early years of systematic musicology terms such as folk music research, research on traditional music and comparative musicology were more often used. The key difference between approaches typical to systematic musicology studying folk/traditional music and ethnomusicology is that systematic musicologists have been more interested in collecting, categorizing and analyzing music of *folk* or *ethnic* origins, while ethnomusicologists emphasize the necessity to interpret findings in social and cultural context.

Definitions of systematic musicology have taken a different stance to the position of ethnomusicology in systematic musicology. In the definition by *Adler*, systematic musicology is described as a subdiscipline of musicology the aim of which was *examination and comparison for ethnographic purposes* [47.43]. Later, ethnomusicology was described as an independent, third major discipline in musicology (historical musicology, systematic musicology, and ethnomusicology) [47.68, 85, 86].

If the beginning of 20th century focused research on classification, categorization and on the question of similarity, in the second half of the century awareness of the function of culture grew. Especially writings by *Allan Merriam* and *Bruno Nettl* caused a paradigm change and increasing interest in interpreting musical behavior in social and cultural context [47.87–89]. Anthropological orientation gave new directions to the studies of folk/traditional music. The new questions were, for example, *what happens if two musical cultures meet?*, *what are the features that are assimilated by another culture?* etc.

Typical for contemporary systematic musicology influenced by anthropology of music and ethnology is an enduring interest in analyzing musical structures, acoustics and physics of ethnic musical instruments [47.90, 91], in developing new information retrieval methods or to analyze *big data* etc., but at the same time awareness of the function of society and culture is growing (Fig. 47.4). On the other hand ethnomusicology has broadened its field by applying traditional ethnomusicological methodology to new musical genres like Western classical music, pop/rock, jazz, contemporary art music and music and media. The geographical distance or ethnicity of music cultures is not anymore what makes research *ethnomusicological*. Melodic, rhythmic, harmonic structures, instruments, dances, costumes and other aspects present in musical performance are not of interest on their own, separated from their social and cultural context. Thus, an ethnomusicologist can study Beethoven symphonies, rap artists' performances, contemporary art music, or Indian classical music in addition to more traditional ethnomusicological topics like African *folk music*. Contemporary ethnomusicologists can study any music of the world, but not by applying any methodology or not taking social and cultural context into account. The new approach is called *cultural musicology* or *new musicology* [47.92].

The demand of understanding the social and cultural background of musical behavior has several methodological consequences. Understanding musical behavior in social and cultural context requires deep knowing of people's social and cultural habits. It is relatively easy to record a song, transcribe it and analyze the intervallic and rhythmic structure of it. It is much more challenging to describe the function of a specific song, for example the function of a song in ritual use, or to explain why certain instruments are allowed to be played only by men or women [47.93, 94].

It is common in ethnomusicology to increase cultural knowledge by living a relatively long time among the people under study (fieldwork). By sharing common experiences with people, observing their everyday life, and participating in musical and other cultural events and activities, understanding and trust between the researcher and the people increases. Trust is in many cases a necessary condition to get reliable and valid information from participants. (One of the first researchers conducting fieldwork by living long periods within music cultures studied was *Richard Waterman*, who studied Australian aboriginal music culture [47.95].)

Fig. 47.4a–d In searching for musical universals, the perception of Sami yoiks by Sami and South African traditional healers was studied. The photos and table above describe different stages of cross-cultural cognitive musicology (cultural musicology), which have connections to traditions both in ethnomusicology and systematic musicology. In addition to (quasi)experimental settings typical to systematic musicology (laboratory experiments), the author of this article aimed at being familiar with the culture of traditional healers (ethnomusicology – social and cultural context) by observation, interviews, and participation (participatory methodology) in ritual dance. Running music-psychological experiments in challenging environments creates several methodological problems (language interpretation, reading and writing skills of participants, reliability of technical infrastructure etc.). **(a)** Observation (ethnomusicology), **(b)** participation (ethnomusicology), **(c)** experiment (systematic musicology), **(d)** data analysis in cultural context (cross-cultural cognitive musicology; cultural musicology) (after [47.57]) ►

Fieldwork is traditionally understood as the basic condition for ethnomusicological research, but today – when the musical genres and objects of ethnomusicological studies are broadened – a more important precondition is that results are interpreted in social and cultural context. If a person has studied classical Western music for several decades, for example studied Chopin's Mazurkas, the need for *fieldwork* is totally different from the situation where he/she would like to study Pedi reed pipe music without any previous understanding of the Pedi society and culture.

Kenneth Pike [47.96] introduced the concepts of ethic and emic approaches, which have appeared to be useful for understanding the role of the researcher in relation to the culture under study. The ethicist approach refers to a situation in which the researcher studies the culture as an *outsider*, and emic to a situation in which he/she is an *insider* looking at the culture from an inside perspective. The ethicist approach gives the researcher an *objective* position in relation to participants. The researcher has no need to interpret certain aspects of the culture more positively in order to please the people. At the same time, representatives of the culture are not perhaps willing to openly speak about their thoughts and about their culture or to get the researcher to participate in certain culturally important events.

The emic approach is often understood to be more typical for ethnomusicology, because it makes possible a deeper understanding of the social and cultural background of people's behavior. In systematic musicology the emic approach has been very rare, perhaps partly because of the special needs of the researchers (living long periods abroad, sometimes in quite primitive environments etc.).

An ethnomusicological approach requires from the researcher skills in methodologies not typical to systematic musicology. Meaningful interpretation of data needs additional information acquired by doing fieldwork, interviewing and observing people, and even

participating in musical and other activities (participatory methodology). It is quite common that ethnomusicologists learn to play local instruments, sing the songs and dance the dances of the cultures under study.

Writings by John Blacking (1928–1990) have had an important influence both on ethnomusicology and systematic musicology. His studies among the Venda people in South Africa were strongly rooted in ethnomusicological tradition. He lived several years among Venda people, systematically collected their music, observed musical behavior and tried to learn to understand Venda music in its social and cultural context. At the same time he understood the significance of music psychology in getting deeper explanations of musical behavior [47.97–102].

47.6 New Trends

In the beginning of the new millennium interest towards the role of the body in musical activities grew [47.103–109]. Musical behavior, such as playing and dancing, is closely connected to body movements. It is actually strange that it took so long for researchers to look at the close connection of music and body (embodiment). Interest in embodiment is rooted in several research fields in musicology, but findings of the role of the body in traditional music was one of the reasons that inspired researchers to look more carefully at the role of the body in musical behavior.

Studies on embodiment focused first on the role of a single body, but recently the interest in interaction (synchronization, entrainment [47.111, 112]) of bodies is growing (social embodiment) (Fig. 47.5). This tendency directs research on embodiment closer to the core of ethnomusicology by emphasizing function of social and cultural factors in musical behavior [47.110, 113, 114].

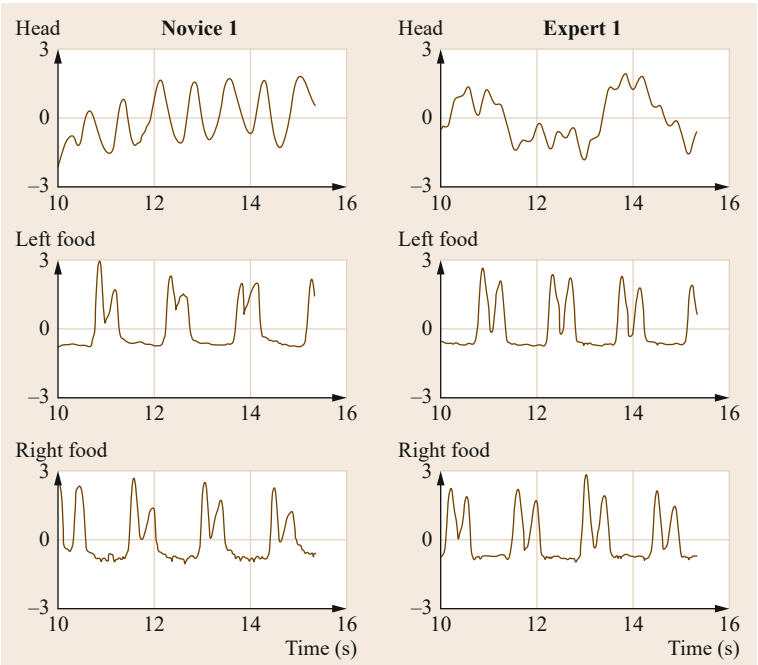

Fig. 47.5 Comparison of South African (experts) and Finnish (novice) choir singers' movements (vertical head and foot acceleration) in singing South African songs has been studied by applying contemporary motion capture technology (after [47.110])

47.7 Function of Ethnomusicology in Systematic Musicology

The function of folk/traditional/ethnic music research in systematic musicology has been strong from the very beginning of the field. Pioneers of systematic musicology, such as Adler, Stumph, Sachs and von Hornbostel, were influenced by *ethnic* music cultures and musics of *other* nations. Findings from research among music cultures not known before by Europeans challenged existing theories about music and increased understanding of the limitations of a purely *European* view of what music may be.

The systematization of data collected by folk music researchers and stored in large archives is one of the areas in which folk/traditional music research, ethnomusicology and systematic musicology has interacted. Folk/traditional music research and ethnomusicology have offered previously unknown findings about music and musical behavior. Folk/traditional music research and ethnomusicology has had an impact on the development of theoretical thinking in systematic musicology. Scales and intonation systems, new instruments, the role of dance and movement and many other findings forced researchers to rethink what music is and especially what is the role of society and culture in musical behavior.

Music as understood by the *Western world* and old theories were challenged by the new findings from *ethnic* cultures. Folk/traditional music research and ethnomusicology sped up theoretical reform and invention of new methodologies in systematic musicology. In addition, especially ethnomusicology increased understanding and need to look at ethical questions and background of people participating in experiments. Questions like *what is the impact of systematic musicology in our society?* or *how relevant is systematic musicology for the society?* came under discussion. Ethical questions are crucial for ethnomusicologists, but were not in the core of discussions in the field of systematic musicology in its early stages.

The most recent new research topics, like embodiment in music, are reflections of increased understanding of the holistic nature of musical behavior. Music is not only *art for the brain*, but *art for the human beings* living in a historical, cultural, and social context and interacting with the environment with the biophysical body.

Figure 47.6 describes the different fields of research and approaches that have interacted with systematic musicology. Over time, the role of these approaches has changed, being sometimes bigger and sometimes smaller. The process of interaction between folk/traditional music research, ethnomusicology and systematic musicology has been, and is still, dynamical in nature.

A few features typical to ethnomusicological research, which probably will be in the future more important also for the studies in systematic musicology, should be discussed. Ethnomusicologists must know well the social and cultural background of the people whose musical behavior they are studying. Due to globalization, cultural homogeneity of Western countries is quickly changing. In conducting empirical research, typical to systematic musicology, participants are needed, but do we know well enough their social and cultural background? Quite typical is to use music excerpts taken from the classical music genre, thinking that every *European* is familiar with this musical style.

How do we select participants for experiments? In what degree do the distribution of participants' cultural background represent the distribution of the population in the country? In some cases also language skills should be taken into account. If the lingual background is different from Europeans, we are faced with new methodological and practical problems in running experiments. These challenges are quite similar to those faced by ethnomusicologists: how do we communicate with participants (language skills)? Do we need language interpretation? Are participants familiar with participating in experiments? If not, how does the unfamiliar testing situation reflect on the experiment and results? How much should we understand the cultural background of participants in order to be able to make relevant conclusions? Quite rarely are these kinds of questions, typical to ethnomusicology, taken into account by systematic musicologists.

The question of sharing results with the participants, and, more generally, the responsibility of researchers for the impact of research on the society, is another topic not taken often into account by systematic musicologists. Conducting research among *ethnic* cultures, among people who have perhaps not much contact with Western cultures, necessarily causes changes to the lives of people participating in the study. If certain members of the society are interviewed and their music, dance or other kind of musical behavior is stored (audio/video recordings, photographs, films etc.), the position and status of the person in the society can change permanently. After researchers visit, he/she is the person towards whom *highly educated people from abroad* were interested. It is not sure if this special new role has a positive or negative consequence to his/her future life. This kind of change of status of participants may be a reality also when we conduct *normal* research in typical Western context.

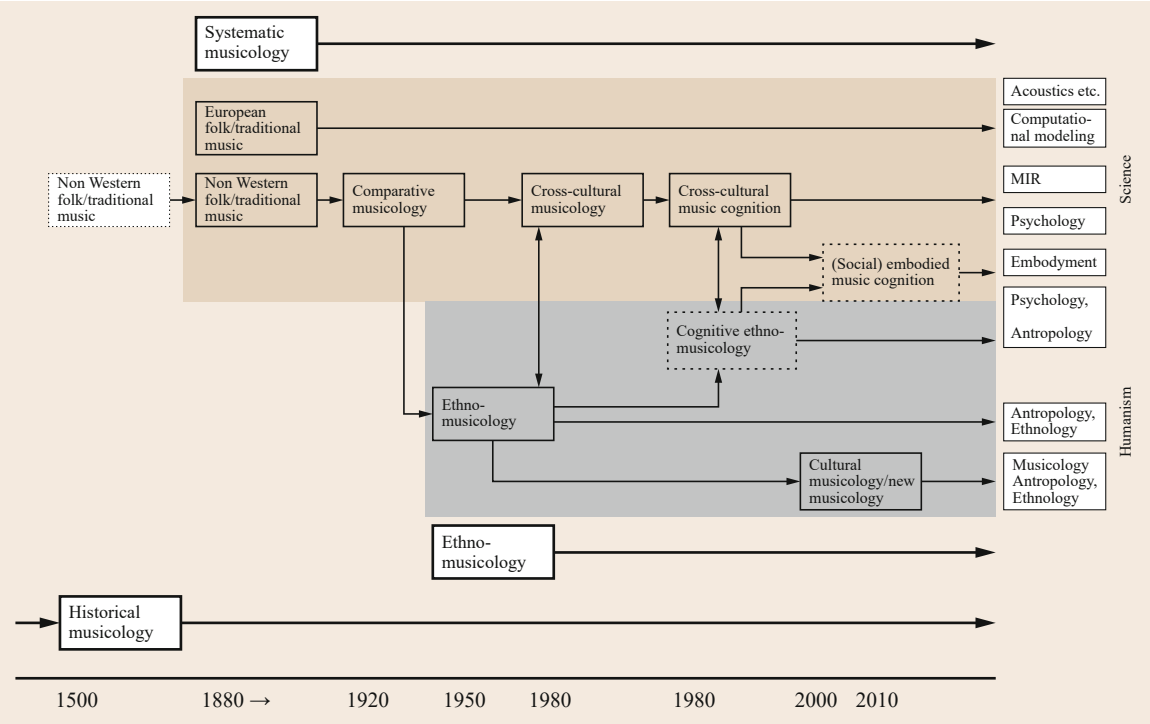

Fig. 47.6 Interaction between different approaches in folk music research, ethnomusicology and systematic musicology from historical perspective

Sharing the results and taking into account the question of immaterial rights is a serious ethical question. Who owns the rights to the data we have collected? How do we ensure that the data benefits the people under study? Or perhaps we don't care about that. We just run experiments, publish the results, and get the academic credits. In the field of ethnomusicology this kind of ethical questions must be taken seriously: What is the impact of the research for the society in general? How do we ensure that the data collected from people would be given back? In systematic musicology it is normally much easier to give feedback about the results by sharing the articles or meeting the people face to face.

It is typical in experimental research to ask permission to conduct the experiment. In Western contexts it is reasonably easy to get permissions and to find the officials from whom these should be asked. In ethnomusicological contexts this process can be much more complex. What is the official authority from where the permissions should be obtained? Among ethnic cultures in some cases local chiefs must be contacted and their acceptance to run experiments must be acquired. This process is not always a straightforward one. The researcher should somehow convince the local authority of the benefits of the research for the people. Often an intermediate person is needed who the local author (chief) knows and trusts.

During these times of increasing diversity of cultural backgrounds of people living in Western cultures, the need to ensure the relevance of research topics becomes more important. In Western context the meaningfulness of measuring for example perception of melodies is not normally doubted. What if the music culture of people participating in the study contains a very different understanding of the key concepts like *melody*, *music*, etc?

The education of most researchers in the field of systematic musicology consists of typical Western classical music education, including courses like tonality, scales, history of Western music (today also often so-called World music), harmony and counterpoint etc. Educational background has a strong impact on how we perceive and understand music as well as on what research topics we choose and believe to be of interest and importance. If one has never heard music sung or played in intonation systems not normally present in the context of Western music, such as neutral thirds, hearing music in *strange* intonation may cause serious misinterpretations, such as interpreting intonation as *out of tune* singing.

An example of *misunderstanding* certain basic elements in musical behavior is related to role of movement (dance). Although in pop/rock/jazz and folk music genres moving along with music is a normal element in performance, also in Western contexts researchers have not thought seriously about the key role of bodily movements in musical behavior. The separation of music from bodily movements has caused difficulties in understanding correctly musical behavior in cultures in which this division is not relevant at all. A better understanding of the function of the body as an integral part of the song helps us look at music from a more holistic perspective. When including bodily movements into analysis of a *simple* and *repetitive* song, the song/dance appears to be a most complex cognitive and physical activity.

African songs are normally transcribed without simultaneous transcription of the dance. This is a serious shortage, because then we leave out one of the essential elements of the musical behavior. Bodily movements create a complex counterpoint with acoustical (musical) elements of the performance. The melodic and harmonic structure can sound simple to the inexperienced listener, but can appear to be most complex when the bodily aspects are taken into account.

Embodiment in instrumental playing is another topic in which ethnomusicology and systematic musicology have a common interest. Interest in performance practices started from the studies of medieval, renaissance and baroque music practices. Later interest in music performance studies has enlarged to the study of performance in general (not limited to certain historical periods).

In systematic musicology (especially music acoustics and physics of music) study of ethnic instruments has had a key role from the early stages [47.2]. Recently, understanding of the role of embodiment in instrument playing and singing is growing. In addition to knowing physical and acoustical characters of instruments, more awareness exists today about the need to understand how the instrument is played, how the sound is produced, what the position of the musician is, how the sound is produced from the bodily aspect, etc.

In order to get a better understanding of the role of the body in instrumental playing, new methodologies have been developed. By combining knowledge of physics of the sound (sound analysis and synthesis) with the analysis of the bodily movements, it has been possible to reach a new level of description of musical behavior [47.82, 115–117]. This approach gives an interesting possibility to diminish the limitations of staff notation.

47.8 Summary

Figure 47.6 gives an alternative to look at the interaction between folk/traditional music, ethnomusicology and systematic musicology discussed in the previous chapters. In the figure the division of systematic musicology into scientific and humanistic tradition introduced by *Richard Parncutt* is taken into account [47.86].

In the early stages of systematic musicology (late 19th century), the field was inspired strongly by folk/traditional music. In addition to studies of folk music of researchers' own cultures, interest towards non-Western cultures grew rapidly. New findings and awareness of musical behavior beyond Western context had a strong influence on the theoretical development of the field. Research on non-Western music cultures created the need to compare musical cultures, which led to the development of comparative musicology. In the middle of the 20th century, anthropology and ethnology had a strong impact on musicology and directed interest of researchers towards looking at music cultures in their social and cultural context (ethnomusicology). This new approach was close to humanistic methodology and quite different from methodologies typical of systematic musicology at the time (empirical research).

In the 1980s, interest in systematic musicology grew towards cognitive sciences, cognitive psychology and computer science. New methodologies were applied to studies of music of non-Western cultures. In systematic musicology it had not been typical to take social and cultural aspects into account. Closest to ethnomusicology was the cross-cultural approach, in which an attempt was often taken to take social and cultural aspects into account.

A cognitive turn in the 1990s was strongly affected by cognitive sciences and especially computer science. Modeling of cognitive processes in music forced researchers to take more seriously cultural aspects. Cross-cultural music cognition and cognitive ethnomusicology were approaches in the 1990s. These approaches were methodologically quite close to each other. The cross-cultural approach typically applies more scientific and cognitive ethnomusicology humanistic methodologies [47.86, 118].

The problems with terms like *folk*, *traditional* or *ethnic* and the interest of ethnomusicologists to enlarge their studies into new areas, such as Western classical music, pop/jazz/rock genres and music and media,

made the use of the term ethnomusicology problematic. The core of ethnomusicology is not today so much in the object of the study, but more on the methodology: to study musical behavior in social and cultural context. This change of research object was the origin of the appearance of a new term, cultural musicology – sometimes called *new musicology* [47.92].

Cultural musicology and systematic musicology do not differ so much in research topics: both fields can study music of non-Western cultures, classical music, pop/jazz/rock genres, music and media etc. The more typical difference between these fields is that the systematic approach applies scientific and cultural musicology humanistic approaches. Social embodied music perception and cognition is one of the fields of systematic musicology in which social and cultural (humanistic) aspects have an important role.

It is apparent that most of the research topics and questions typical to the early stages of systematic musicology still exist, such as interest in folk/traditional music (variation, similarity etc.), acoustics and physics of music. In addition to the traditional research topics and methodologies, new topics and approaches have emerged into which ethnomusicology has had a clear impact, such as cross-cultural music cognition.

It remains an open question when systematic musicology and cultural musicology (ethnomusicology) and the third major field in musicology, historical musicology, will find more common interest. In order to get a holistic understanding of a complex musical phenomenon in its historical, social and cultural context, a closer cooperation between these three major subjects is needed.

48. Analytical Ethnomusicology: How We Got Out of Analysis and How to Get Back In

Leslie Tilley

Analysis has had a long and somewhat tenuous history under the umbrella of ethnomusicology. In this chapter, we examine the trajectory of analytical ethnomusicology, from its parallel beginnings in late 19th-century Europe and North America through its relative obscurity in the field in the mid-20th century to its panoply of new methods in the late 20th and early 21st centuries. The aim of the chapter is threefold. Looked at in one way, it is a simple historical overview of analysis in ethnomusicology: an examination of the major players, from Erich Moritz von Hornbostel to Alan Lomax to many of today's central scholars, as well as the major trends and intellectual frameworks influencing its execution, from cultural evolutionism to cultural relativism to interdisciplinarity. Yet it is also designed as an exploration of the myriad methods and approaches in the analytical ethnomusicologist's toolkit, from transcription and trait listing to structural analysis, computational analysis, and the new comparative analysis. And finally, woven throughout is the story of the place of analysis in ethnomusicological research: its strengths and weaknesses, successes and mistakes, practitioners and detractors. Through these discussions, we then begin to unpack the ebbs and flows of its use, reception, and usefulness in the field.

Analysis has had a long and somewhat tenuous history under the umbrella of ethnomusicology. Beginning as one of the central activities of both North American music ethnologists and European comparative musicologists in the late nineteenth century, it fell out of favor in the post-World War II era with the rise of anthropology-based ethnomusicological studies, and since the late 1960s has been rather relegated to a status of red-headed stepchild within in the discipline. *Joseph Kerman*'s provocatively titled *How We Got into Analysis, and How to Get out* might equally have been leveled at ethnomusicologists [48.1]. Yet there has remained throughout a subset of ethnomusicologists dedicated to developing newer, more applicable, and more culturally sensitive analytical methods, which have increasingly diversified through the twenty-first century to include computational and interdisciplinary approaches, among others. This chapter will explore the changing trajectory of analytical ethnomusicology over the course of the last 130 years, examining its practitioners and detractors, its insights and mistakes, and its mosaic of methods.

48.1 Ethnomusicology's Analytical Roots

In this first section, we will explore the analytical methods that arose in the early history of the field – both in Europe and in North America – and examine some of the larger goals behind these early analyses. Some of this history will be familiar to scholars of systematic musicology (SM), particularly as regards the early European scholars. Yet, while the current chapter will act as a complement to other chapters in this volume, it is designed as an overview of analytical techniques used by ethnomusicologists and their predecessors, and

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_48

will thus not focus on those techniques unique to SM. Readers interested in the historical connections between these fields should refer to *Albrecht Schneider*'s 2006 article on the topic [48.2].

Although the commonly accepted narrative of ethnomusicology's history has its inception in mid-1880s Europe, we will begin instead by examining some of the studies of early North American music ethnologists. Generally less concerned with formulating grand, far-reaching theories of musical evolution and origins than their European counterparts in comparative musicology, these North American scholars tended to present more modest lists of musical traits. Starting our examination of ethnomusicological analysis here will allow us to begin grappling with analytical techniques and concepts from a simpler vantage point before then turning to the methods of European comparative musicologists.

48.1.1 Modest Beginnings: North America

The beginnings of ethnomusicological research in North America were largely focused on preservation: early American music ethnologists like Alice Cunningham Fletcher (1838–1923) and Frances Densmore (1867–1957) set out to collect and transcribe what they considered to be dying traditions, mostly Native North American musics. This was actually a key interest of many late-19th and early-twentieth century music scholars, including important European collectors not discussed in depth in this chapter. Among these were Hungarian scholars Béla Bartòk (1881–1945) and Zoltán Kodály (1882–1967), who compiled extensive collections of folk music from across Eastern Europe, as well as the less-often-cited Finnish folk music collector Ilmari Krohn (1867–1960), whose folk music categorization method later influenced both Bartòk and Kodály. Key to the efforts of all such scholars, of course, was the invention of Edison's phonograph in 1877, which allowed music scholars, for the first time, to record music in the field and then replay it for more accurate transcription and analysis.

Both Densmore and Fletcher were prolific collectors of Native American music. Densmore, for instance, *studied the music of* 76 *tribes, recorded more than* 2500 *songs, and published at least* 22 *monographs and* 175 *articles*, all between 1901 and 1940 [48.3, p. 53]. Many of these publications involved song classification and categorization alongside basic analysis, and all relied very heavily on transcriptions in Western notation. *Densmore*'s 1910 collection of Chippewa songs [48.4], for instance, comprises transcriptions of 200 songs categorized according to their social function. In this study, Densmore engages in two main styles of analysis, both of which were common in these early years: trait listing and descriptive analysis.

Trait Listing

The most basic analysis style in Densmore's study is trait listing. In this approach, the analyst begins with a list of seemingly objective musical parameters regarding scale type, melodic characteristics (range, contour, and intervals), ornamentation, tonal organization, rhythm and rhythmic organization, and form. S/he then makes a chart with all parameters listed and fills in the details for a given piece. Trait listing may be used to analyze characteristics of a single piece of music or to present a tabulated analysis of multiple songs. Figure 48.1 shows Densmore's tabulated analyses of accidental use and rhythm in Chippewa songs.

Trait listing was designed to be scientific and objective, a central goal of many nineteenth and early twentieth century music scholars. And, though more complex and comprehensive forms of analysis have arisen in the interim, similar approaches are still used today, subsumed under Mervyn McLean's category of *standard analysis*. This componential approach to music, *McLean* maintains, *is simple, relatively easy to apply, and* [. . .] *has served its purpose well* [48.3, p. 292].

Descriptive Analysis

The second approach that Densmore and other early American music ethnologists used was descriptive: prose outlining general facts about the music as well as presenting more specific observations on individual songs. In Densmore's work, each song category is first introduced with a few paragraphs for cultural context, and each song is given a handful of sentences regarding its source. Then, following each transcription is a brief analysis of its individual musical characteristics. Figure 48.2 shows an example of *Densmore*'s transcription and descriptive analysis style, this time from her study of Native songs in British Columbia [48.5].

This descriptive analysis, like basic trait listing, makes no special attempt to either uncover or reinforce a larger theory; it is simply an outlining of the observable musical characteristics of a single song. In this example, Densmore's analysis focuses on meter, phrase length, pitch use (in relation to an assumed tonic), and the more subjective evaluation of melodic character. Other analyses in the same collection touch on small-scale thematic development, melodic motion, interval use, and so on. Yet, what will hopefully be immediately apparent is that these descriptions and trait analyses are as much an analysis of the author's *transcriptions* as they are of the songs themselves. Thus, one of the first lessons we learn from examining the work of these early scholars is that transcription is, in fact, a form of analysis.

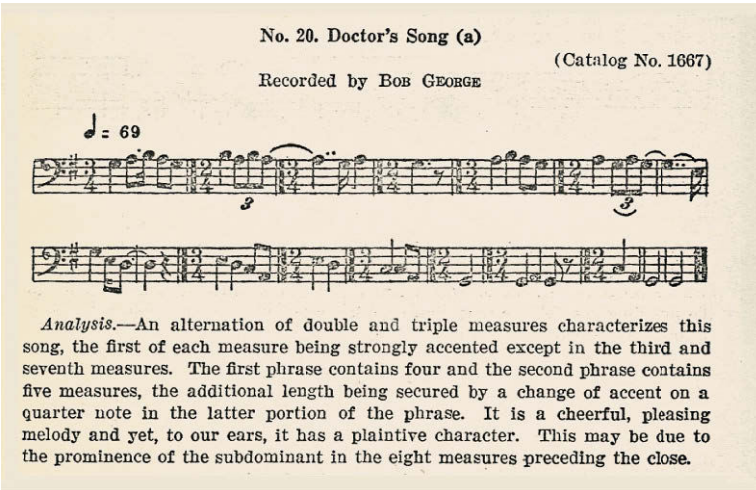
ACCIDENTALS

Songs containing no accidentals	3	112, 203, 224
Sixth lowered a semitone	1	181
Total	4	

RHYTHMIC ANALYSIS

Beginning on accented portion of measure	2	181, 203
Beginning on unaccented portion of measure	2	112, 224
Total	4	
Metric unit of voice and drum different	3	181, 203, 224
Recorded without drum	1	112
Total	4	

Fig. 48.1 *Densmore*'s trait listing, tabulated analysis (after [48.4, p. 160])



No. 20. Doctor's Song (a)

(Catalog No. 1667)

Recorded by BOB GEORGE

♩ = 69

Analysis.—An alternation of double and triple measures characterizes this song, the first of each measure being strongly accented except in the third and seventh measures. The first phrase contains four and the second phrase contains five measures, the additional length being secured by a change of accent on a quarter note in the latter portion of the phrase. It is a cheerful, pleasing melody and yet, to our ears, it has a plaintive character. This may be due to the prominence of the subdominant in the eight measures preceding the close.

Fig. 48.2 *Densmore*'s descriptive analysis (after [48.5, p. 37])

Transcription as a Form of Analysis

Undertaking transcription of oral musics involves myriad decisions. In Fig. 48.2, for instance, how does Densmore choose the key of the piece? Is a Western conception of tonal hierarchy even relevant in this tradition, and if so, how did Densmore establish that it was? Further, why the changing meter in this transcription? *Densmore* has stated of her collections that *the transcription of a song is divided into measures according to the vocal accent* [48.4, p. 5]. But why discount the possibility of syncopation within a stable metric framework, or even the idea that the music is not strictly metered at all? Further, what about allowance for variation in song performance? Densmore often records multiple versions of a single song, but only one is ever transcribed [48.5, p. 39]. Without a discussion of the differences between variants or the reasons for one particular variant being chosen over others, this reifies a single version of the song for analysis. Even seemingly small details must be decided upon when transcribing. For instance, how accurate should a transcription be in terms of pitch placement? *Densmore* admits that *ordinary musical notation does not, in all instances, represent the tones sung* in the music she transcribes [48.4, p. 3], but still staunchly clings to the idea of music based in tones and semitones, ignoring *Alexander Ellis*' strong arguments to the contrary [48.6]. She states [48.4, p. 4]:

> *At present the only standard generally available for the measurement of musical intervals is the tempered musical scale. This is artificial, yet its points of difference from the natural scale are intervals less frequently used in primitive music than those which the two scales have in common. Chippewa*

> *singers have been found who sang all the tones correctly except the fourth and seventh.*

Here I draw the reader's attention to the use of the term *correctly*, which *presumes* a musical system that uses a Western European standard of tuning, and implies that the Chippewa singers have simply not yet mastered it. Thus, every decision in transcription comes with a set of assumptions. John Comfort Fillmore (1843–1898), who often collaborated with Alice Fletcher as a music expert, had even more audacious ideas about this question of precision in pitch placement for ethnomusicological transcription. To Fillmore, the actual pitches sung were *a matter of comparatively little importance*. He claimed that [48.7, p. 288]:

> *the really important question is what tone* [the performers] meant *to sing, and on this point there can be no doubt whatever. The song as given* [in the transcription] *is exactly as they meant and sang it.*

What's more, Fillmore often transcribed Native American melodies with piano accompaniment, erroneously presuming that *the forms assumed by primitive songs are determined (unconsciously to those who make them) by a latent sense of harmony* [48.8, p. 305].

Some early scholars of non-Western music attempted to avoid the potential misrepresentation exhibited by Densmore, Fillmore, and others, either by including an enormous level of detail in their transcriptions or by creating unconventional staves. Hungarian music collector and composer Béla Bartòk was known for his meticulous detail in pitch placement (with the use of arrows to show deviance from tempered tuning) as well as in the notation of rhythm and ornamentation. American music scholar *Benjamin Ives Gilman* (1852–1933) went a different route, inventing a 45-line quarter-tone staff for the notation of Hopi songs [48.9]. Unfortunately, while putatively objective and exact, the visuals of such a transcription lead to an analysis that favors the minutiae of pitch placement and intervallic content over melodic motion or phrasing, for instance, which are visually obfuscated by the level of pitch detail present.

The choices made in the transcription process, then, are very much a part of the analytical process. As *Hornbostel* has stated, *notation, in order to be readable, must reduce facts to formulas* [48.10, p. 38]. And when a scholar's analysis is based not on the performance but on the transcription (and all of its assumptions and reductions), much of the music's nuance can be lost. That none of these early scholars performed the music they studied is equally relevant; there was no opportunity to verify their findings cognitively or experientially, nor to discuss questions of performance practice or cognition with the culture-bearers themselves. Through our twenty-first-century lenses, of course, it's easy to see the ethnocentric bias in many of these earlier studies, but the issue of transcription's subjectivity has remained to the present day. Despite the availability of better technological resources and the cognitive perspectives that modern ethnomusicological fieldwork has given us, transcription in its very nature is still an imperfect art and science, both. Thus, it is always important to ask the question posed by *Jason Stanyek* in his 2014 *Forum on Transcription* [48.11, p. 104]: *how do the practices, products, and politics of transcription fit into an ever-changing landscape of ethnomusicology?*

Concluding Remarks on Early Music Ethnology

There are undeniably numerous intractable problems inherent in both transcription and standard analysis. Yet these methods can be invaluable assets to the ethnomusicologist; we must simply be aware of their limitations, as we must be of the limitations in *any* analytical tool, be it musical or cultural. Despite their shortcomings, the analytical methods used by these early music ethnologists – descriptive analysis, trait listing, and transcription – are still central features of an ethnomusicologist's analytical toolkit. They are an excellent starting point. However, as *Mervyn McLean* points out, we should always be searching for *improved ways of looking at each of the* [musical] *components and their relationships with each other* [48.3, p. 292].

48.1.2 European Comparative Musicology

The creation story told to most budding ethnomusicologists about the origins of our discipline generally does not begin with the transcription-for-preservation, descriptive analyses, and trait listing of the early American school that we have been discussing. It begins in Europe in the late 1800s with the emergence of Vergleichende Musikwissenschaft: comparative musicology (CM). As the name suggests, comparative musicologists saw as their task not just the collection and classification but also the comparison of all the world's musics. In this pursuit, they attempted to trace historical connections between traditions through the application of empirical and analytical methods, many seeking universals in music or positing other grand theories supported by their analyses.

Most of the important nineteenth- and early twentieth-century comparative musicologists hailed from German-speaking lands, and of these, many were associated with the Berlin Phonogramm-Archiv, a collection of thousands of phonograph cylinders founded in 1900 by philosopher, acoustician, and psychologist Carl

Stumpf (1848–1936) and developed by his students: chemist, philosopher, and musicologist Erich Moritz von Hornbostel (1877–1935) and physician, psychologist, and auditory perception specialist Otto Abraham (1872–1926). Initially assembled for Stumpf's *psychological interest in the sensual experience of tones and intervals and their ordering into tone systems* [48.12, p. 204], the Phonogramm-Archiv became, through Hornbostel, a repository of recordings for academic inquiry that went far beyond the confines of psychology.

In his 1905 lecture *The Problems of Comparative Musicology*, *Hornbostel* outlined the general goals of the field, beginning with the reasons for comparison [48.13, pp. 249–250]:

> *Comparison is the principal means by which the quest for knowledge is pursued. Comparison makes possible the analysis and the exact description of an individual phenomenon by comparing it with other phenomena and emphasizing its distinctive qualities. But comparison also characterizes individual phenomena as special cases in which the similarities are defined and formulated as* laws. *Systematization and theory depend on comparison.*

Hornbostel was particularly interested in methods for the comparative study of scales and tone systems, and these would remain a central concern of CM. But his 1905 lecture also presented ideas on the analysis of melodic construction and rhythm, encouraged explorations into the nature of the musically beautiful, and incorporated some quite forward-looking musings on the inherent problems of analyzing musical systems different from our own. Many of Hornbostel's early studies, and those of his contemporaries, grappled with these tasks. In 1906 for instance, *Hornbostel* published articles on the recorded musics of both the Thompson River Indians of British Columbia [48.14] and the people of Tunisia [48.15]. Like many early American studies, these articles contain Western-style transcriptions and analyses with heavy focus on melodic characteristics and tone systems. Both attempt a statistical understanding of scalar types and seek to ascertain the inherent tone hierarchy of the music's supposed *tonalities*. *Bruno Nettl* has noted that [48.16, p. 75]

> *what has sometimes been called the* Hornbostel paradigm – *focusing on scalar structures and pitch relations and giving attention to singing style and tone colour – seems to have been developed in part for establishing an approach to a description of music that might facilitate a comparative method.*

Yet, although European comparative musicologists would use many of the same standard analysis techniques as the early Americans – examining music componentially through trait listing and descriptive analysis – they had loftier goals too.

A Basis in the Sciences: Grand Theories of Origins and Evolution

Most early comparative musicologists approached the study of music as a science in the tradition of the great syntheses of *Helmholtz* [48.17] – not surprising, given the fact that many of them, like Stumpf, Hornbostel, and Abraham, were trained as acousticians, psychologists, and physicians first. And many would take their studies further than simple description, categorization, and comparison, turning to theories and discoveries in other academic fields as a scientific basis for their research. For instance, the then-current belief that there were universals in music was based in psychology. *Hornbostel*, for example, claimed that certain musical gestures, like a descending melody moving from tension to rest, were *natural, i. e., rooted in the psychophysical constitution of man, and* [could] *therefore be found all over the world* [48.10, p. 34]. And Darwin's theory of evolution was understood to support two of the more commonly espoused theoretical orientations of CM: cultural evolutionism and diffusionism.

Cultural Evolutionism. Cultural evolutionism stemmed from the belief that all cultures evolve from primitive to civilized – and their musics from simple to complex – but that each does so at a different rate. Supporting a theory of the polygenesis of musical attributes, cultural evolutionists posited that we could understand the music of our distant ancestors by studying the music of more *primitive* cultures: our so-called *contemporary ancestors*. Aesthetician *Richard Wallaschek* of the Vienna School of CM, in his 1893 *Primitive Music* [48.18], presents a musical world tour in 300 pages, describing and categorizing each so-called primitive music in terms of its evolutionary stage. At the core of Wallaschek's study is a belief in cultural evolutionism, held without question. He says [48.18, p. 145]:

> *I can take it for granted that there are still savage tribes, whose culture has remained stationary ever since the stone age. If this is so, it seems – to say the least – extremely improbable that such tribes (as Bushmen, Australians) should at the same time have made any progress in music alone.*

The book examines everything from instrument type to singing style to a people's understanding of harmony and harmonic progression, in order to place musical characteristics and (by extension) societies along a continuum of evolution, speculating on the origins of these attributes and connecting links between societies

along the way. An ambitious early example of CM, as *Mervyn McLean* notes, *it is also compiled substantially from unreliable secondary sources and is full of mistakes and misinterpretations* [48.3, p. 241].

Carl Stumpf, the father of the Berlin School of CM, was also very concerned with evolutionary theory in his work. He theorized [48.19, 20]:

> *that a tonal system with stable steps required an intellectual development* [...] *whose consecutive stages and inner properties no one ha*[d] *yet demonstrated for us in a psychologically credible way.*

In his 1911 *The Origins of Music* [48.21], *Stumpf* attempts to do just that: to discover and lay out the *main forms of primitive melodic formation and their gradual refinement* [48.21, p. 62]. In it, he discusses the ways in which melody-making developed from the use of *noisy sounds* (*Geräusche Töne*) through the use of fixed musical intervals, to the development of a sense of tonality and melodic centralization, and so on, all as a way of categorizing music on an evolutionary scale and thus speculating upon its origins.

Diffusionism. The closely related theoretical framework of diffusionism espoused a *mono*genetic theory of evolution: all cultural traits (including musical characteristics and forms) are invented in a single location and spread outward from that point. *Curt Sachs*, one of the more ardent supporters of diffusionism, justified it over the polygenetic theories explained above by appealing to a personal logic based on the relative complexity of musical instruments and characteristics [48.22, pp. 62–63]:

> *We may believe that a tool such as a hammer can be invented everywhere at a certain stage of human evolution; the progression from the use of the bare fist, through the use of a stone in the fist, to a stone on a wooden handle, is quite logical and natural. But a bull-roarer? Is it really acceptable that every human tribe must invent an oval board, held by a cord and whirled around the head, for certain magic purposes? Is it convincing that merely because of natural evolution such a bull-roarer should have been almost universally connected with the fish, and that Paleolithic hunters in France as well as modern Eskimos should both have the idea of dentating its rims?*

Convincing though his argument may sound, of course, it is still more conjecture than proof.

One of the more commonly adopted diffusionist theories among comparative musicologists was the theory of culture circles (*Kulturkreislehre*), where cultural traits were thought to spread in ever-expanding circles from their point of origin, and where those traits most distant from the center were considered to be the oldest (Fig. 48.3).

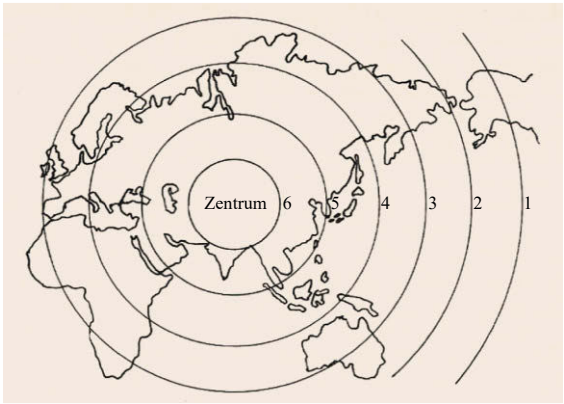


Fig. 48.3 The theory of culture circles (after [48.23, p. 29])

Diffusionist scholars theorized, among other things, that *the more widely an object is spread over the world, the more* primitive *it is* [48.22, p. 62]. *Sachs* claimed that the strung rattle, for instance, which is *used by modern primitives of a very low cultural standard as well as by Paleolithic hunters*, must be *among the earliest instruments* [48.22, p. 26]. In his 1929 *Geist und Werden der Musik Instrumente* [48.24], *Sachs* developed 23 historical strata for musical instruments based on distribution patterns, later adopted and adapted by *Hornbostel* for consideration of African musical instruments [48.25] and further refined by *Sachs* in 1940 [48.22]. Again, the most widely distributed instruments – like rattles – were considered to belong to the oldest strata.

Diffusionist theories not only allowed researchers to conceive of the age of certain musical or cultural traits; they also allowed them to hypothesize on the geographical route by which these traits traveled from one culture to another, and thus to build theories of cultural influence. In 1911, for instance, *Hornbostel* published a study on the tuning systems of xylophones in Southeast Asia and Africa [48.26]. Surprising similarities in the pitches, expressed in vibrations per second, led to a largely unsupported theory of monogenesis and cultural influence.

Concluding Remarks on Comparative Musicology

As *Savage* and *Brown* have noted [48.27, p. 158]:

> *One of the weaknesses of early comparative musicological work was a reliance on what we will call* remote comparison*, in which small numbers of songs from very distant regions were com-*

pared, often to support arguments of monogenesis *about long-distance similarity between regions. Such projects often involved the cherry-picking of particular songs that satisfied preconceptions of musical similarity.*

Moreover, the inherent racism in these evolutionary theories will probably be obvious to the twenty-first-century reader: it was not only allowed but encouraged to equate our Stone Age ancestors with our contemporaries in more so-called primitive cultures, in terms of their evolutionary stage. This supported a hierarchy of musics (and therefore cultures) ranging from primitive to advanced, thus justifying the goals of colonialism – and beliefs in Western superiority – through musical *science*.

For these reasons, the theoretical orientations of evolutionism and diffusionism, questions of origins, and concepts of universals were all eventually rejected by the academic community. And with that dismissal, the comparative approach to a large degree fell out of fashion also.

48.2 The Mid-Century Pendulum Swing: The Rise of Anthropology-Based Studies

While analysis of non-Western musics and the comparative approach did continue to have a few supporters and practitioners (discussed below) after the rejection of evolutionary theories, the second half of the twentieth century saw the development and eventual dominance of a very different form of ethnomusicological research. This was accompanied by a change in the name of the discipline from *comparative musicology* to *ethnomusicology* (a term coined by Jaap Kunst in 1950, later to lose the hyphen). As *Martin Stokes* has noted [48.28]:

Academic music theory and ethnomusicology parted company in the 1960s. Ethnomusicologists turned increasingly to Geertzian hermeneutics and ethnoaesthetics, viewing the application of western theoretical methodologies to non-western musics with concern and suspicion.

And given some of the emerging misgivings about what Western analytical techniques had wrought, this was an understandable reaction. Alongside the above-mentioned concerns of Eurocentric racism, scholars in the newly minted field of ethnomusicology feared that the kind of comparison undertaken in CM was a classic cart-before-horse blunder. *Mantle Hood* (1918–2005), who at mid-century promoted direct engagement with musics of the world through performance as a way to better understand music cultures and music systems (bimusicality), stated [48.20, p. 233]:

It seems a bit foolish in retrospection that the pioneers of our field became engrossed in the comparison of different musics before any real understanding of the musics being compared had been achieved.

He maintained that this approach had *led to some imaginative theories but provided very little accurate information* [48.29, p. 299].

Other objections to CM ran even deeper. As a new generation of American ethnomusicologists increasingly received training in anthropology, these scholars began questioning the very essence of the way we studied music. Suddenly anthropologists like Franz Boas (1858–1942), and his ideas of cultural relativism, began profoundly impacting the discipline as a whole. Scholars realized that music could not be studied in a vacuum; cultural factors *must* be taken into account so that *all people, in no matter what culture,* [would] *be able to place their music firmly in the context of the totality of their beliefs, experiences, and activities* [48.30, p. 3]. Enter *Alan P. Merriam*, an anthropologically trained ethnomusicologist, who developed a tripartite model for the study of music as culture, outlined in his influential 1964 book *The Anthropology of Music* [48.31]. According to Merriam's model, ethnomusicologists must begin by examining the culturally specific *concepts* about music as revealed to them by the practitioners themselves, use these concepts to inform observations about the *behaviors* of music-making, and only then tackle the music *sounds*, now from a deeper, more culturally sensitive place of understanding. This new approach would gain widespread appeal and support among many ethnomusicologists, particularly in the newly dominant North American branch of the field, calling into question the older practices of CM. As important English ethnomusicologist *John Blacking* (1928–1990) argued two years later [48.32, p. 218]:

A logical outcome of Merriam's approach to the study of music is surely the need for entirely new methods of analysis of music sound [. . .] If we accept the view that patterns of music sound in any culture are the product of concepts and behavior peculiar to that culture, we cannot compare them with similar patterns in another culture unless we

> *know that the latter are derived from similar concepts and behavior. Conversely, statistical analysis may show that the music of 2 cultures is very different, but an analysis of the cultural* origins *of the sound patterns may reveal that they have essentially the same meaning, which has been translated into the different* languages *of the 2 cultures.*

Scholars like *Charles Seeger* (1886–1979), alongside Blacking and Merriam, called for a discipline focused on *the advancement of knowledge of and about music* [and…] *the place and function of music in human culture* [48.33, p. 217]; as *Hood* put it, a study of music *not only in terms of itself but also in relation to its cultural context* [48.29, p. 298]. As mentioned, these new attitudes were especially strong in American ethnomusicology, where the teachings of Boas held considerable sway.

The putative goal of these mid-century scholars was to create a balanced, inclusive approach to the study of music – as the influential *Bruno Nettl* (b. 1930) [48.34, p. 26] described it:

> *a sort of borderline area between musicology (the study of all aspects of music in a scholarly fashion) and anthropology (the study of man, his culture, and especially the cultures outside the investigator's own background).*

A necessary shift in consciousness and understanding, this radical change in thinking among ethnomusicologists had a rather unfortunate, if inadvertent, side effect: a sudden and distinct disinclination among most ethnomusicologists to engage in deep musical analysis of any kind, and a subsequent paucity of analytical studies in the field. Ethnomusicology became a study of *music in culture* and *music as culture*, and its publications became overwhelmingly dominated by these anthropology-based studies. A survey by Timothy Rice of articles published in the journal *Ethnomusicology* from 1979 to 1986 showed that only 10% of these emphasized music analysis, while 34% focused on social processes and another 17% on individual processes [48.35, p. 476]. I performed a similar survey 16 years later with comparable results [48.36, pp. 108–109]:

> *In the annual list of dissertations and theses published by* Ethnomusicology *in the winter of 2001, only six of the over* 120 *papers had a distinct analytical bent. And, of the* 129 *articles published in that journal in the last ten years* [1993–2003]*, only fourteen contained major music-theory analyses. Many articles did not contain a single musical example.*

The effects of Merriam's pendulum swing, then, have been deep and long lasting. As *Nattiez* has noted [48.37, pp. 241–242]:

> *Since the 1960s ethnomusicology ha*[s] *become increasingly an* anthropology of music *under the influence of Merriam (1964) and Blacking (1973).* [… And] *because of the widespread assumption that only a knowledge of the cultural environment would permit a true understanding of music from an oral tradition, all analytical activity, which, it was suspected, substituted the tools of the Western researcher for the values and concepts of the native musician, began to disappear gradually from ethnomusicological monographs.*

There were, however, a few pockets of the ethnomusicological community doing analysis – and encouraging analysis – in the second half of the twentieth century. In the next few sections, we will discuss some of the major trends and a handful of the most important scholars and methods in these decades.

48.2.1 Analysis in a Relativist World

The few scholars left attempting close musical analysis in the second half of the twentieth century now had to do so with a new relativist understanding of the world. One of the more engaging analytical experiments undertaken in the 1960s was a symposium on transcription and analysis published in a 1964 issue of *Ethnomusicology* [48.38]. This study, which began as a colloquium presented at the Society for Ethnomusicology conference in 1963, was an unabashed demonstration of the subjectivity of transcription and therefore of analysis. Four respected scholars, Robert Garfias, Mieczyslaw Kolinski, George List, and Willard Rhodes were invited to transcribe and analyze a recording of a Hukwe song performed with musical bow. The participants were given some background information on the Hukwe people and a small description of the bow's playing technique. They were invited to transcribe and analyze the recording any way they saw fit, with very little instruction, no communication among them, and a stated desire for individual approaches. There are certainly elements common to the resulting transcriptions, such as agreements regarding pitch content and the timbral quality and rhythmic material of the bow. But as we can see in the synoptic view of the four transcriptions in Fig. 48.4, they are also utterly different. Two of the scholars choose to transcribe the whole recording while the other two focus in on smaller sections; one uses a graphic-style notation for the vocal melody; each decides on a different level of detail for the bow's pitch

Fig. 48.4 Synoptic view of transcriptions from the 1964 symposium (after [48.38, p. 274])

content. Their accompanying analyses show even more breadth of perspective. While Garfias analyzes the piece from a culture-specific approach, both List and Kolinski apply the universalist sound-based theories still in vogue at the time, each focusing on his own particular areas of expertise: Kolinski alone, for instance, deals with tonal modality, which is of special interest to him.

The exciting thing about this symposium is that it addresses issues of subjectivity, recognizing *that in fact transcriptions bear within them the result of a transcriber's analytical understanding* of the music [48.39, p. 543], without then rejecting these methods out-of-hand. It is an experiment celebrating the relativism that turned many ethnomusicologists away from analysis in the later twentieth century, stating *one great strength of our Society lies in the varied individual approaches that are (and have been) made toward the data of our discipline* [48.38, p. 233]. It is with this attitude that the scholars discussed in the next sections moved forward with analysis in the latter half of the twentieth century, despite a virtual field-wide reaction against it.

48.2.2 Later Comparative Studies

Though comparative research largely passed out of vogue with evolutionary models, it did not entirely disappear in the second half of the twentieth century. In fact, as *Nettl* has noted, comparative study in the 1960s and 1970s actually *continu*[ed] *to occupy about the same proportion of research as it did before 1950; it* [simply] *received less attention and respect* [48.16, p. 67]. Two scholars forging new approaches to comparison in these decades were Mieczyslaw Kolinski (1901–1981) and Alan Lomax (1915–2002). Though studies of both men have been questioned and their approaches largely fallen into disuse, they were among the last to attempt to capture the full scope of the world's music in analytic terms. While Lomax was interested in cross-culturally examining singing style with enormous breadth of focus, Kolinski was concerned with deeply exploring the minutiae of very specific musical parameters across genres and cultures.

Alan Lomax's Cantometrics Project

Like many of the early comparative musicologists and music ethnologists, Alan Lomax was a prodigious collector of music, largely of the folk musics of Europe and North America. He was interested in comparing song styles and hypothesizing how differences among them might correlate with differences in the social structure of their respective cultures. *Lomax* is most well known for his multidecade project in what he called Cantometrics, or *measure of song* [48.40, 41]. An advanced form of trait listing analysis, Cantometrics measures 37 (later to be 36) distinct musical parameters of a song, from its various rhythmic and melodic features (e.g., regular versus irregular overall rhythm, melodic shape, type of polyphony, etc.) to ornamentation, level of group cohesiveness, and vocal qualities like nasality, vocal width, enunciation, and rasp. Lomax also designed a coding sheet on which each of these parameters could be judged. Figure 48.5 shows parameters 32–37 of the coding sheet – those dealing with vocal quality – including the various points on the rating scale for each parameter. The researcher would select the most appropriate point on each scale of the coding sheet and this would provide a *speedy characterization and classification* of the song's musical style [48.41, p. 8].

The same coding sheet could also be used to comparatively analyze two distinct music traditions, as we can see in Fig. 48.6. Here, the various vocal qualities of the so-called *African Gatherer* style are circled, and those of the *Urban East Asian* style are marked with rectangles. As *Lomax* asserts, these two profiles *define the extremes of the human stylistic range. There are, of course, other styles whose patterns fall along the middle of the profiling system* [48.40, p. 19].

Yet what really interested Lomax was determining how musical features might reflect social features. He sought to show, by comparing song measurements with preexisting ethnographic data, that [48.42, p. 97]

32) *Vocal Pitch* (Register)
(1) very high V-Hi (2) high Hi (3) mid Mid (4) low Low (5) very low V-Low
33) *Vocal Width*
(1) narrow NA (2) mid M (3) wide W (4) yodel Y
34) *Nasality*
(1) extreme or steady Ext (2) much Much (3) intermittent Int (4) some Some (5) little or no Ø
35) *Rasp*
(1) extreme Ext (2) great Gt (3) mid or intermittent Int (4) slight Sli (5) little or no Ø
36) *Accent*
(1) very forceful V-fo (2) forceful Fo (3) mid Mid (4) relaxed Re (5) very relaxed V-Re
37) *Enunciation*
(1) very precise V-Pre (2) precise Pre (3) moderate Mod (4) slurred Slur (5) very slurred V-Slur

Fig. 48.5
Lomax's Cantometrics coding sheet for vocal quality (after [48.40, p. 67])

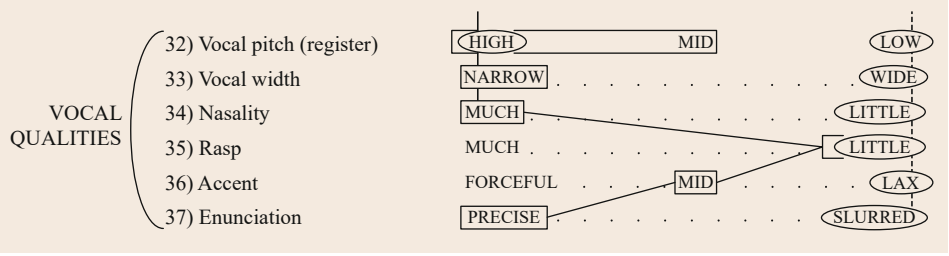

Fig. 48.6
Lomax's comparative analysis for vocal quality, *Urban East Asian* versus *African Gatherer* (after [48.40, p. 18])

> *song styles shift according to differences in productive range, political level, level of class stratification, severity of sexual mores* [...] *level of social cohesiveness,* [and so on].

Lomax's research team used a computer program to search for correlations between musical and societal features across the cultures they examined. Cultures were then organized into groups to create a geography of song style, and these larger profiles were analyzed in terms of their level of similarity in an attempt to show an evolution of style traditions. In the tree graph in Fig. 48.7, double lines represent the strongest cultural links, and the numbers on the bottom represent the proposed evolutionary stage of each culture group.

The Cantometrics system is flawed in a number of ways. It has been criticized for its evolutionist leanings and its unevenly distributed and often highly subjective parameters (how does one accurately judge a level of rasp, for instance?). Other critics have questioned its small sample sizes based on the mistaken assumption that most folk culture areas participate in a homogeneous style of music-making, and its use of *broad culture-areas as the basic units* of musical analysis [48.27, p. 155]. But, despite its not insignificant shortcomings [48.43, p. 101]

> *the Cantometrics system deserves credit for having moved vigorously in a direction previously uncharted: the description of singing style and of the nature of musical sound in general, things in the realm of what is usually called* performance practice.

Mieczyslaw Kolinski's Grand Schemes

While Alan Lomax was devising Cantometrics, Mieczyslaw Kolinski was developing a very different kind of grand scheme for comparative analysis. Yet, unlike Lomax, whose Cantometrics project is still cited in virtually all texts on ethnomusicology, Kolinski's methods are often only discussed *to recommend mostly against them* [48.3, p. 294]. Like earlier comparative musicologists, Kolinski was interested in discovering universals in music and comparing large bodies of data. He believed that all musics, no matter how diverse, could be [48.43, pp. 98–99]

> *subjected to comparison through a single classificatory system, a system reflecting and determined by the outer limits of and range of possibilities with the* [psychophysically rooted] *constraints* [of each musical style].

Kolinski published a series of articles through the 1950s, 1960s, and 1970s, each of which attempted a comprehensive examination of all possibilities for a given musical feature, from the 348 scalar and modal arrangements described in his *Classification of Tonal Structures* [48.44] to his detailed calculations of melodic movement [48.45, 46]. In these latter, Kolinski developed formulae and charts for comparatively analyzing melodic contours of diverse bodies of musical works.

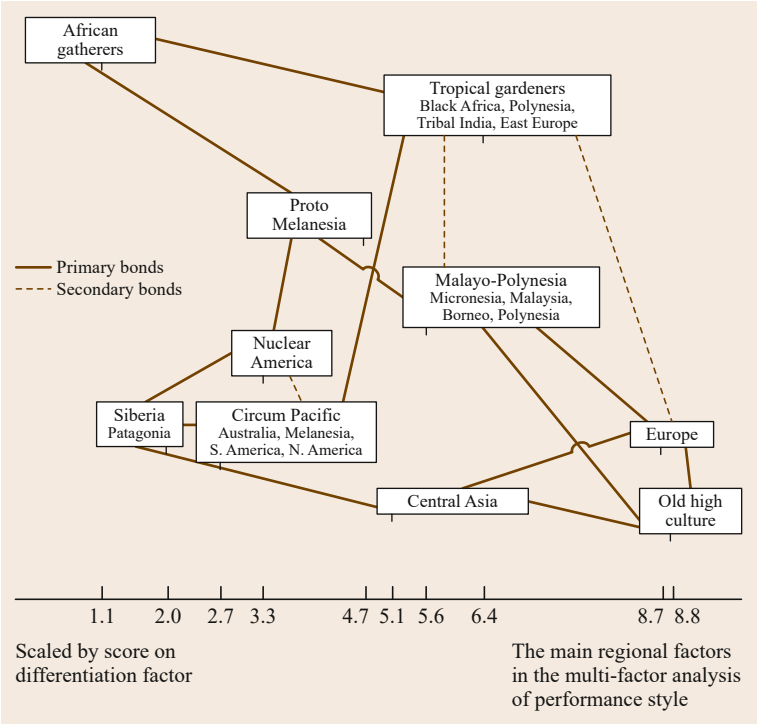

Fig. 48.7 Lomax's geography of song style (after [48.40, p. 35])

In *The General Direction of Melodic Movement* [48.45], for instance, *Kolinski* develops a method for comparatively analyzing different musics by charting the initial and final note of a melody in relation to its range. For a large body of works within a single tradition, Kolinski calculates what he calls *level formulae* – the average initial and final *melody level* expressed as a value from 0 to 100, where 0 is the lowest pitch and 100 the highest. For instance, among the songs of the Papago of Southern Arizona, Kolinski calculates the average initial pitch as being 64% of the piece's range higher than its lowest pitch, and the average final pitch as 32% higher. This gives the style a level formula of 64° : 32° and a level shift or pitch change of −32°, descending 32% of the full range over the course of the piece. By contrast, statistics of songs from the Menominee of Wisconsin exhibit a level formula of 89° : 4°, thus presenting a much sharper level shift of −85°.

Kolinski then expresses these level formulae in more detailed graphs showing the frequency distribution of songs with different initial and final levels across the repertoire, thus illustrating how the averages for level formulae were obtained. Figure 48.8 comparatively charts the distribution of initial pitch levels across the repertoire for Papago and Menominee songs. Kolinski divides the *x*-axis into 12 ranges – 0° (the lowest pitch in the range), 1–9°, 10–19°, 20–29°, and so on, up to 90–99°, and finally 100° (the highest pitch in the range). The *y*-axis shows the percentage of songs in the repertoires with an initial pitch in each of the given ranges. An average of all initial pitches in the graph gives the numbers from the level formulae above: 64° for the Papago songs and 89° for the Menominee songs. One can see that the Papago songs have a lower average initial level because a smaller percentage of songs begin on 100° than in the Menominee tradition and a larger percentage begin in the 20–29°, 30–39°, and 40–49° ranges.

The benefit of this sort of analysis is that it allows general melodic direction of different repertoires to be compared seemingly objectively regardless of the scale type or range of a given piece. Yet, for a number of reasons, Kolinski's methods have generally been rejected in the ethnomusicological community [48.47], [48.3, pp. 294–297]. This analysis of melodic direction, for example, takes no account of vastly different melodic contours presented with the same initial and final pitches and range. A melody beginning with a large leap up then proceeding with a slow descent back to the same pitch would generally be perceived as a descending melody where another differently contoured melody starting and ending on the same pitch could be perceived as wave-like or ascending. Yet these would be given the same level formula and thus erroneously analyzed as having the same melodic direction.

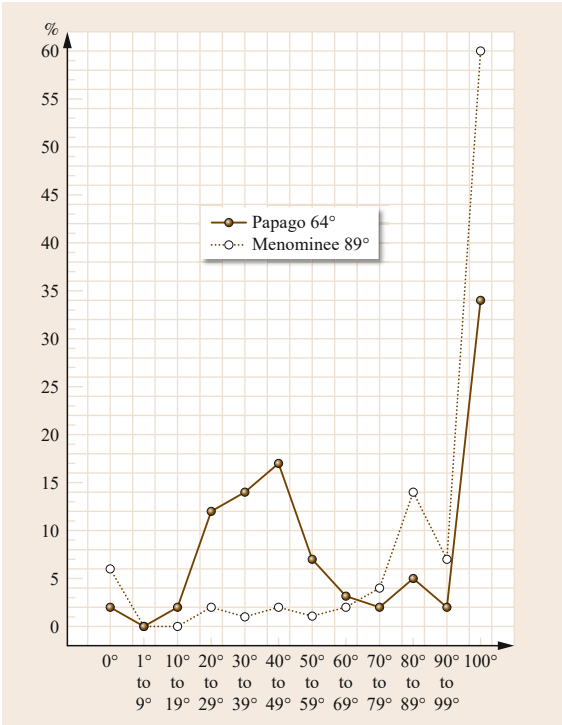

Fig. 48.8 Kolinski's comparative analysis of initial pitches; Papago versus Menominee songs (after [48.45, p. 241])

Kolinski's comparative study of tempo [48.48] has equally come under attack for its oversights and assumptions [48.47]. In this study, the author defines the tempo of a piece in terms of the number of notes per minute with no concern for the underlying beat of the music, as perceived by either cultural insider or outsider. Again, an attempt to provide a wide-spanning, seemingly objective comparative framework falls far short of its goal in terms of important perceptual details as well as *emic* (insider) considerations of the music.

Though much of the work of these mid-century comparativists has been largely rejected, we can appreciate the scope of their aspirations: using comparison, as *Kolinski* stated, as *an essential tool in* [our] *quest for a deeper insight into the infinite multifariousness of the universe of music* [48.49, p. 160].

48.2.3 Inspiration from Linguistics

Continuing the trend set by the late nineteenth-century comparative musicologists, many mid-twentieth-century analytical ethnomusicologists not predominantly interested in comparison turned to other disciplines for inspiration and guidance. The post-WWII era saw an academic atmosphere in which the study of symbols – and by extension the study of culture as a symbolic system – became increasingly popular across many disciplines, as Levi-Straussian structural anthropology [48.50] and semiotics [48.51] gained recognition. And for scholars attempting analysis in ethnomusicology, *an alternative to a behavioral approach to identifying symbols from a culture* [was] *to use language, the central symbolic code of humans, as a point of departure* [48.43, p. 305]. These scholars, then, turned to the work of structural linguists such as Ferdinand de Saussure, Roman Jakobson, and Noam Chomsky in the hopes of examining musical systems in the meticulous ways they had developed for examining linguistic systems. Scholars like George Herzog, the father of the American school of CM, were already asking questions about the overlap between musical and linguistic phenomena [48.52], but interest in applying linguistic *models* to musical analysis was something that developed through the 1960s and 1970s.

Saussurian structural linguistics is concerned, as the name suggests, with the underlying structures of language. Saussure made a distinction between the abstract linguistic system common to all speakers of a given language – what he called *langue* – and the discrete, unique utterances of individual speakers – *parole*. And for Saussure, the scientific study of language was a study of langue: a study of the rules behind the utterances. This he then divided into surface and deep structures. *Syntagmatic* analysis focused on the surface syntactical rules, such as the grammatically correct order of article, adjective, and noun in a given language: article-adjective-noun in English (the green house), article-noun-adjective in French (la maison verte), noun-adjective in Indonesian (rumah hijau). *Paradigmatic* analysis focused on the deeper paradigms, or preexisting sets of signifiers (letters, words, etc.), within the langue. This style of analysis could be applied to languages at several levels: the Roman alphabet is the paradigm from which English words are made; a full lexicon is a paradigm from which sentences are made, and this lexicon may be divided into paradigm sets according to things like word function (e.g., verbs). Paradigmatic analysis involves comparing the chosen signifiers (be they letters in a word, words in a sentence, etc.) with other signifiers that might have been chosen instead and to consider the significance of those choices. A common test in paradigmatic analysis is a commutation test, in which a signifier is selected and replaced with a different one to see whether or not the meaning – the signified – changes; this determines the distinctive signifiers within the language, defines the importance of those signifiers, and creates categories or paradigmatic classes of signifiers [48.53]. For instance, at the phonemic level, replacing *f* with *p* in an English word changes its mean-

ing; *fast* and *past* do not have the same meaning. But in Indonesian, *f* and *p* are very often interchangeable; *breath* can be spelled and pronounced either *nafas* or *napas*. This sort of commutation test becomes rather more subjective at higher levels of analysis, but its basic use is to discover the paradigms of the language: to determine at what level a change would affect the meaning; the signified.

The first musicologist to conceive of a paradigmatic analysis of music was *Nicolas Ruwet* [48.54]. He and his successors worked almost exclusively with notated music from the Western tradition. It was *Simha Arom*, in his studies of polyphonic traditions from the Central African Republic [48.55], who developed these techniques of classification and paradigmatic analysis most fully for ethnomusicological research. Arom used the natural commutation test of a cyclic music with repeated variation to discover culturally equivalent variations in diverse polyphonic musics, thus uncovering the paradigms of their musical languages. Through identifying common aspects between like patterns, Arom was able to decode a model for different rhythmic and melodic patterns and their possible variations. In Fig. 48.9, we see an example of what Arom calls a paradigmatic block: a group of rhythms that are deemed *culturally equivalent* among the Banda-Linda in the context of a specific ritual – rhythms that are freely interchangeable in their given position in the cycle.

A closely related form of linguistic analysis that also bled over into ethnomusicological research was *Chomsky*'s transformational-generative grammar [48.56], which aimed at [48.57, p. 163]

> *separat*[ing] *the grammatical sentences of a language from the ungrammatical ones and* [...] *provid*[ing] *a systematic account of the structure of grammatical sentences.*

An early example of the transformational model being applied to music is Edward Sapir's 1969 study of Diola-Fogny funeral songs [48.58]. Sapir incorporates insider (*emic*) names for different song structures while applying to those structures a transformational analysis that shows features shared by all the songs, and revealing each of the ways new variants can be derived. *Johan Sundberg* and *Björn Lindblom*'s 1976 article on generative theories [48.59] describes both Swedish nursery tunes and melodic variants of Swedish folksongs using generative rule systems. The authors then point to similarities between the two systems as potential guiding principles for composing simple melodies. They further hypothesize that connections between those musical rule systems and Chomsky and Halle's generative phonology of the English language reflect general characteristics of human cognitive capacities. *Vida Chenoweth* and *Darlene Bee*'s comparative-generative study of melodic structure in New Guinea [48.60] takes a different approach. The authors present three models of Awa song types (melodic structures) in the hopes of giving cultural outsiders simple visual tools with which to compose syntactically appropriate melodies in each structure. Figure 48.10 shows the authors' flow chart and associated formula for describing the simplest melody type. All syntactic units (notes) are described in terms of their interval relationship to the tonal center (TC), with *L* representing intervals below it (lower than) and *H* representing those above it (higher). As can be seen in the accompanying description, the flow chart and formula show all the possible choices that a composer can make, thus presenting a generative grammar:

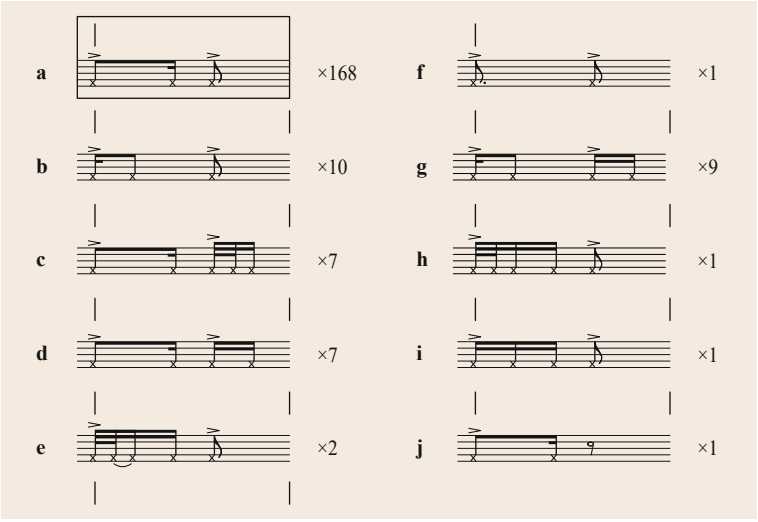

Fig. 48.9 Example of Arom's paradigmatic block (after [48.55, pp. 256–257])

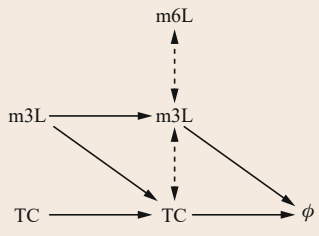

{m3L; TC + TC} + {(TC) + m3L + (m6L + m3L); m3L + TC} $n + \phi$

An Awa melody composed on this pattern may begin on either a minor third lower than the tonal center or on the tonal center. If it begins on the tonal center there must be at least one repeat of the first note. The melody may end with either the tonal center or the minor third. The core of the melody consists of alternations between these two with an optional progression of a minor third plus a minor sixth and back to a minor third.

Fig. 48.10 Chenoweth and Bee's flow chart (*left*), formula (*top right*), and description (*bottom right*) for one Awa song type (after [48.60, p. 779])

a set of rules representing all the syntactically correct ways to generate new melodies in this melodic structure.

Concluding Remarks on Linguistic Approaches

Like all the methods discussed thus far, linguistic approaches to ethnomusicological analyses also have their critics. In an atmosphere of cultural relativism, one of the major points of contention is that these scholars, like many of their forebears in CM, were often unconcerned with how music related to culture. Further, ethnomusicologists like *Stephen Feld* [48.61] have questioned the practice of asserting equivalence between music and language without really demonstrating it, calling attention to studies that assume rather than explain the validity of using linguistic models for musical analysis. These detractors warn against what *Aniruddh Patel* calls the *distraction of superficial analogies between music and language* [48.62, p. 5], and promote the need for skepticism when considering studies that claim strict equivalence between them. As *Lerdahl* and *Jackendoff* argue [48.63, p. 5]:

> *Many previous applications of linguistic methodology to music have foundered because they attempt a literal translation of some aspect of linguistic theory into musical terms – for instance, by looking for musical* parts of speech*, deep structures, transformations, or semantics.* [...] *One should not approach music with any preconceptions that the substance of music theory will look at all like linguistic theory.*

Flawed though these approaches may have been, however, like the early comparative approaches, they helped to build a toolkit of methods that an ethnomusicologist could turn to – with a critical eye – to help with analysis.

48.3 Analysis in Modern Ethnomusicology

As we have seen in this chapter, analytical ethnomusicology is in its very nature subjective and imperfect. But, as *Judith Becker* has maintained (wisely if somewhat idealistically) of these many approaches attempted over the decades [48.64, p. 113]:

> *In each case, ethnomusicologists had the good sense to learn from these movements what was useful to us. In the process we became enriched theoretically and methodologically. Eventually, the realization sets in that this or that approach does not, as first assumed, solve all our problems or answer all our questions. But we move on with a richer arsenal of ways to think about music. We do not discard approaches that once seemed stunning in their ability to reveal insights into music and musical behavior, but subsequently were shown to be partial and vulnerable. Rather, we carry within ourselves, like a palimpsest, each theoretical methodological approach with which we have seriously engaged, and we are richer for it.*

This assertion, unfortunately, is the ideal, not yet the reality. Thus, in this final section, we will attempt to understand the still-uncertain status of analysis within the field – and perhaps look to the increased prominence that it *could* enjoy in the future – through a discussion of our field-defining rhetoric and an examination of a few of the new analytical methods evolving within the discipline.

48.3.1 The Still-Shaky Position of Analysis in Ethnomusicology

Despite the rocky history examined here, many ethnomusicologists do see the value of music theory and anal-

ysis, and a not insignificant number of us include them in our studies. As *Gabriel Solis* has argued [48.39, p. 533]:

> *Such music theory* [...] *should be – and, indeed, is – neither of limited value to questions about music as social practice, nor marginal to the discipline of ethnomusicology at large, but rather of central importance in practice and in principle to both.*

And *Michael Tenzer* contends [48.65, pp. 6–7]:

> *Once observed, sound patterns can be mobilized for many purposes: to demonstrate or inspire compositional depth or ingenuity, to discover an archetypical sound-structure model on which a music or repertoire is based, to symbolize or reflect a philosophy, social value or belief (of the analyst, the composer(s), performer(s), or their society), to reveal a historical process of change, to unearth suspected connections to music elsewhere, to embody a mathematical principle. Good analysis demystifies by cracking sound codes, better enabling the ear to collaborate with the mind in search of richer experience.*

That music theory and analysis are an integral part of ethnomusicological research thus seems an already accepted norm. Yet, since the so-called *great divide* of the discipline at mid-century, they have never regained equal footing with the more anthropology-based studies in the field. As *Jonathan Stock* observes [48.66, pp. 224–225]:

> *music analysis per se has been and continues to be questioned by the influential anthropological bloc within ethnomusicology* [...] *Whether the distrust by music anthropologists for what they see as the analysis of acontextual musical features is indeed academically well-founded may be contended with on a number of levels, but, in that it is analysis of the interplay between musical context, behaviour and sound that continues to dominate ethnomusicology* [...] *the anthropological view remains a powerful one in the shaping of ethnomusicological discourse.*

Mervyn McLean agrees, calling attention to the still-prevalent *notion that the earlier specifically musical approaches (especially those involving transcription and analysis) are no longer acceptable* [48.3, p. 330]. He argues fervently that a *complete* ethnomusicologist must be equally competent in both music and anthropology, and warns that [48.3, p. 333]

> *one of the most pernicious outcomes of the application (or more accurately misapplication) of Merriam's model* [of concept–behavior–sound] *is that it has led to the* sound *component of the model effectively becoming lopped off in favour of the remainder, because analysis of* mere sound *is supposed to obscure the reality of whatever it is that lies behind it.*

Indeed, many ethnomusicologists today still shy away from analysis or even warn against it. In his *Very Short Introduction to Ethnomusicology* [48.67], for instance, *Timothy Rice* expresses concern that the goals of music analysts like *Michael Tenzer* [48.65, 68], *reposition ethnomusicological study within a European, universalizing definition of what art is in contrast to the last thirty years of ethnomusicological work* [48.67, p. 62]. These analyses, in *Rice*'s estimation, are problematic because they elevate a Kantian view of music as art, which [48.67, p. 62]

> *has been used to valorize a limited, European view of art as always about beauty and to relegate non-European practices to a category of non-art or functional or applied art.*

These definitions of both music and analysis, however, seem narrow: Rice implies that analysts always consider music to be art, assumes that one would not wish to analyze something that was not high art, and by extension insinuates that analysis seeks to categorize and exclude, not to explore and discover.

Yet, though the role of music theory and analysis has been the subject of an ongoing negotiation since ethnomusicology's inception, to the credit of Tenzer, Stock, McLean, and other scholars passionately addressing the relative scarcity of analysis in our field, the tenor of this dialog has shifted in recent years. We have seen the establishment of the *Analytical Approaches to World Music* (AAWM) journal and conference, both of which rely heavily on the contributions of self-proclaimed ethnomusicologists. Further, *Tenzer*'s 2006 *Analytical Studies in World Music* [48.65] – a compendium of work from both ethnomusicologists and Western music theorists – was successful enough that Oxford University Press released a sister volume in 2011 [48.69]. And *Gabriel Solis* reports that in the *British Journal of Ethnomusicology* about 30% of recent articles have included significant music analysis [48.39, p. 535]. This is certainly an improvement over the aforementioned surveys of the North American *Ethnomusicology* journal by Rice and myself. Further, many recent published books and theses – like *Marc Perlman*'s *Unplayed Melodies* [48.70] and, in very different ways, *Thomas Turino*'s *Music as Social Life* [48.71] and *Michael Tenzer*'s *Gamelan Gong Kebyar* [48.68] – have also engaged in close musical analysis.

Yet there is still a significant imbalance of analytical versus anthropological studies; the pendulum has

yet to return to center after its mid-century swing. Solis attempts an explanation for this by shining a light on our own rhetoric surrounding analysis. He reproaches many ethnomusicologists for giving music theory and analysis short shrift in their field-defining metatheory, citing a recent article by *Timothy Rice* aimed at delineating the tasks and directions of the field [48.72]. While Rice, in his own research, does occasionally engage in what *Solis* (and I) would term a music theory and analysis of Bulgarian music, in his field-defining writing *he seldom metadiscursively acknowledges the ways that ethnomusicologists engage in theory about musical sound* [48.39, p. 531]. In fact, he even goes so far as to present an *off-hand dismissal of music theory as an exogenous and currently marginal practice to the discipline* [48.39, p. 532]. While Rice is perhaps extreme in his view of music theory's tangential role, *Solis* points to *the limited role of explicit language about music theory and analysis* [48.39, p. 546] and a general lack of deep engagement with these approaches in many of our major field-defining writings as a potentially dangerous precedent. He points to two seminal introductory texts on ethnomusicology as prime examples: *Helen Myers' Ethnomusicology* [48.73] and *Bruno Nettl*'s *The Study of Ethnomusicology* [48.43]. In these works, despite prefatory remarks embracing an integrated view of the field, *considerations of musical sounds become somewhat buried or separated from the main body of the work*. Myers, for instance [48.39, pp. 545–546],

> *includes major, very important articles* [... on transcription and analysis]*, but questions of music theory and analysis, and their role in answering anthropological questions are largely missing from other chapters in the volume.*

And ironically, though I have attempted here to present connections between anthropological and musicological concerns in ethnomusicology, the current chapter may simply be another in a long line of writings that separate analysis from the rest of the field.

Though many ethnomusicologists are now engaging in intensive music theory and analysis, then, the *metatheoretical ambivalence* [48.39, p. 541] facing those studies may perpetuate their second-class status. I am continually surprised at how many ethnomusicologists – when I talk to them at conferences – admit to being interested in music theory and analysis, because I do not hear about it in their papers. It seems almost a case of so-called pluralistic ignorance, where *virtually every member of a group or society privately rejects a belief, opinion, or practice, yet believes that virtually every other member quietly accepts it* [48.74, p. 161]. The end result of this metatheoretical silence on the topic, then, becomes a vicious cycle where each new generation learns from teachers who, themselves, were not trained to do analysis. Absent from our metatheory, music theory and analysis do not play a large role in most of our *Intro to Ethno* classes, requirements for graduate programs, or conference themes. As the graduate students of this generation become the next generation of teachers and writers, they will not necessarily think to include music theory and analysis approaches in their own writing or teaching; they have been acculturated into the thought-habits of the previous generation. Were music theory and analysis to enter our rhetoric, conferences, and grad programs in a more meaningful way, we would surely see more scholars engaging with music theory *as well as* social theory. And that deepening can only strengthen and enrich us. So how do we proceed from here?

48.3.2 A Panoply of Analytical Methods

Over the last half-century, ethnomusicologists interested in analysis have been grappling with the lessons of anthropological study and relativism, and we have learned that we cannot apply the same analytical approaches to every music culture. The paradigmatic analysis that Arom used to unravel underlying models and rules of variation for Central African polyphony, for instance, might quite aptly be applied to the Anlo-Ewe drumming examined by *Locke* [48.75]. Like those musics discussed by Arom, this tradition centers around short cyclic patterns varied by individual players, thus allowing the analyst to establish rhythmic models and equivalences. Or, as I have done for my analyses of Balinese improvised *arja* drumming [48.76], Arom's method could be emulated but then tweaked to suit the different style of cyclic variation in that tradition: one in which each set of paradigms does not trace to a single identifiable composition but rather a constellation of possible patterns then varied upon. For yet other styles, like the alap in a Hindustani rag performance, which does not have a steady rhythmic framework upon which equivalences may be found, paradigmatic analysis will probably be a much less fruitful approach. The analyst must choose from her/his toolkit of methods those that best suit the genre, so that, as *Marcia Herndon* puts it, *our conclusions about a particular piece* [can] *be checked by actual events within that piece, actual events within related pieces,* [or] *by informants* [48.77, p. 252].

Jonathan Stock has noted that detractors of analytical ethnomusicology *regularly censure music analysis as drawing on the values of the external scholar to the exclusion of those of the cultural insider*. He argues vehemently that *this criticism is intellectually unsatisfactory* and asserts that analysis lies [48.78, pp.189–190]

> *much closer to sensitive interpretation than dispassionate description when done well. Like ethnography, analysis is ultimately a means to develop and recontextualize understandings as we communicate them to our readers.*

Most of the analytical studies published in the last few decades fly in the face of the so-called anthropology-musicology divide, and many scholars are attempting to amalgamate music theory with social theory in their writings. *Thomas Turino* in his *Music as Social Life* [48.71] examines the ways that music can be socially meaningful. But the book is also [48.71, pp.1–2]

> *an introduction to some basic conceptual models that might help to illuminate why and how music and dance are so important to* [. . .] *fundamental aspects of social life,*

thus blending social theory with music theory. This more integrated approach has been at the center of many recent offerings in the field. In her article *Riffs, Repetition and Theories of Globalization*, for instance, *Ingrid Monson* presents a *detailed knowledge of musical practice* [as] *crucial in situating music within larger ideological and political contexts* [48.79, p. 33]. Marc Perlman agrees. In his work on Central Javanese *pathet* he has tried to show [48.80, p. 68]

> *how very close analyses of* the music itself *need not be divorced from issues of status, gender, or colonial history. The more detailed our technical analyses,* [he asserts,] *the more opportunities we will have to show how sounds and context are subtly intertwined.*

In my own studies of diffusion and change in Balinese *arja* drumming [48.81], a musical analysis of patterns from seemingly unconnected drummers was what led me to dig deeper, thus finding musicogenealogical links between them. Music analysis and social analysis, then, can be mutually beneficial, reinforcing and informing one another.

Anthropological approaches have also informed analysis in other ways. Methods of fieldwork have allowed many analytical studies to draw on concepts from local music theory. In his 2004 *Unplayed Melodies* [48.70], for instance, *Marc Perlman* relies heavily on the insights and expertise of master musicians from Java in order to unravel the implicit *unplayed* melodies upon which Central Javanese gamelan music is based. In his study of Balinese *gamelan gong luang* [48.82], *Wayan Sudirana*'s analyses are very much informed by ideas and terminology from interviews and casual conversations with individual musicians. And *Andrew McGraw*'s *Musik Kontemporer* [48.83] and *Radical Traditions* [48.84] equally draw upon ethnographic perspectives from contemporary Balinese composers and musicians.

In this more well-rounded world of analysis, each scholar chooses her/his own approach. What we have seen over the last 20 years is an explosion of new methods as well as attempts to resurrect and improve upon older ones. There is no style of analysis that dominates the scene. Some scholars will choose to apply well-established techniques to their studies, but often in surprising ways. *Jonathan Stock* [48.66], for instance, has suggested that Schenkerian analysis may be appropriate for some ethnomusicological studies, applying it to such diverse musics as the Kalasha praise songs of north-western Pakistan and Beijing opera. Others look farther afield, exploring interdisciplinarity in ethnomusicological analysis. Many of these scholars are revisiting Carl Stumpf's early interest in the psychology of music, borrowing theory and method from cognitive science. An important book from the 1990s incorporating musical analysis with cognitive studies is *Benjamin Brinner*'s *Knowing Music, Making Music* [48.85]. This insightful work sheds light on ways of knowing and concepts of competence through the lens of Javanese gamelan practice and performance. More recently, an article on improvisation in Indian classical singing by *Richard Widdess* [48.86] uses the concept of schemas – or cognitive maps – to examine processes of variation (*laykārī*). *Widdess* explores the idea that [48.86, p. 198]

> *both the singer's improvisation, and the listener's comprehension of it, depend on the simultaneous combination of pre-existing schemas, which enable the singer to arouse, and the listener to feel, varying degrees of uncertainty, expectancy and resolution.*

These are just two of many applications of cognitive science for analytical ethnomusicology.

In an environment where new approaches are encouraged and past approaches revisited and refined, there are far too many analytical methods in the modern toolkit to discuss them all here. In the following sections, then, we will briefly explore two quite different directions taken in recent years, both innovative, interdisciplinary approaches: the development of computational ethnomusicology and a return to comparative analysis.

48.3.3 Computational Ethnomusicology

The rise of new computer technologies has provided many opportunities for ethnomusicological analysis in recent decades. The use of computers and other machines by ethnomusicologists is by no means new – Charles Seeger developed the Melograph for graphic

transcription and the real-time analysis of pitch, dynamic, and timbre back in the 1950s – but a trend of using electronic tools for transcription and analysis did not follow for another 50 years. *Nicholas Cook* hypothesizes that much of this had to do with the strong reaction against comparative work in the mid-century [48.87, p. 103]:

> *Perversely* [...] *the possibility of computational approaches to the study of music arose just as the idea of comparing large bodies of musical data – the kind of work to which computers are ideally suited – became intellectually unfashionable.*

In the interim, some isolated studies have arisen, dispersed throughout various journals in many disciplines. Only in the last decade has there been a concerted effort to *gather relevant, high-quality research on computational methods and applications in ethnomusicology* into a unified, accessible forum for ethnomusicologists [48.88, p. 111]. Two important recent sources are *Tzanetakis* et al.'s introductory article in the *Journal of Interdisciplinary Music Studies* [48.89] and a special issue of the *Journal of New Music Research* (JNMR) from 2013 that presents several different studies on the topic (including [48.88, 90–92]).

Computational ethnomusicology, or CE, is understood to be *the design, development and usage of computer tools that have the potential to assist in ethnomusicological research* [48.89, p. 3], and beyond that, may have the capacity to develop [48.88, p. 111]

> theories *or* hypotheses *(not just* tools *as a spreadsheet or a statistical package can be) about processes and problems studied by traditional ethnomusicologists.*

Many recent CE studies are taking advantage of music information retrieval (MIR) techniques: tools that allow users to organize, search, and understand very large collections of data. Until recently, such techniques were largely used for popular applications, such as selecting music for personalized radio stations, query-by-humming [48.93], automatic genre classification, and tempo tracking. The potential benefits of such tools for the academic musical analysis of large data corpuses have only begun to be examined: analyzing pitch use or finding recurring rhythms or melodic patterns in collections far larger than a human could do by hand, transcribing for microtiming, analyzing minute physical performance gestures, searching for structural patterns in large collections, and so on. *Joren Six* et al.'s contribution to the JNMR special issue [48.92], for instance, introduces a modular software platform called Tarsos, which is designed to precisely extract pitch in recorded music of any tradition and, more importantly, to analyze pieces for their pitch distribution and organization. Figure 48.11 shows the various components of the Tarsos platform, which begins with a digital audio input, extracts pitch estimations, draws a histogram of pitch distribution, and finally creates an audio output of the result.

A tool such as this, if sensitively applied, could provide accurate cross-cultural pitch distribution analysis of a kind Ellis and Hornbostel could only dream.

Other applications of CE focus on the precise analysis of rhythm and timing, something for which computers are better suited than the human ear. In *Rhythm Analyzer* [48.94], *Kenneth Lindsay* uses computational analysis to measure *swing* in various recordings of Reggae, Afro-Brazilian music, and Western pop. *Cornelis* et al. [48.91] discuss the problems in using a computational approach to address tempo perception and levels of meter in Central African music. And even as early as 1993, *Jeffrey Bilmes* [48.95] was [48.89, p. 10]

> *work*[ing] *with multitrack audio recordings of Afro-Cuban percussion, extracting note timing, modelling note timing* [...] *and finally applying machine learning techniques to produce stylistically correct expressive timing for new phrases.*

Yet other applications of CE involve the classification of different pieces based on recurring rhythmic or melodic patterns. *Lin* et al. [48.96] have developed a method for determining the genre, or class, of a piece of music by identifying *significant repeating patterns* and then matching them to similar recurring patterns in other pieces of the same genre. Though their study shows varying levels of success depending on the genre being examined, its computational techniques provide interesting potential for more specific applications of pattern analysis. In his 2013 *Antipattern Discovery in Folktunes* [48.90], for instance, *Darrell Conklin* analyzes a large corpus of Basque folk tunes from different genres and identifies what he calls *antipatterns* – those patterns that are very common in most genres of folk tunes but rare or absent in one genre or set. In this way, he creates *negative association rules* for the identification of songs within certain sets of music, thus *predicting the absence of a genre based on the presence of a pattern* [48.90, p. 166].

Other studies using computational techniques attempt further levels of interdisciplinarity, interfacing with not only ethnomusicology but other fields of inquiry as well. In their *Computational Models of Symbolic Rhythm Similarity*, *Toussaint* et al. [48.97] test computational judgments of the relative similarities of different rhythms against human perception, thus touching not only on ethnomusicology, computer science, and mathematics, but also cognitive science.

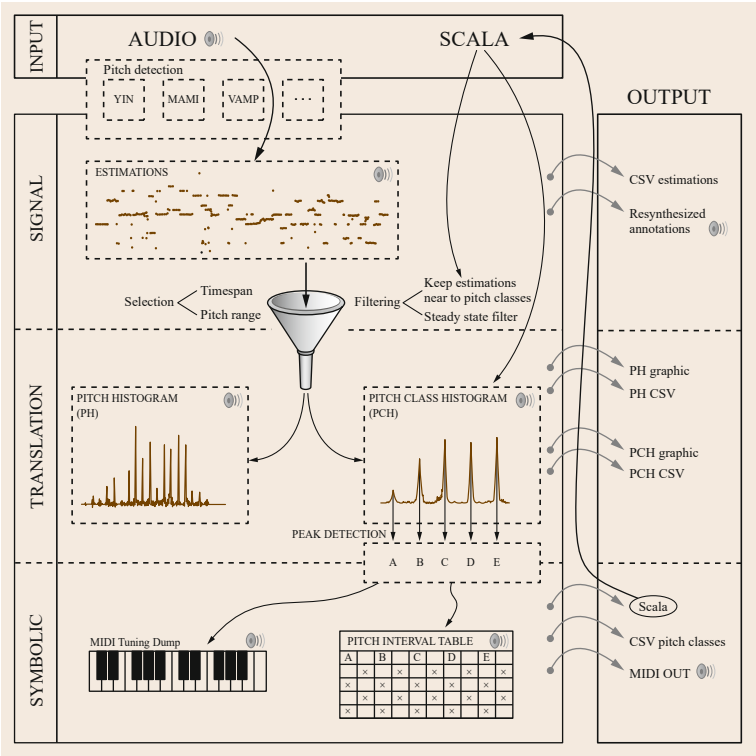

Fig. 48.11 The components of the Tarsos platform (after [48.92, p. 115])

It is hopefully clear from this limited examination that, though still a young field, computational ethnomusicology presents a number of new avenues for analysis and research. What will hopefully also be obvious, however, is that many computer-based tools are very useful for low-level analysis but, to be truly insightful, require refinement and, more importantly, interaction with music specialists. As *Tzanetakis* et al. state, we must [48.89, p. 12]:

> *actively seek interdisciplinary collaborations that include music scholars and technical researchers. Experimental results should generally be interpreted by music scholars with an understanding of the specific music(s) involved.*

Only in this way can domain-specific techniques and custom software be developed to tackle less general questions geared toward individual music traditions.

48.3.4 The New Comparative Musicology

The interest in interdisciplinary approaches currently fueling the growth of CE has also helped to reinvigorate comparative research. This renewed focus opposes the general perception in the field [48.3, p. 315]

> *that comparison is not only* old fashioned *but also in some sense unacceptable or even indefensible.* [... Of course] *most early comparative musicology was based on now long-discredited theories related to Kulturkreise and evolutionary ideas* [...] *No one wants to be tainted with such a brush, and there is irrational distaste for the whole idea of comparison as a result.*

Yet it seems premature to throw the baby out with the bath water. Comparative musicology was in many ways a groundbreaking, forward-looking, wonderfully experimental field. It brought together scholars of diverse specializations – both scientific and humanistic – and tried to grapple with some of the most basic questions of human existence: Why do we make music? What unites all musics and thus all peoples? Can we trace connections across the world through music? Perhaps these questions are impossible to answer in full, but without the latent Eurocentrism of Hornbostel's generation – or, more accurately, with a reconstructed, self-aware ethnocentrism cognizant of its own dangers – and with the benefit of a century's worth of insight and experience, old comparative methods and interests are leading to new analytical studies.

Comparative research in modern ethnomusicology takes many forms. In some cases, it involves the es-

tablishment of general theories that are cross-culturally relevant. *Michael Tenzer*, for instance, both in individual articles [48.98, 99] and edited works [48.65, 69] has established broadly applicable approaches for the classification and comparison of music according to its temporal organization. *Tenzer* asserts that *periodicity is really a universal, inseparable from a conception of music. This justifies choosing it as a framework* for analysis that may be applied across genres and across cultures [48.65, p. 23]. In his *Temporal Transformations in Cross-Cultural Perspective* [48.99], for instance, *Tenzer* examines concepts of time transformation cross-culturally by comparing instances of temporal augmentation in three distinct pieces of music – from Europe, South India, and Indonesia – and exploring how that temporal augmentation interacts both with the piece's musical structure and with the listener's orientation in musical time. He hypothesizes *that studying processes of* time transformation *cross-culturally can lead to musical and cultural insights* and, more broadly, *that cross-cultural research on musical temporality can lead to the discovery of some cognitive universals* [48.99, pp. 1–2]. In a very different way, *Judith Becker*'s *Deep Listeners* [48.100] sets up a theoretical basis for the cross-cultural analysis of high emotion and trance responses to music by drawing on new research from the fields of neuroscience and biology.

These sorts of universally applicable theories present their own unique set of problems. We know from earlier attempts at comparison that creating appropriate comparative categories can be daunting. At the first AAWM conference in 2010, Simha Arom raised this matter in a plenary session entitled *Ethnomusicology, Music Theory, and Music Analysis*. There, Arom made the contentious claim that if we wished to examine the concept of meter cross-culturally, we needed to provide the most neutral possible framework. Meter could not be defined as intrinsically multilevel and hierarchic as the growing consensus on the matter since the publication of *Lerdahl* and *Jackendoff*'s *A Generative Theory of Tonal Music* [48.63] asserted, because Arom did not see African music as having more than a bare skeleton of a hierarchy which, moreover, did not meet other accepted criteria for meter (typified by Lerdahl and Jackendoff's *preference rules*). Accounting for African meter in any encompassing definition meant abandoning what Arom suggested were biases favoring the structure of European musics, and therefore implied that asserting anything universal or cross-cultural meant only going for the minimal. At worst, this contention suggests that cross-cultural studies can only be shallow. Whether or not that is the case, the problem of defining meter nonetheless remains, and engaging in cross-cultural study demands reflection on these more difficult questions and the careful development of new solutions to old problems.

Two of the most avid proponents of reestablishing the comparative approach, *Patrick Savage* and *Steven Brown*, have proposed parameters and directions for a new comparative musicology [48.101], one that [48.27, p. 148]:

> *seeks to classify the musics of the world into stylistic families, describe the geographic distribution of these styles, elucidate universal trends in musics across cultures, and understand the causes and mechanisms shaping the biological and cultural evolution of music.*

This newer incarnation of the subdiscipline would avoid some of the pitfalls of earlier comparative studies by using larger sample sizes, focusing primarily on regional comparison, selecting appropriately sized units for analysis (e.g., individual songs, phrases, etc. as opposed to whole genres or cultures), creating culture-specific as well as more general and universal systems of classification, cross-culturally analyzing nonacoustic features of music – Merriam's *behaviors* and *concepts* – as well as music sounds, and so on [48.27].

The new comparative musicology demands mutually beneficial cross-disciplinary research, where anthropological, historical, biological, and linguistic studies, among others, help to inform discoveries in music research, but where the reverse is also true: where [48.27, p. 151]

> *knowledge of music's cultural evolution can be useful in illuminating* human history *more generally, including such phenomena as migration, colonialism, globalization, and other forms of cultural contact.*

In his provocative *Echoes of Our Forgotten Ancestors*, *Victor Grauer* [48.102] has attempted to do exactly that for the ancient populations of Africa. A collaborator on Lomax's Cantometrics project, Grauer uses song classification techniques to hypothesize that Pygmy and Bushmen groups, long isolated by geography, both maintain salient structural features of the same ancient musical practices. The striking similarities in their musics – interlocking polyphony made up of short phrases of continuous sound, repeated and varied, and sung in open-throated, blended voices with yodeling – he ascribes to a common ancestor. And he backs his theory with current research in genetic anthropology that has compared the DNA of Pygmy and Bushmen groups with that of other groups of black Africans and found

that the former two groups tend to have older mitochondrial and Y haplotypes [48.102, pp. 8–9]. Thus, the musical and the biological research support each other. And although Grauer's theories have not gone unquestioned [48.103], they provide a model for a very different kind of interdisciplinary analysis.

Much narrower in geographical scope but with the potential for large-scale insights is *Brown* et al.'s *Correlations in the Population Structure of Music, Genes and Language* [48.104]. This study examines the traditional group-level folksongs of nine indigenous populations in Taiwan using a modified Cantometrics system, called CantoCore [48.105]. The distance between each tradition in terms of its musical features is measured against existing information on mitochondrial DNA in the same populations to search for correlations. As we can see in Fig. 48.12, these measurements are most certainly connected.

In fact, this study shows stronger parallels between music and genes than between language and genes, and is thus [48.104, pp. 1,4]

> *the first quantitative evidence that music and genes may have coevolved* [and that music] *might serve as a useful marker to study human migrations and human origins more generally.*

Related to this sort of evolutionary study are the phylogenetic analyses undertaken by scholars like computer scientist Godfried Toussaint. Phylogenetics, which is a biological classification method that traces genetic links between organisms, is [48.107, p. 1115]

> *used to create a nested series of taxa based on homologous characters shared* [...] *by two or more taxa and their immediate common ancestor,* [and] *offers a means of reconstructing artifact lineages that reflect heritable continuity.*

For larger datasets in comparative study, computational methods are very useful, and *Toussaint* certainly uses these [48.97], but a smaller study will elucidate the method. *Toussaint*'s article on African ternary rhythm timelines [48.106] presents an analysis of ten 12-pulse, 7-stroke bell patterns from various African and African diaspora communities, shown in Fig. 48.13.

Toussaint measures the rhythmic similarity of these 12 patterns in terms of *swap-distance* – the minimum number of times one would have to move a note onset by one pulse in order to transform one pattern into another. These swap distances are then represented in a number of ways, including the swap distance matrix and phylogenetic SplitsTree shown in Fig. 48.14. Here the reader will notice a similarity between this style of distance tree and the one used by Savage et al. in Fig. 48.12. And, as *Toussaint* points out, with further research *these mechanisms may in turn shed light on the evolution of such rhythms* [48.106, p. 34].

48.3.5 The Challenges of Interdisciplinarity

It seems, then, that many of the most innovative new directions in analytical ethnomusicology are interdisciplinary. So now the question becomes how to do work in a multidisciplinary project that speaks faithfully to each field involved. Whether or not we wish it were so, each field to some extent speaks its own language and has its own assumptions and priorities. And while scholars like *Victor Grauer* [48.102] synthesize ideas from quite divergent fields without the help of collaborators, Steven Brown, in his presentation at the 2012 AAWM conference, opined that most of us cannot hope to become experts in all of these branches; we must instead build working partnerships with specialists in other fields. Indeed, part of the reason that Savage et al.'s study of Taiwanese folksongs was so insightful was that, of the five authors contributing to the brief seven-page report, one worked in musicology, one in evolutionary genetics, one in psychology, neuroscience and behavior, and the final two in the medical profession in Taiwan. Specialists from divergent fields working toward a common analytical goal can lead to insights in all these different disciplines, and I believe that this open collaborative approach is the future of analytical ethnomusicology.

48.3.6 What Happens Now?

With all these opinions and methodologies at our disposal, the role of an ethnomusicologist now is to select, from an ever-expanding toolkit, those approaches best suited to the individual genre or piece under examination. Each may draw into focus (and conversely, obscure from view) certain aspects of the music, and thus the researcher may wish to attempt analysis of a given piece or genre through several approaches. Some of the earlier methods – general description or trait listing or classification – are perhaps more broadly applicable. Others, like Schenkerian, paradigmatic, or phylogenetic analysis will only be useful for the examination of certain genres or pieces or datasets. The researcher may even need to invent her/his own method, inspired by some of those explored here and always informed by the music theory (oral or otherwise) of her/his teachers and collaborators within the culture under examination. And, as we have learned from many of the more recent studies in analytical ethnomusicology, interdisciplinarity and an openness to collaboration with scholars in other fields – from anthropology to biology to computer science – will be what leads to some of our deepest analyses, our most exciting discoveries, and our most insightful new questions.

49. Musical Systems of Sub-Saharan Africa

Simha Arom

The following chapter is a brief overview of Sub-Saharan music traditions based on our current knowledge. It seeks to fill a gap that exists in the studies done thus far because, to the best of our knowledge, no inventory of the essential parameters that go into the constitution of this region's musical systems has been made. This is probably due to the fact that ethnomusicologists specializing in African music as well as many others give priority to the cultural or anthropological context in which music practices have a function, rather than considering the subject itself – music – as a system.

In light of this situation, and while I am aware of the weaknesses and imperfections such an approach will have difficulty avoiding, it nevertheless seems worthwhile to make an attempt.

This chapter is not intended to be exhaustive but is rather, beyond its specific content, an attempt to provide a tool for study that is easy to use and practical to all those who are interested in and curious about the *grammar* that underlies the Sub-Saharan African music traditions: scholars, teachers, students, not to mention those on the creative end, notably jazz musicians and composers, and more generally all people interested in music from beyond Europe and those interested in the *manufacturing* of African folk music.

In my mind, the value of this work extends beyond the text to include collections of references and the selective but very rich *bibliography*. These collections are divided into the following categories: general characteristics of African music, the acquisition of musical knowledge, taxonomy, scales, time organization, form and structure, variations, polyphonic techniques in general, hocket and polyrhythm. Each one lists authors whose work covers these categories. Readers can then consult the bibliography for further study of an author or subject presented in the text.

Traditional Sub-Saharan music can generally be described as follows:

- It is transmitted *orally* with no written support.
- It is collective: the community as a whole ensures its perennity.
- It is most often *anonymous and undated.* We don't know *who* created it or *when*.
- It is *functional* – or more precisely, *circumstantial*. It is not conceived for use outside its sociocultural context.
- It is not the subject of abstract speculations by the people who practice it, so the theory that underlies the music is essentially *implicit*.

For *general characteristics* of African music, see [49.1–13].

The diversity of traditional music coincides with the diversity of the ethnic groups and subgroups as reflected in their specific languages and dialects. Each ethnic group or subgroup has its own dialect or manner of speaking that distinguishes it from all others. This same diversity exists in music. There are as many musical idioms as there are ethnic communities or languages and dialects in Sub-Saharan Africa.

The acquisition of the basis of musical knowledge goes hand-in-hand with language learning, ie, it occurs empirically. In the first phase, passive newborn babies absorb the music that surrounds them; as their motor functions develop, children progressively join in the various musical activities, first by clapping their hands in rhythm, then by singing, and finally by trying to play an instrument (for more concerning *music learning in traditional societies*, see [49.5, 12, 14–22]).

The consistency of African traditional music is manifested within each ethnic community, firstly through its *functionality* – in other words the social and/

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_49

or religious circumstances with which it is intimately linked – through the groups that are required for its performance, and lastly through the elements that constitute its systemic framework.

It seems important to immediately point out that functionality and musical systems are closely linked within ethnic communities. The relationships between the repertoires and the circumstances can be of three types.

Each circumstance that requires musical accompaniment corresponds to a particular repertoire, characterized by a specific number of songs, a predetermined instrumental ensemble and a set of rhythmic or polyrhythmic formulae that belong only to the music associated with this circumstance. Each repertoire is thus the equivalent of a musical category distinct from all other categories (on the subject of *categorization*, see [49.10, 12, 14, 18, 21, 23–37]).

One given situation may draw on several repertoires. Several repertoires may use the same rhythmic or polyrhythmic formulae. Within the same language group, people can share repertoires with the same name and functions. In some regions, the repertoires and the contexts with which they are associated are part of a broad dissemination network. Two or several populations with different languages share one or several repertoires with names and performance contexts that are the same.

The constituent elements of this music include the following parameters: pitch, time structure, timbre, form, structure, performance procedure and technical process. We will examine them one by one.

The *pitch system* is obviously related to the musical scales, which vary widely. They range, according to region or ethnic group, from the anhemitonic pentatonic system to the equiheptatonic scale, pentatonic intervals of whole or equidistant steps, tetratonic, hexatonic, diatonic scales and still others, without overlooking those that have movable degrees (depending on whether the melodic movement is upward or downward). In many cases, the same community uses various types of scales that are respectively linked to different repertoires (for more regarding *scale systems*, see [49.6, 9, 11, 12, 24, 25, 27, 31, 33, 38–58]).

The *structuring of time* is based on music that is almost always measured, i. e., within which the durations have strictly proportional relationships.

The great majority of forms of African music are based on a strict *periodicity*, determined by the occurrence of similar events at identical positions in a temporal cycle.

Periods are most often subdivided into a constant number of isochronic – i. e., equidistant – pulses, which constitute the *organic* standard with respect to which all of the durations are organized both horizontally – in the case of monody –, and vertically, within polyphonic and/or polyrhythmic structures. The *aksak* rhythm is the only exception to this rule. Borrowed from Ottoman music theory, this Turkish term means *limping*, i. e., *irregular*. It designates a rhythmic system in which pieces or sequences *performed in a lively tempo* are based on the continuous repetition of a module characterized by the uninterrupted repetition of alternating binary and ternary rhythmic cells (such as $2+3$, $2+2+3$, etc.). These cells are most often grouped in odd numbers. These groupings and the manner in which they are arranged determine the form, the structure and the articulation of the *aksak*. In Sub-Saharan Africa, *aksak* is used by the Mofu (Cameroon), the Bulia (Democratic Republic of Congo and Republic of Congo) and the Ju/'Hoansi-San (Namibia).

It can be seen that this time organization differs considerably from the Western conception, in that it most often ignores the intermediate level of the *measure*, i. e., a regular accented scheme based on the alternation of a *strong* beat with one or several *weak* beats.

The pulse is subdivided into smaller values, according to a binary or ternary principle. These are the *minimum operational values* through which all durations – in both vertical and horizontal terms – are organized (for more concerning the *structuring of time*, see [49.2–5, 10, 12, 14, 18, 23, 30, 31, 33, 34, 37, 40, 41, 46, 48–50, 54, 59–87]). However, in certain geocultural areas, much of this music contains two simultaneous pulses in a ratio of $2:3$, one involving two minimum values, the other three. This is the *hemiola* principle.

Timbre refers to the *tools* that contribute to the materialization of the music, i. e., the voice and the instruments.

Certain repertoires require only male voices, while others make exclusive use of women's voices. Others still are reserved for only children's voices. Collective music most often combines both voices and instruments.

The combinations of instrumental timbres may be put into three categories, described below in descending order of frequency of use.

- Different types of instruments played together (a xylophone accompanied by two slit drums, a rattle and a pellet, for instance).
- Various instruments of the same type, e.g., two or three xylophones, accompanied by one or several different percussion instruments, such as idiophones and membranophones (as above).
- Lastly, groups in which all of the instruments are of the same type, but of different sizes. This is often the case for ensembles of horns or whistles, which can

include up to twenty instruments, such as xylophone and drum ensembles.

Let us remember that in a traditional environment, the instrumental group, i. e., its specific composition, considered in terms of the instruments that it includes is most often closely associated with a particular circumstance or set of circumstances.

With regard to *forms and structures*, it is important to draw a distinction between music that allows for no modification and music that is renewed and recreated with each performance. The former is very rare and almost always associated with events of a historical nature or part of primordial liturgies. It is *frozen* music, as opposed to the great majority of forms that allow, within extremely strict periodic, metric and rhythmic structures, a degree of freedom left to the performers, thereby allowing them to produce numerous variations, and in some cases genuine improvisations (for more regarding *forms, structures and patterns*, see [49.2, 4–6, 10–12, 14, 18, 23, 34–37, 41, 46, 49, 54, 56, 60, 62, 74, 80, 88–99]).

A second distinction must be made between music that is strictly cyclical, i. e., repetitive, which can be referred to as *closed*, and forms of music that can be called *open* because its performance is based on the irregular alternation of diverse juxtaposed periodic structures, leading to very substantial works. But regardless of whether they are open or closed, these forms of music – with rare exceptions – always leave the performers a wide range of freedom within which their spontaneous creativity can be expressed (for more regarding variation, see [49.2–5, 9, 12, 14, 20, 21, 23, 40, 42, 45, 46, 49, 50, 63, 64, 66, 68, 71, 74, 77, 83, 96, 100–108]).

The *modalities of performance* refer to the distribution of roles within a musical event, for example:

- Between a vocal soloist and a choir
- Between a singer and an instrument on which the singer accompanies himself or herself
- For more diversified groups, between the sung parts and the parts of the instrument that accompany them.

In the first case, the most frequent situation is a regular alternation between the two protagonists: either the choir exactly repeats the melodic unit sung by the soloist, in which case we say that the singing is *antiphonal*, or the choir completes it, making the music *responsorial* in nature.

In general, a singer who accompanies himself or herself on a melodic instrument also divides the period of the song into several segments, some assigned to their own voice, which the instrument of course supports, and other segments which respond to it. An ongoing dialogue develops between these two elements, instilled with the same spirit.

Such a distribution of roles is not random. On the contrary, it stems from a perfect rationale based on the *principle of complementarity*. By corroborating the coherent segmentation of the musical discourse, the performance procedures constitute a precious clue for the discovery of its underlying structure.

With respect to the *technical processes*, we must make a distinction between *monody* and *plurivocality*, i. e., polyphony in all of its aspects.

Monody can be vocal and/or instrumental. When the singing is duplicated by a melodic instrument, it is frequent that the melodic and rhythmic coincidence between the two is not absolute. This sporadic phenomenon – which is often deliberate – generates the most rudimentary form of plurivocality called *heterophony*.

Polyphony in the strict sense involves one of the following processes:

- *Overlapping/tiling* (*tuilage*) This refers to the sporadic overlapping of two musical sources for which the realization follows a principle of alternation between two protagonists (soloist and choir, two soloists, or two choirs) in antiphonal and responsorial singing, which is very common in Africa. There is tiling when one of the protagonists intones before the intervention of the preceding one is finished.
- *Drone* This refers to one or several notes that act as a base for one or several melodies performed simultaneously.
- *Parallel movement* This is very widespread in vocal music; it proceeds mostly with either intervals of fifths and fourths, or with sixths and thirds.
- *Divergent motion* This can be either *homophonic*, when the rhythmic articulation is the same for all of the parts present, or *contrapuntal*, when the various parts are rhythmically independent. The use of counterpoint, while relatively widespread in instrumental music, is quite rare in vocal music. It is used however by Pygmy and San people (in Central Africa, Namibia, and Botswana) as well as by the Dorze (Ethiopia) and the Bateke (Gabon) (for more on *polyphony in general*, see [49.1, 6, 8, 11–14, 18, 20, 23, 29–32, 35, 42–46, 49, 50, 54, 60, 66, 69, 73, 78, 83, 85, 97, 101, 102, 104, 106, 109–131]).
- *Hocket* This can be used in three ways:
  - *Strictly vocal*, or *a cappella*
  - *Instrumental*, with instruments of the same type (horns or whistles), each of which usually produces the same sound at a predetermined pitch

  - *Vocal-instrumental*, where each of the performers alternates between sung sounds and instrumental sounds (concerning the *hocket technique*, see [49.11, 12, 14, 23, 29, 32, 40, 42, 46, 78, 96, 102, 108, 116, 127, 129, 132–134]).
- *Polyrhythm* Most African folk music is supported by instrumental ensembles composed of instruments that are strictly percussive in which the pitch relationships are not relevant. They provide the periodic and the metric framework for the superimposed melodic events and the music that these ensembles play is based on the *crossing of diverse rhythmic patterns in which the reciprocal accents are offset.* The result of this is an extremely dense – but always coherent – entanglement of antagonistic rhythms and through this a polyrhythm in which the matrix is as dense as it is complex (for more regarding *polyrhythm*, see [49.2, 3, 5, 9, 11, 12, 14, 18, 23, 34, 40, 42, 45, 46, 49, 50, 54, 60–62, 64–66, 68, 71, 73, 74, 76, 80, 83, 88, 92, 94, 96, 101, 106, 107, 112, 114, 135–139]).

Over the course of time, within each geocultural area, and often each ethnic community, musical heritage has followed a process of evolution through innovation and/or borrowing. This explains the extraordinary richness and the enormous variety of the types of music found on the African continent.

While the depositaries of these forms of music do not make them the subject of abstract speculation, all traditional musical idioms in Africa, inasmuch as they always obey a set of rules, are well and truly covered by a theory and thus constitute a *system* in the full meaning of the term.

Acknowledgments. I express my gratitude to Sylvie Le Bomin for agreeing to read this text and for her judicious remarks.

50. Music Among Ethnic Minorities in Southeast Asia

Håkan Lundström

In the countries of mainland Southeast Asia there are several ethnic minority groups, particularly in the mountainous inland and in forest areas. There is much variation between the customs of these peoples but it is also possible to see similarities on a metalevel. In this chapter strong traits in the village-based music culture of the ethnic minorities are presented, in some cases on purely historical grounds. These traits are in many cases paralleled in the tradition of the majority peoples. Against this background follows a discussion on musical change and matters of sustainability.

The geographic and cultural location of mainland Southeast Asia, bordering the influential old cultures of India and China, is evident in its traditional music as well as in many other aspects of life. Generally the modal systems and the use of microintervals, as in the Vietnamese classical tradition, are seen as influences from India. Certain musical instruments and music dramas appear to have a Chinese background like the *tuong* in Vietnam. In the most southern part there are also influences from the Middle East.

On the other hand, Southeast Asia, including insular Southeast Asia and the southern parts of China, has since early times been a cultural area with a number of distinct practices that have spread to the courts of imperial China, Korea and Japan. Musical instruments made from bamboo are abundant, including tube zithers, from simple bamboo tubes with one string to modern refined zithers. Gongs and xylophones, in combination with the musical organization called colotomic, are present in Thai and Laotian ensemble music and all over East and Southeast Asia. Another factor considered original for the area is the free reed, a construction present in mouth organs like the Laotian *khene*. To this can be added the manner in which poetry and music have met in partly improvised vocal music, as in Laotian *mo lam* and Vietnamese *quan ho*.

These are some of the musical practices in Southeast Asia that have resulted from people moving from one place to another and from political power. They have been integrated through history and developed into what are now recognized as characteristics of Southeast Asian music. This is not to forget the influence of European music from colonial times on – chiefly Christian music, school music and classical music – or various forms of popular music in the global age and the emergence of hybrid musical styles.

This chapter will deal with the music of the many ethnic minorities in Southeast Asia, some of which are lowland farmers of irrigated rice, while others grow dry rice on mountainsides and mountaintops. Al-

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_50

though the terms majority and minority peoples are not unproblematic, they will be used here for practical reasons. The focus will be mainly the highlanders in the mountainous inland areas, including Yunnan in southernmost China, which is culturally related. These are the peoples that sometimes have been referred to as *hill tribes* or *mountain people* belonging to four dominant language families, namely the Sino-Tibetan, Austroasiatic, Tai-Kadai and Hmong-Mien languages. Most are traditionally villagers for whom dry rice farming, hunting and fishing have been the main source of food.

While the published sources are limited, *The Garland Encyclopedia of World Music* contains an overview [50.1] as does *Neues Handbuch der Musikwissenschaft* [50.2]. There are only a few monographs on music of minorities [50.3–6], musical instruments [50.7, 8] and verbal arts including songs [50.9–14]. The majority of the available material is in the form of articles in various journals and ranges from general descriptions of minority music cultures to studies of songs and specific musical instruments. There are a fair number of audio recordings, often with valuable comments. There are very few studies that attempt to present the music as integrated in a cultural context so the best sources in this regard are actually anthropological studies, which often include information on music. Beside some old iconographic sources and ancient Chinese writings, information about more recent history can be found in publications by explorers – mainly French – from the latter part of the 19th century and the beginning of the 20th century.

The music cultures of the ethnic minorities demonstrate a wide variety of musical expressions and musical instruments. Traditionally most of these peoples live in villages in the mountainous inland areas and are mainly rice farmers and hunters. This is reflected in their music, which is often related to major seasons during the farming year, particularly the harvesting season. The music also reflects the religious life. Ceremonies directed to the ancestor spirits or to the rice soul are especially important, like the buffalo ceremony when a water buffalo is slaughtered as a sacrifice to certain spirits. In such ceremonies gongs and drums usually play a central role.

The social uses of the music are evident in ensembles where each member can produce only one or very few tones. This is the case in the gong ensembles, but also in certain flute ensembles. Much of the singing is done as alternating singing, often between a man and a woman or a group of men and a group of women, often when courting or as pastime during festivities. Typically the singing uses a basic melody frame that is lengthened or shortened depending on the words. It is a kind of poetic recitation that often leaves room for variation and improvisation.

The examples considered in this chapter stem from a few of these cultures and while they are representative in a general sense it must be mentioned that even though the musical traditions may seem similar on the surface the amount of variety is astounding, even between neighboring villages of the same minority. Many of these minority cultures and their languages are now counted as endangered. The musical practices that are mentioned in this chapter will serve as a background for a discussion of change and sustainability.

50.1 Singing Manners

One of the earliest transcriptions of a song – in French translation – is a sung dialog between a boy and a girl recorded in north Laos in an area inhabited mainly by Kammu (Khmu or the similar) people. As is still done today, the boy starts by praising the girl's beauty while she politely replies belittling herself as being ugly [50.15]. A couple of decades later another song was published in the author's own transcription of the Kammu language. This was the time of year when the forest was to be burnt in order to make fields and a ceremony was held that included bronze drums, gongs and cymbals. One group of boys and one group of girls then sang in alternation and the author says [50.16, p. 197]:

> *I have in vain tried to learn the meaning of these two songs. Oddly enough everybody knows them by heart and no one can explain them. Could it be a foreign language or an ancient form of today's Kammu which now has become incomprehensible?*

Though the words may actually be incomprehensible to some extent even to the singers and indeed very difficult to translate, this particular song still exists and can be found in variants [50.14, p. 181] or reconstructions [50.13, pp. 5–6].

These are examples of the few but important cases where historical records can provide a background for the study of contemporary practices. In the case of alternating singing there is definitely continuity: the practice is still very widespread in this area and found among practically all the minorities. Alternating singing occurs in a number of situations when there are two or more

people present, who take turns singing either as a response to a sung statement, or in continuation through songs linked to the previous song by some sort of association. It could be a sung dialog between two persons of the same sex or between a male and a female, particularly in a courting situation. As quoted above, alternating singing may also be performed by two groups of singers responding to each other. At parties where more people are present alternating singing may take the form of chains of linked songs. Courting singing is not always a private matter between a boy and a girl, but can also be a more ceremonial situation where the parent generation is present as is the case among the Lisu in northern Thailand [50.17, p. 51ff.]. A well-known ceremonial courting tradition with alternating singing belongs to the Hmong New Year, spring and harvest festivals in Yunnan, China, and with some variations among Hmong in Southeast Asia [50.12].

50.1.1 Monomelodic Styles

The words of the songs may be preexisting orally transmitted poems – normally with an amount of variation – or they can be totally or partially made up on the spot. The singing is normally based on one basic melody, a melodic template that can be altered with regard to pitches and length as different words are sung. Such a template usually has a rather distinct starting formula as well as ending formulae at the end of the phrases, while the middle part is where variation will occur. Often it starts high with a word meaning *oh*, *hey* or similar and then ends lower, but there are variations to this (Fig. 50.1).

People may sing like this when they wander alone in the forest or in the fields, but the most special singing situation is when there is a party in a village, in connection with certain ceremonies or when somebody visits the village. People sit down in a circle and sip rice wine through straws from a common large earthenware pot. At these times people sing to each other and a song is expected to get an answer. The poems deal with many things. Loneliness during travels and yearning and love songs are common categories, but a very high proportion deal with human relations. This kind of singing did not appeal musically to early explorers or musicologists, who found it monotonous and primitive, as in this case referring to *Kha* in Laos [50.18, p. 46]:

> *The singing of the jar is limited to the 'tribal' phrase, often short and monotonous. In no way do they re-echo the magnificent and important ensembles, choirs and drums . . .*

This reflects the fact that singing cannot be understood by analyzing the music alone, but that the language aspect and the context must also be taken into account. In so doing this kind of singing turns out to be a complex creative activity.

Taking the Kammu in northern Laos as an example, in principle each dialect area has its own melodic template, each village its own variant of it and each individual a personal variant of the village template. Basically the melodies of neighboring villages are rather similar, but the farther away you get the more different the melodies. Looked at from an outside perspective these melodies may at first seem very much alike, but to the insider all the nuances are perceptible. Parts of the template include vocalices – particularly in the beginning and end of phrases – and other parts contain the words of the poem or song. In some dialect areas – like Kammu tonal dialects in the western part of north Laos with two tones – the vocalice parts are short, while in the nontonal Kammu dialects to the east large portions of the template consists of vocalices. There Kammu women may play the vocalice part on the flute while also sounding their voice. In the parts where the words

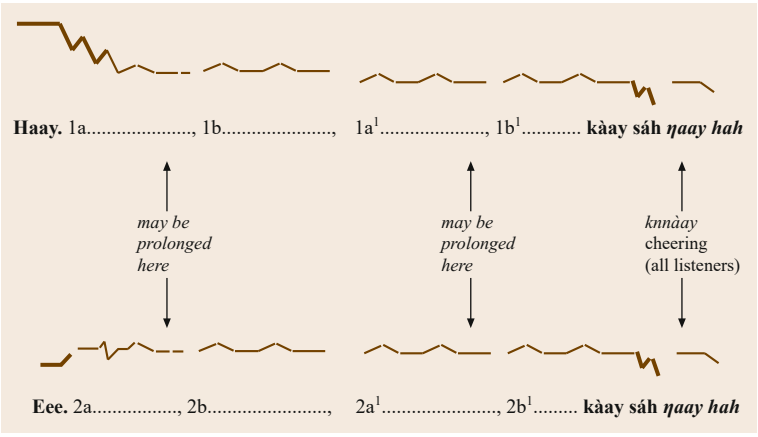

Fig. 50.1 Approximate graph of the west (Yùan) Kammu musical template including introductory and final formulae (in *bold*)

Table 50.1 Situational framework for singing in Kammu culture

Social	Sex/age: Status: Relation:	Man/woman/young/old Higher/equal/lower Friend/relative/formal
Spatial	Local level: General level:	Village/fields/forest Individual/village/area/country
Chrono-logical	Taboos:	Calendrical/seasonal/life cycle

are sung they use only the voice and then again return to the voice-and-flute playing of the next melisma [50.19].

In a singing dialog one is expected to praise and beautify the person(s) the song is directed to and to deprecate and belittle oneself and one's own belongings. Several songs exist in pairs of praise and belittling functions, particularly for beginning or ending of a singing dialog. The songs do not necessarily build up to a continuous and straight conversation, but rather resemble a chain of telegram-like units, often also including symbolic messages. This singing has a strong social meaning and taking part in the singing means expressing one's own identity and reinforces one's cultural belonging.

This manner of singing is called *tɔ́əm* and the poem that is performed is called *trnə̀əm*. Each song can be understood as recreated in the performance situation by the combination of traditional poems, stock words or phrases and occasionally instantly improvised words and a melodic template. This is a creative process involving *musicopoetic* (musical, poetic, linguistic) competence as well as *situational* (social, spatial, chronological) competence since the singer must choose words, polite phrases and even melodic template with regard to the context: Where does the singing take place? What is the occasion? Who is present? The aim is a functional and aesthetically satisfactory performance [50.6] (Table 50.1).

A common denominator in alternating singing is the use of one basic melody or tune: a melodic template that is varied according to the words. This can be referred to as a *monomelodic* practice and it is very common among most peoples. The Lisu in northern Thailand have different templates for singing in courting, festival and soul-calling contexts [50.17, pp. 56–59]. The songs of the Mnong Gar of Vietnam are reported to have a high degree of variation from one singer to another and evidently also by the same singer. One song can be used in several situations. To sing is called *tong* and to sing in exchange is called *tâm tong* (*tâm* = exchange) [50.20–22]. This practice is also found in other places, notably the *shange* (or *mountain songs*, a term often used to designate monomelodic exchange songs among various peoples) of southern Jiangsu in the Shanghai area in China that have *tune regions* and *textual regions*. Texts have a *supraregional* distribution whereas tunes are limited to smaller geographic units that to some degree coincide with dialect areas. Some singers know up to ten such tunes, usually with a strong preference for one of them. Singers sometimes attach the name of their village or county to it [50.23, pp. xii, 1298–1131, 267]. This is very similar to the Kammu of northern Laos and certainly several other minorities. It also parallels practice in traditions of the Laotian major population where local styles of *lam* or *khap* singing are are often named by city, village or area [50.24, pp. 96–100].

50.1.2 A Monomelodic Organization of Vocal Genres

Many – or most – ethnic minorities in Southeast Asia have vocal genres similar to the Kammu *tɔ́əm*. Among the examples in the literature are studies of songs among Sino-Tibetan peoples such as the love dialog songs among the Hmong Blanc in northern Thailand [50.12] and Lisu singing [50.4], [50.17, p. 56ff.]. The songs of the Lawa in northern Thailand are sung to one melody, which is adjusted to the rhythms and intonation of the Lawa language [50.25]. In insular Southeast Asia similar types of singing exist, for example in Sabah [50.26, pp. 50–51]. This mono-melodic singing is often described as not really singing and characterized by terms like *recitation*, *chanting* or *heightened speech*, which indicates that these English language terms are culture specific just like the terms *song* or *singing* are. Therefore they are actually ethnocentric and not applicable in all music cultures.

This becomes clear when one looks closer at monomelodic singing. In the same Kammu village tradition there are several genres, each with its individual name, its individual melodic template and its individual use context. Though some poems, *trnə̀əm*, are specific to certain situations many of them can be performed – or recreated – in any of these genres by a person who knows the techniques involved. The genres thus function as different representations of the *trnə̀əm* in different contexts. These are represented in Table 50.2.

While the terms for each genre are quite specific, Kammu people would normally differ between *singing* and *talking* in a general sense. For instance, *tɔ́əm* would be considered *singing* and *hrlɨ́ɨ* would be described as more like talking. One must accept that general terms like these are not very specific, neither in Kammu nor in English. In a scientific context they are therefore not very useful and could actually mislead a researcher trying to understand a specific music culture. In order to

Table 50.2 Vocal genres in Yùan Kammu tradition

Vocal genre	Melody	Situation	Performed by
Táɔm	Template, longdrawn, falling	Partying, in village	Male/female
Hrlíi flattering words	Template built almost totally on word tones (Yùan Kammu languages have two word tones)	In village when no party, in fields	Children, youths, male/female
Hrwə̀	Template built on a short melodic motif	Fields, forests	Adolescents, male/female
Húuwə̀	Like *hrwə̀* with recurring refrain	Fields, forests	Adolescents, male/female
Yàam weeping	Template built on a recurring melodic motif	Fields, forests	Mainly female, also children

avoid this the term *vocal expression* is useful for describing a performance that is neither song nor speech – or a little of both – and *vocal genre* may be used for the subcategories of vocal expressions [50.6, pp. 15–16].

Aside from a number of other categories of vocal expressions belonging to rituals, ceremonies or other situations, the vocal genres of the Kammu may be seen as a system of monomelodic organization. Evidence in written sources points toward the existence of similar organizations in other minority cultures. Among the White Hmong in Thailand there are different singing genres and each has its own fixed melody [50.12, p. 14]. Similar systems may lie behind two reports concerning the Mon-Khmer-speaking groups Jeh and Rengao in Vietnam [50.27], [50.28, pp. 153–163]. It is likely that the lack of literary references to similar category systems stems from the fact that this special feature has not been particularly studied. Therefore more research is needed in this area in order to reach an understanding of vocal tradition.

50.1.3 Tone Languages and Music

Many of the languages in Southeast Asia are tone languages, which means that anything from two up to seven tones are used to decide the meaning of spoken words. In most of the traditional singing the language tones are also reflected in the pitches that are sung, though this can be done in many different ways. Normally the beginnings and ends of phrases are determined by the melodic template, (*music centration*), while the rest of the template may be dominated by the word tones (*language centration*).

The execution of the word tones may make two performances built on the same template sound quite different. It is therefore possible to perform a song by whistling or on a leaf, a flute or a fiddle so that a listener who knows the language, the culture and the context can understand it. This means that instrumental performances may sometimes actually be specific songs performed on an instrument. This capacity is commonly used in the courting situation where mouth harps or other instruments may serve as voice disguisers or voice surrogates. In this way a secret message can be communicated without actually pronouncing it with one's natural voice.

Hmong girls in Sapa, close to the Chinese border in northern Vietnam, usually play the mouth harp in order to call a boyfriend. The player thinks the words of a song and plays them on the instrument so that a listener can recognize the song and understand its contents – and often recognize who is actually sending the message. Mouth harps that may be made from bamboo or from laminated bronze in the shape of a bamboo leaf produces a buzzing low tone and the player can alter the harmonics by changing the form of the mouth cavity. In this way a whistling melody built on harmonics can be created. This is a widespread practice and in Kammu and Lamet tradition the mouth harp is primarily a boy's instrument used by boys for serenading outside a girl's door. The girl can recognize who it is from the playing style [50.13, p. 381ff.], [50.29, p. 100], [50.30].

Some wind instruments are equipped with a free reed of bamboo or metal fastened to the side of the instrument. The player will cover the section with the reed with his lips and it will produce a characteristic sweet and mellow sound when blown. One such instrument is a side-blown horn from a gaur or a water buffalo with a free reed of copper fitted onto its side. When it is played the opening is covered by one hand and a small hole at the narrow end of the horn is alternatively open or covered by the thumb of the other hand. It was used for signaling when a larger animal – like a deer or a gaur – had been killed in hunting. The side-blown horn with a free reed is widely spread among ethnic minorities in Southeast Asia and it often has ceremonial or ritual functions. Among the Mnong people in Vietnam it is played to call, inform and entertain during community activities such as the buffalo ceremony, when a buffalo is sacrificed to the ancestor spirits.

Similar constructions can be used on side-blown flutes as well, but the reed may also be placed near the top end of the flute and kept inside the mouth cavity when the flute is played so that it is held aslant. Though this construction can be found elsewhere, for instance among the Tai people, it is often referred to as the *Hmong flute* since its mellow sound is considered char-

Fig. 50.2 Detail of the top end of a free-reed Hmong flute. A narrow tongue has been cut out from the rectangular brass piece. When the flute is played it is held so that the lips cover the whole area and the reed that produces the tone can swing freely. (Photo: H. Lundström)

acteristic of the Hmong people (Fig. 50.2). This kind of flute is often used for love songs performed so that the melody reflects the different tones of the language and a listener can understand the words from listening to the flute (cf. [50.31]).

In the mouth organ several free-reed pipes of different lengths are placed together in a wood, bamboo or calabash container that the player blows into. It can sound more than one pitch at a time and usually one or more pipes also serve as drones. The mouth organ exists in a number of different shapes and is unique to Southeast Asia and East Asia. In the *khene* of Laos, the pipes are arranged in two flat rows parallel to each other and protrude below the wind chamber.

The Hmong variety of the *khene* (*qeej*, pronounced *geng*) has six rather long free-reed pipes in a wooden wind chamber. It is played by males in combination with movement and has many functions, particularly for love exchange and for communicating with spirits at ceremonies. In funeral ceremonies the *khene* is used for a set of melodies for the different steps of the ritual. In this ritual context the *khene* speaks by playing the words of the ritual songs using the seven word tones of the language. Like with other instruments it is not a simple illustration of the word tones. The words are rather transposed into the idiomatic resources of the instrument and may not be easily understood by a listener [50.32]. At certain times after a funeral the song of guidance to the dead person's soul is performed on the *khene*. This is an instruction to the soul explaining how to get to the land of the dead [50.33] (see also for Kammu ritual *Svantesson* et al. [50.34]). The Samre and other peoples in the Cardamom mountains in northwest Cambodia also use mouth organs at funerals as well as other ceremonies and often as accompaniment to singing [50.35].

50.2 The Sounds of Bamboo and Metal

Bamboo that grows in the area from insular Southeast Asia to Japan in the East is a cheap, strong and versatile material of great importance in many aspects of life. It is used for house building, for constructing tools and kitchenware as well as for musical instruments. Another material that has played important roles in this area is manmade, namely metal and various alloys of metal. The knowledge necessary to produce metal objects is known through archaeological findings and is believed to have started in the so-called Dongson culture that existed in the most northern part of today's Vietnam more than 2000 years ago, which is famous for its bronze drums.

50.2.1 Bamboo and Musical Instruments

Since it is hollow, a simple piece of bamboo emits a sound when bounced on the ground, when struck or when clapping one's hand close to the opening and can be fine-tuned by adjusting its length to the air it contains to get the best resonance. In some places stamping tubes are used as single tubes bounced against the ground, for instance at Kammu house-building feasts, but they are also made in series of different sizes tuned so that they produce different pitches when bounced against the ground, a wooden log or a stone. Each individual may handle one or two tubes, producing as many pitches. Among the Senoi and Temiar in Malaysia such ensembles of stamping tubes are used at trance-dancing ceremonies where a medium, often female, serves as a lead singer and brings words that are repeated by a chorus [50.5].

The sound of stamping tubes is rather warm and soft as it is created by the shock when the tube hits the ground or log, which sets the air inside the tube in motion. A similar effect occurs when clapping one's cupped hands in front of the opening of a tube, much in the same manner as producing sound by clapping the

hands together in front of the mouth cavity. A tube of a particular length will produce a distinct pitch. Several tubes of different sizes can then produce different pitches like the *k'long put* of the Sedang, Jarai and Bahnar in Vietnam. Among the Brau one man holds two long bamboo tubes cross-wise and one female at each opening creates the sound. Two of them clap their hands together alternately in front of either opening of the same tube. One of the two beats a rhythmic pattern while the player at the opposite end of the same tube alternates between dampening that sound by hitting that opening with the palm of her hand or permitting it to sound. This is *ding buk*, played in connection with clearing trees for making fields (Fig. 50.3).

Bamboo tubes can be further fine-tuned by cutting off a piece aslant so that it gets the shape of a large goose quill – or a bamboo spear for that matter – with one end serving like a tongue and the other as a resonating chamber. Such tubes occur as single tubes struck with a beater of some kind or as concussion tubes made from a pair: one large tube and one shorter, like in the *kltɔ̀ɔŋ* of the Kammu that can be found all over the area. Its sound is generally more percussive than that of the stamping tubes. The *ko kleh* of the Sedang in Vietnam consists of three such tubes of different sizes tied together in a frame and struck with a short wooden stick, producing both rhythm and pitches. When such tubes of different sizes – and pitches – are placed lying down on two parallel ribs or on the player's outstretched legs they become a xylophone. A xylophone may also be made by suspending them hanging on parallel ropes like the *trung* of the Bahnar in Vietnam.

Fig. 50.3 The *ding buk* of the Brau people. Three women sound the tubes by clapping their hands in front of the opening. The fourth (*far left*) dampens the sound of that tube. This photo has a foklorized touch to it. Minorities are also often depicted in pastoral situations like this one in scientific documentations. (Photo: Vietnamese Institute for Musicology)

The Kammu *tàaw-tàaw* is an idiophone made from a piece of thin bamboo, which is split and cut so that two tongues are produced, which vibrate when struck and thus produce sound. The instrument is held in one hand and the split end is struck against the wrist of the other hand. It produces a buzzing sound, which serves as a drone when partials are produced, much like a mouth harp. A fingerhole on the handle side, handled by the right hand thumb, and sometimes a second hole on the other side of the tube, operated by the first or second finger, increase the sound possibilities of the drone and consequently also the partials. Further variation is obtained if the open handle-end of the tube is dampened by pressing it to the chest or thigh. This instrument is typically used by Kammu women while walking along forest paths as the sound is thought to scare off wild animals [50.36, p. 199].

Pitches may also be produced by cutting out a string from the rind of the bamboo, which produces an idiochordic bamboo zither. The string is kept stretched by means of a stick serving as bridge at either end. In the middle of the tube, under the string, there may be a small sound hole. The tube is open at both ends. If there is a node at one end, a small square opening will be cut through the wall there and the sound quality can be changed when dampening it by pressing the end of the tube to the chest. There may be more than one string or strings of other material may be fastened to the tube. It may be plucked by the fingers like the *kərantuŋ* of the Temiar in Malaysia and equipped with resonating chambers made from calabash like the *goong* among peoples in the North Central Highland in Vietnam.

Bamboo is perfectly suited for a variety of musical instruments. Many of the instruments mentioned here can be easily made in situations when there is much material at hand like during house building or when working in the fields, and they can easily be thrown away unless they have a ritual meaning of some kind. The variety of constructions and of sonorous qualities is very large. Some of these variants, like zithers and tubes, are considered to have had important roles in the evolutionary processes that have led to instruments that are particularly common in the majority cultures, like tube zithers and xylophones [50.37].

50.2.2 Bamboo Ensembles

Around the year 1900 a French traveler described how he was greeted by bamboo orchestras when approaching Kammu villages in northern Laos and was accompanied by villagers into the village. He even reproduced a photograph of such a group, which is one of the few documentations of minority music from that time. In this passage we get a vivid picture of an ensemble of

idiophones, where the quill-shaped bamboo idiophones were played according to a repeated rhythmic pattern supported by stamping tubes and other bamboo instruments [50.38, pp. 159–160]:

> *Very complex this fanfare. I count six different rhythm parts and most refined at that. Movement of four beats. Three players strike a crotchet at the second half of the fourth beat and two other ones on horseback at the end of the first and the beginning of the second. Not one single time do they falter. The counterrhythm of the alto is likewise perfectly reproduced. The ensemble is harmonic and of correct rhythm . . .*

This is a fine early description of a so-called *colotomic pattern* that functions as an organizing principle in this music. One of the instruments used at that time was the series of concussion tubes that the Kammu call *kltɔ̀ɔŋ*. In the Yùan area usually five pairs of *kltɔ̀ɔŋ* of different sizes are played together. The members of the ensemble strike their individual *kltɔ̀ɔŋ* according to a certain rhythmic pattern. The result is not only a percussion orchestra but also a melodic motif, which varies with each new pattern. The typical pattern of the Rmcùal village – also used for stamping tubes – is remembered by a mnemonic song. Each pair of tubes in the ensemble has a name from lowest pitch to the highest, meaning: beginner, followers (two pairs), stopper and never-stopping (= bourdon). In this manner each person knows the individual position in the ensemble and each person knows the mnemonic song (Figs. 50.4 and 50.5).

The *kltɔ̀ɔŋ* has a number of uses played in ensemble or individually. The overriding function ascribed to them is that of calling and leading a soul of a person or an animal from one point to another, for instance leading the soul of an important visitor or of a slain animal into the village. Another use was leading human souls back to the village in the case when one had concluded that an illness had been caused by one or more of the person's souls going astray [50.39]. Similar concussion tubes are known from many peoples in the area and also from peoples in Borneo and the Philippines with similar uses.

The technique of making music where each person plays only one pitch is sometimes called the *hocket* technique, a term that stems from the musicological term hoquetus that refers to similarly constructed music in the Western medieval church tradition. In Southeast Asia it may be used for instruments other than percussion, like the *dinh tut* of the Edê people in Vietnam that consists of five bamboo pipes of different sizes. The bottom end is closed and the head is cut flatly. It is performed by five females each of whom plays one pipe. It is usually performed in the field or in such rites as the new rice celebration. It is believed that the sound will wake up the rice mother's soul, which will help the rice to grow quickly.

50.2.3 Gongs and Cymbals

Various gongs and cymbals exist among most of the ethnic minorities in the area. In the western part of Southeast Asia the bossed gong dominates and is generally played in combination with a pair of cymbals, while in the eastern part ensembles made up totally or to a large extent by gongs dominate.

Thus gongs and cymbals form a basic unit in much of the music for festive occasions among the Karen and other minorities in Burma [50.40] as well as the Kammu in Laos. The large kettle gongs – or bronze drums as they are commonly called – are gongs with very wide rims. They have a long history and exist in several distinct types [50.7]. Up to the mid-20th century kettle gongs were still manufactured in Burma particularly by the Karen people [50.41]. Karen, Shan, Lolo and Kammu are among those groups who still use

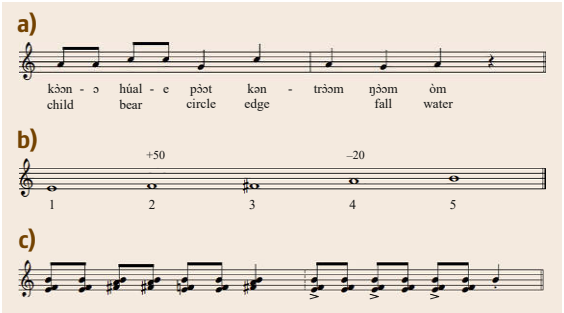

Fig. 50.4 **(a)** Mnemonic song for playing *kltɔ̀ɔŋ*, Rmcùal village, Laos. Translation: The bear cub went around the edge and fell into the water. **(b)** Approximate tuning of *kltɔ̀ɔŋ*. **(c)** *Kltɔ̀ɔŋ* pattern of Rmcùal village, Laos

Fig. 50.5 A set of four pairs of *kltɔ̀ɔŋ* of the Kammu. The photo was taken in northern Thailand in 1979 not in a ceremonial context but as a demonstration. (Photo: D. Tayanin)

kettle gongs to some extent. When played the kettle gongs are often suspended so that the surface is vertical.

Kettle gongs represent large spiritual and economic value. Most of them are inherited goods that belong to individual families and a family's economic status is measured by the number of kettle gongs they own. In Kammu belief the kettle gongs belong to an underground spirit called *róoy yàk* who controlled the underground metals and was dangerous [50.42]. The ancestor spirits are believed to protect the living from evil spirits who could cause sickness, and the living-house – particularly the fireplace – is considered to be the home of the ancestors. The sound of the kettle gongs will call the ancestor spirits to the village and they are thought to be present during the ceremonies where kettle gongs are used.

If a kettle gong is handled with care, i. e., if it is played only on the proper occasions and if the correct sacrifices and prayers are made before using it, it will bring luck and prosperity. If, on the other hand, it is mistreated, the spirits will be angered and the kettle gong will turn into a dangerous object that can produce famine, sickness or even death. There are many stories about kettle gongs being possessed by evil spirits.

A kettle gong of the type commonly used has figurines of frogs on the rim of its face and on its side small figurines depicting elephants, snails, cicadas or rice loafs. Most of these figures as well as other patterns are symbols of fertility and wealth. Depending on these figurines each kettle gong is considered to have certain powers. The main situation for using the kettle gongs is at funerals. The occurrence of a death is first signaled by beating a kettle gong fast and loudly. Villagers and people in neighboring villages working in the fields or hunting in the forest can understand which family is signaling by combining the direction of the sound with the sound of a particular kettle gong.

Fig. 50.6 Cymbals (*left*), kettle gong or bronze drum (*center*) and bossed gong (*right*) being played by Kammu in Yunnan, China, in 1986. The bronze drum is suspended so that its surface is vertical. In the center the star or sun pattern can be seen and two circles have been painted around it. In this case the same person beats the bronze drum and the gong (more often they are played by two persons). Judging from the people watching in the background this seems to be a demonstration or possibly recording situation. (Photo: courtesy of Li Daoyong)

Another important situation for using kettle gongs is buffalo ceremonies, when one or more buffaloes are sacrificed in the case of serious illness, at house-building feasts and at harvest feasts. On these occasions the kettle gongs are played slowly and in an elaborate way, and other instruments like gongs, cymbals and wooden drums may join (Fig. 50.6). In Kammu tradition the kettledrum, which is the largest of the instruments with the longest reverberation, will play a slow pattern consisting of a number of long beats and with a final cadence of three faster beats called *yàal* (slow) and *kmtʎʌn* (fast), respectively. If larger gongs are present they will play shorter beats and a special rhythmic pattern coordinated with the final faster beats. The cymbals are beaten in rhythm, every other beat open with a roll and every other closed. This is actually a slower variant of the same colotomic pattern as that of the bamboo ensemble discussed above. Colotomic patterns of this type with an ending cadence are common in Southeast Asia [50.43].

50.2.4 Gong Ensembles

In the east part of Southeast Asia, particularly in the border area of the Central Highlands of Vietnam, Laos and Cambodia, large ensembles of gongs are common. Gongs are also often played in ensemble with drums and bamboo percussion instruments as well as with flutes and singing. The gong ensembles vary in size but can consist of a large number of gongs. The community thus owns a set of gongs that belong together and range from the largest to the smallest one. Both flat and bossed gongs occur. In the ensemble each player holds one gong that hangs on a string held in the left hand or strung around the shoulder and produces one pitch. The players often move in a long line or in a circle. In each piece they play they are coordinated by a certain pattern. The playing involves striking the gong with the right-hand fist or with a mallet – both soft and hard mallets occur – combined with various damping techniques.

The gongs are played on ceremonial occasions, particularly buffalo ceremonies in which a water buffalo is sacrificed to spirits when it is decided that they need to be placated, for instance in case of severe sickness. The *Muong* people play the gongs at the New Year's festival (according to the lunar calendar) and on other

Fig. 50.7 A gong ensemble of Sedang with flat gongs being struck with beaters on the inside (*four players to the left*) and bossed gongs struck on the boss on the front side by bare fist or beater respectively. The photo was taken in a communal house, a so-called *rong* with a very high pointed roof, near Kontum in central Vietnam, during a recording session in 2007. (Photo: H. Lundström)

Fig. 50.8a,b A transcription of an ensemble of six gongs of the Ma in Lam Dong Province, Vietnam. **(a)** For each gong the pitches of the fundamental are shown, along with the first partial of one octave higher and the second partial of another fifth higher. **(b)** The melody pattern and the ostinato pattern. After booklet accompanying the CD *Vietnam. Musiques des montagnards* [50.45, p. 70]

happy occasions like celebrating the building of a new house or greeting distinguished guests. In other cases, as with the Sedang, the gong ensemble is used at buffalo ceremonies (Fig. 50.7). Colotomic structures in which the largest gong provides the basic slow pattern and the increasingly smaller gongs are played faster are used by the Bunong in Mondolkiri in northeast Cambodia (Fig. 50.8) [50.44, p. 34].

A gong will produce a fundamental tone and partials. In many cases it is the second partial (the fifth in the octave above the fundamental tone) that dominates the sound and creates melodic movement that varies with the pattern that is used. In an ensemble of only gongs the largest ones often produce an ostinato motif while the smaller gongs produce a melody. As was the case with the above-mentioned Kammu bamboo ensemble the pattern may be remembered by a mnemonic song.

The practice of building music on a combination of colotomic patterns and the hocket technique is widespread in Southeast Asian majority cultures as well. This manner of ensemble playing is well known from the *gamelan* orchestras of Indonesia to the *gagaku* court music of Japan. There is an interesting relationship between bamboo and metal ensembles, which in an evolutionary perspective has been taken as a historical relationship, starting with bamboo and developing into metal ensembles. This is no simple matter, however, for there are actually instances where metal ensembles are replaced by bamboo ensembles for economical or practical reasons.

50.3 Music and Village Life

In traditional village life people who make music and the music they make exist in a framework where not only social conventions but also calendar rules, taboos and religious practices decide when it is appropriate or inappropriate to perform a certain kind of music. There are auspicious days for various activities and inauspicious days that concern everybody in their daily lives. Taboos may be general for a whole village or specific for a particular family or person. There are examples of taboos against music and singing for up to three years in a family where a death has occurred. Other taboos may have the function of reinforcing social conventions or avoiding angering some spirit. Though there is much variation in detail certain religious beliefs are rather general on the level of principle. The dominating belief systems are usually summarized by the terms spirit cult or animism, which means that most living beings and objects are considered to have a spiritual aspect [50.46]. In most cases there are also influences from Hindu and Buddhist practices and thought and in some areas also Christian beliefs.

50.3.1 The Spiritual Context

There is a hierarchy among the spirits depending on what power they are believed to have with which

they can influence the living. Those given great importance are placated through ceremonies of various kinds that often include sacrifices – or gifts – consisting of certain plants or objects and also blood sacrifice, where the water buffalo nowadays is the highest one. In this way the village spirits, ancestor spirits and certain malevolent spirits are treated and balance is upheld. Most spirits are not necessarily evil but nevertheless dangerous for the living. For instance ancestor spirits, who are generally believed to protect the living, may cease doing so if somebody did something wrong or didn't care for them properly. Then people would fall ill and perhaps even die. If this happens, a buffalo ceremony, which in turn is surrounded by a number of taboos, could be staged on a well-chosen day. Similarly, living beings are believed to have souls and there is a hierarchy of souls as well. Apart from human souls the souls of rice and of large game are especially important. These also demand proper action from people. Beside its soul a living animal may also be considered a representation of a certain spirit.

The spiritual aspect is thus very present and in many cases this also involves music. Villagers in general must know the most important of this framework of calendar rules, taboos and religious beliefs in order to handle daily life. In the case of larger ceremonies that involve the whole village, for example harvest feasts, the village elders, village headman and sometimes a master of rituals must be consulted. In most areas there are also shamans, who are considered to be able to communicate directly with spirits and who are called upon in cases of illness. The shaman séances normally involve music in one way or another. Among the Kammu a special set of songs and music on gongs and cymbals send the shaman off to the spirit world and call the shaman back. The shaman will sing with a special voice believed to be that of the spirit in question and in the curing process the shaman will sing certain magic songs or spells. The Hmong shaman travels to the spirit world on a symbolic horse and besides chanting uses gong and rattling metal sounds, like a rattle-sword made from a sword and metal rings [50.39].

50.3.2 Praising the Rice Soul

All matters relating to the farming of rice are of extreme importance since a successful harvest guarantees basic food for the coming year, whereas a small harvest due to weather conditions or other circumstances could cause a village to starve unless other sources of food could compensate, or unless there is wealth enough to buy food. A number of rites are performed in order to call the rice soul to the fields and to make it want to stay there. The details of the ceremonies or rites differ from people to people and also between villages of the same people, but the overall functions have much in common.

Those minorities that live on mountain slopes, like the Kammu people, will make their fields on the mountainside a bit away from the village. An area will be burnt to make a field and the Kammu use a rotation system so that they return to the same place a number of years later. In that manner the forest can recover. Once the field is cleared and the rice has been sown and begun to grow, young people will stay in field houses to watch over the rice and protect it from various animals. In this season there is time for singing, learning songs, and making music on instruments from material at hand. It is also the season when people in Rmcùal and surrounding villages may present their wife-taking clan with certain objects in order to please the rice soul. These objects are a fragrant herb, *crwàaŋ*, and materials for a decorated pole, *cóh*, to be placed by the field house, and three bamboo clappers, called *pɔ́h*, that are placed at the top, the bottom and the middle of the field. The pole and the clappers are made from different sizes of bamboo, including the plated decorations and tassels. The bamboo clappers are connected by ropes to a pole just beside the field house, from where they can be operated (Fig. 50.9).

The large clapper on top, *pɔ́h mòk*, is made from giant bamboo and the smaller one at the bottom, *pɔ́h yíaŋ*, from a large bamboo variety. Their main sounding part is a bamboo culm in which a slit has been cut lengthwise. When one of the ropes is pulled, it lifts the split bamboo of the clapper it is connected to, so that the slit opens and then emits a sound when it closes. In this way, the three clappers can be played in ensemble from the pole in the center of the field. A bamboo clapper can produce several different sounds. The loudest and most resonant one is achieved when the clapper is pulled up with a sudden jerk so that it claps together in upright position. A softer sound is obtained when the clapper is arrested in the middle position. Each of these sounds can be followed by weaker sounds when the two halves of the clapper are allowed to bounce two or more times. When it falls back into its original position against the anvil (*téñ-téñ*), the weakest sound is heard: a thump that cannot be heard from a distance. The third clapper, *pɔ́h làk-làk*, consists of a piece of bamboo with a lengthwise slit placed on top of a pole. A narrow waist is cut so that the slit opens easily. This clapper has a high-pitched rattling sound.

The large and small clappers are played in similar ways, but the large one is too heavy to be played

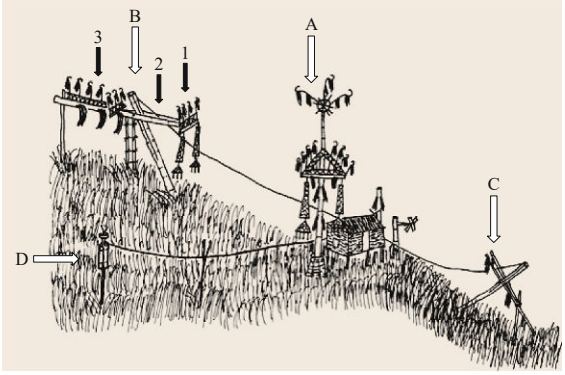

Fig. 50.9 Outline of the placement of the Kammu bamboo clapper family for the rice soul in a field. A) decorated pole, *cóh*; B) large clapper, *pɔ́h mòk*; C) small clapper, *pɔ́h yíaŋ*; D) third clapper, *pɔ́h làk-làk*; 1) forehead, *ktáh*; 2) carrying sling, *prnɔ̀*; 3) hump, *pɔ̀*. (Drawing: D. Tayanin)

rapidly. Once a steady tempo has been achieved, two rhythm patterns are played in alternation, called *yàal* (slow) and *kmtʌ́ʌn* (fast). The third clapper will rattle along in a rather fast tempo. This is exactly how the kettle gong, gong and cymbals are played in the village when there is a ceremony of the kind where the ancestor spirits are called upon. The rice soul thus gets a bamboo version of this ensemble where the largest clapper corresponds to the kettle gong, the smaller clapper to the gong and the smallest third clapper to the cymbals.

There are still other meanings of the clapper ensemble which serves as a symbolic buffalo sacrifice. The front part of the largest clapper is called forehead (*ktáh*) and the hind part hump (*pɔ̀*): this refers to the same body parts of a buffalo, which has a ritual role as sacrificial animal. The part behind the forehead is called carrying sling (*prnɔ̀*), which refers to a carrying sling for babies that in turn implies the rice soul, which is thought of as a small child: the rice child (*kɔ́on ŋɔ́*) (Fig. 50.9).

While the bamboo clappers are set up some members of the recipient family return to the village to prepare food, and then bring the food and wine to the field for a feast. Two cups of wine are offered to the rice soul and a good singer from the recipient family sings in praise of the clappers. A singer in the giver's family sings in reply, praising the rice of the recipient family's fields and belittling the gift [50.47, p. 100ff.].

While the clappers have important social and spiritual meaning they also serve to scare off birds and other animals that might harm the rice. The season when the rice grows is in many places characterized by the sounds of various sound sources designed to serve as scarecrows. Many of them are powered by wind or by water and they range from simple constructions like the humming propeller seen on Fig. 50.9 just beside the field house (*táalɛ́ɛ lòm*) to the complex machines of tuned bamboo tubes like the Sedang *tang koa* [50.18, p. 56ff.], [50.48, pp. 24–25].

Table 50.3 Music during the Kammu farming year, village Rmcùal, Yùan area

Activity	Music	Ascribed meaning
Burning season		
Clearing the fields	Side-blown horn	Calling and the rice soul from the forest to the new field
Sowing season		
Sowing	Music taboo	Loud sounds would anger the *rice child*
Village ceremony	Concussion tubes, drum, gong and cymbals	Receiving the *rice child* to the village common house
Weeding and growing season		
Calling rain	Song; ground harp or ground friction drum	Arousing the dragon spirit to make it rain
Cursed field ceremony	Bumble pipes (by steam over fireplace), gongs and cymbals (side-blown horn taboo)	Main purpose: driving out area spirit that owns a part of the field
Pig ceremony	Music taboo (kettle gong, gong and cymbal) except singing during the party that follows	Calling ancestor spirit to ask protection against evil spirits considered active in this season. Gongs and drums would make the ancestors think a buffalo was sacrificed
Clappers raised in the field	Bamboo clappers; songs	Pleasing the rice soul and making it stay in the field
Harvesting season		
Harvest	Taboo side-blown horn, kettle gong, gongs, cymbal	Loud sounds would anger the *rice child*
Harvest feast in the village	Drum, gongs, cymbals; songs	Greeting the rice soul
Year-end season		
Begging	Song	Getting rid of waste spirits: youths go begging for crops that will be thrown away to the west outside the village

50.3.3 The Farming Year

The greeting of the rice soul is one of a cycle of ceremonies during the farming year that starts with the initiation of the clearing of the fields and ends with the New Year festivities when the old year is finished off (Table 50.3). Most of these ceremonies have a relation to a certain kind of music or musical instrument, sometimes even in the form of taboo against music.

The ascribed meanings of these activities are totally within the spiritual world. This is the insider (or emic) perspective. In an outsider (or etic) perspective one might think of other explanations. It is quite obvious that spiritual beliefs and rules help to regulate human life. Even more so, the cycle of ceremonies during the farming year signals important seasons and the passages from one season to another and also serves as a calendar. Sowing and harvesting are particularly important and critical phases and in the case of the Kammu this is marked by the taboo against music. The different village cultures have variants of this cycle of ceremonies and music [50.21, 49–52]. Many of the beliefs and practices also have parallels among the majority peoples [50.53–56].

50.4 Village Music and Modern Society

The basic units of the minority communities are the villages and the clans in them. The music, rituals and beliefs serve to hold the villages together. The collectively shared systems of music making and its organization therefore play important roles in making the music culture stable over time. Maybe the strongest symbol of the village community as a unit is the wooden drums that in many cases are collectively owned, used in collective ceremonies and kept in the village common house. Thus the wooden slit drum of the Wa people in south China is surrounded by a number of rituals [50.57, 58]. In some areas gongs or bronze drums have a similar role.

50.4.1 Change in Village Cultures

That village cultures are stable does not mean that they are static. Music traditions are known to have gone out of use, for instance the Kammu in north Laos used to have a wooden slit drum much like that of the Wa but it has long ago been replaced by a long wooden drum with two skins [50.59]. In other cases new practices have been integrated into the existing systems or added to them, like music, instruments and songs from neighboring peoples, including the majority peoples. There is a more or less pronounced hierarchy between the minority peoples living in a specific area that may make those who want to raise their status adapt to the culture and life of those who are considered higher in status. In the long run this may lead to hybrid forms of culture and to changed experienced identity [50.60].

These things are part of the continuous change, but change can be more drastic. Historically, for instance, it is believed that the Kammu were once the dominant people in Laos, but that about one thousand years ago they were forced to move up the mountainsides by a migration of the Thai people from the north, who are now the majority population. As recently as the beginning of the 19th century conflicts in south China made many Hmong move into northern Laos and Vietnam where they generally made their villages and swiddens on the mountaintops.

The Kammu village Rmcùal that has been used as reference several times in this chapter is actually an example of rather dramatic change in recent times. In fact it no longer exists, so all information about its music and traditions is historical. After a period of depopulation the last family left the village in 1999 and actually the whole area where Rmcùal was is now deserted. The reasons for this are many. Wars – particularly the internal war in Laos in the 1960s and early 1970s – made Kammu people in the area become soldiers on different sides in the conflict. Young men left their villages and eventually there were too few people in the area to uphold a necessary production of rice. Gradually people started moving to new settlements in the lowlands or to suburbs of nearby towns, like Nam Tha. This has meant that the music that was related to work and to social organization has lost its base and become abandoned or recontextualized. On the other hand, people have better access to education, healthcare and trade centers [50.61]. This development is not limited to this particular area, but also occurs elsewhere [50.62, pp. 4–5].

Generally speaking, while the systems of music organization that have been exemplified in this chapter have started to dissolve, those kinds of music that can be more easily recontextualized are music relating to important ceremonies, like funerals, and social singing. Thus the recited prayer that guides the soul of a dead person to a place of rest located in China is still being used among Hmong in the US and those who live in exile, have started cultural associations that also promote

musical instruments, like the Hmong mouth organ or the gongs and cymbals of the Kammu [50.63].

Wars and political changes have affected minorities in the whole of Southeast Asia and continue to do so when it comes to national policies and legislation concerning land rights. Generally the uphill farmers who use swidden techniques are believed to cause deforestation and soil erosion, which has led to reforestation programs and resettlement programs that have changed their practical circumstances thoroughly.

50.4.2 Survival in Modern Society

In this chapter the music of the ethnic minorities has so far been treated as belonging to their own separate universes on the village level. Though there is interaction with neighboring peoples the music of villages of the same people tend to share the same instruments, instrument names, vocal genres and genre names over long distances. Similarly, even though there is interaction with the majority peoples, the ethnic villages have more in common with other villages of the same ethnicity than with the majority in their vicinity. This holds true as long as the village traditions are rather intact. The radical changes these communities have undergone, particularly since the mid-20th century, are changing this picture and is a development that can be expected to continue. Therefore the music of people of minority background must also be seen as part of the whole national music culture in the country where they live. Still, the music cultures of the ethnic minorities cannot be seen as subcultures of the national music culture, but rather as separate music cultures.

In Vietnam music of ethnic minorities was incorporated in the development of a new national music that began in the north in the mid-1950s and nationally after the Vietnam War in 1975. In line with politics in the Soviet Union and China the aim was to build a revolutionary music culture. This would be achieved by eliminating aspects of the old society considered negative, transforming customs considered backward and building a new music culture [50.64, p. 93]. This is usually referred to as *neotraditional music* and consists of reformed traditional music, political songs and modern compositions [50.64]. The latter are often composed with motifs and rhythms inspired by ethnic music. The neotraditional music includes modified versions of the bamboo xylophone *trung* and the bamboo tubes *k'long put* along with modified versions of Vietnamese instruments and is performed by conservatory-trained musicians in official situations, nationally and abroad (Fig. 50.10) [50.65]. On a symbolic level it represents a nation consisting of all its ethnic groups of which the majority people Viet (or Kinh) is one. The procedure is selective and those instruments and musical pieces that have an ethnic background were moved from their traditional contexts and placed in a new context.

Traditional Vietnamese music, for instance the music of the zither *danh tranh*, was moved from intimate music situations to stage and TV performances involving less – or no – improvisation [50.64]. Similarly, ethnic music performed by musicians of minority background has, much after the Chinese model, also become staged, particularly at festivals and at competitions. This is another example of selective recontextualization since the stage and television contexts have their own sets of practices and criteria that the music is adapted to. Staging is closely related to tourism, whether music is literally performed on a stage or in a village specializing in tourism [50.66–69].

In 2008 the *Space of gong culture* was inscribed on UNESCO's list of Intangible Cultural Heritage of Humanity. The gong traditions of the Central Highland in Vietnam became the first ethnic music to get this status. Other countries in East Asia have been active with cultural heritage designations for some time, particularly so Japan and in the 2000s China [50.70]. In Vietnam this has been used in order to safeguard and revitalize music that was not previously cared for or – as in the case of the vocal chamber music *ca trù* – discouraged

Fig. 50.10 An ensemble from the Lam Dong province in the Central Highlands of Vietnam performing at the national festival for traditional instruments in Da Lat, Vietnam, 2014. It appears to be a local neotraditional ensemble with modified instruments consisting of Viet musicians representing the minorities of the province. *From left to right*: suspended gongs, suspended bamboo xylophone, bamboo xylophone with resonating tubes, festive decorated pole (Fig. 50.9); behind the pole a variant of the *klong put* bamboo instrument, drum, stone xylophone, *klong put* bamboo instrument. (Photo: E. Wettermark)

or even banned [50.71]. While this status will serve as a support for those who carry on the tradition it also leads to an increased focus on that certain activity by media and tourist agencies [50.69, 72].

Since its start in the 1950s the Vietnamese Institute for Musicology has conducted fieldwork studying and documenting folk music, including music of the ethnic minorities [50.73]. The recordings are archived and are gradually being digitized. Documentation is also organized in collaboration with local culture centers and many recordings that are published on CD, VCD or DVD formats are aimed at local use. Documented recordings are an important asset once a music has been discontinued and revival movements may occur. The fieldwork normally consists of field study, documentation, archiving and publishing. In many cases knowledge is lost in ethnic villages and often only the oldest people know the music. One has noticed loss not only of musical knowledge in general but also loss of knowledge for making musical instruments: selecting material, treating the material and handling the instruments. In recent years fieldwork has also been combined with education in order to revitalize the transmission process: senior folk performers recognized by the communities will teach people of the whole community with priority on the young generation [50.74, pp. 39, 57–59]. These transmission classes aim at empowering people to revitalize their music culture as a living culture rather than preserving its music as frozen objects. Similar initiatives may be taken from within the culture, which is the case among the Tampuan in Ratanakiri Province, northeastern Cambodia, where songs in the traditional style that deal with modern topics are being created and used [50.75].

The Vietnamese example demonstrates that the music culture of an ethnic minority group or village cannot only be seen as a separate unit but also must be seen in relation to the national music culture of which it is a part and to the processes going on there. This is crucial when thinking of the future of this music. The circumstances differ in detail between the countries in the area but are similar on a general level [50.76]. The processes that are mainly conducted by *external* agents like politicians, producers, researchers and development workers are complex and need to be problematized in order to understand their effects [50.62]. There are many and often conflicting views on how these various agents relate to the future of the music cultures of the minorities and these conflicting views can also be found within the group of ethnomusicologists. The old relation to traditional music that advocates preservation with arguments of authenticity stands against the view that the music cultures should be left alone to handle the situation and that loss of music traditions is a normal and unavoidable thing. There are those who see stage shows, competitions and tourism as leading to folklorization that is opposed to authenticity, while others prioritize the fact that these are some of the few areas where performers can make a financial gain.

It is a fact, though, that all these circumstances, which are both opportunities and threats to the minority music cultures, exist and will continue to exist for the foreseeable future. The situation is not unique to Southeast Asia but can be seen in a wider perspective. In the international research project *Sustainable futures for traditional musics* matters of sustainability in 11 different contexts in the world were studied by a comparative method in order to increase knowledge of these processes [50.77, 78]. As the understanding of the situation in Southeast Asia may benefit from studies in a wider geographic perspective, likewise interdisciplinary approaches are important, not least with linguistics, where endangered languages have been an issue for some time and are also debated [50.79, 80]. Music loss among endangered musics has much in common with language loss – actually the two are closely connected particularly in the area of singing, which in many cases demands a full command of the language.

This chapter has included examples of traditional village-based music cultures of the Southeast Asian minority peoples and it has dealt with the present-day situation after substantial changes in life patterns and a degree of recontextalization into the main national music cultures. What lies in the future is a large and important field for musicological research that takes into account both the traditional and the present conditions, includes local culture politics, and also relates to global musicological and interdisciplinary research.

50.A Appendix: Recordings

50.A.1 CDs

- *Baishibai. Songs of the Minority Nationalities of Yunnan*. PAN 2038CD (Pan Records, Leiden 1995)
- *Bamboo on the Mountains. Kmhmu Highlanders from Southeast Asia and the United States* SFW 4056 (Smithsonian Folkways Recordings, Washington 1999)
- *Karenni. Music from the Border Areas of Thailand and Burma*. Pan Records Ethnic Series, PAN 2040CD (Pan Records, Leiden 1994)
- *Music from Vietnam 3. Ethnic Minorities*. CAP 21479 (Caprice Records, Stockholm 1995)
- *Music from Vietnam 5. Minorities from the Central Highland and Coast.* CAP 21674 (Caprice Records, Stockholm 2003)
- *Music from Villages in Vietnam 1–2*. (Vietnamese Institute of Musicology, Hanoi 2009)
- *Music of Laos. Khmou', Oï, Brao, Lao, Phou-noï. Kui, Lola, Akha, Hmong and Lantene traditions*. W 260118 (Maison des Cultures du Monde, Paris 2004) inedit
- *Vietnam. Music of the Montagnards*. CNR 2741085/6 (Le Chant du Monde, Arles 1997)
- Vietnam Institute for Musicology: Series of CD, VCD and DVD recordings

50.A.2 LPs

- *Cambodge. Musique "Samrê" des Cardamomes recueillie par Jacques Brunet*. LD 112 (Disques Alvarès, Paris 1969)
- *Musique des tribus Chinoises du Triangle d'Or*. ARN 33535 (Arion, Paris 1980)
- *Musique Mnong Gar du Vietnam*. Collection Musée de l'Homme, OCR 80 (Disques Ocora, Paris, recorded in 1958)
- *Musiques du Cambodge des forêts*. Anthologie de la Musique des Peuples (1976)
- *Musiques du Viet-Nam*. Disques BAM LD 434, n.d.
- *The Protomalayans of Malacca*. An anthology of South-East Asian Music, BM 30 L 2563 (Bärenreiter-Musicaphon, Kassel, recorded in 1963)
- *The Negrito of Malacca*. An anthology of South-East Asian Music, BM 30 L 2562 (Bärenreiter-Musicaphon, Kassel, recorded in 1963)
- *The Senoi of Malacca*. An anthology of South-East Asian Music, BM 30 L 2561 (Bärenreiter-Musicaphon, Kassel, recorded in 1963)

51. Music Archaeology

Ricardo Eichmann

Music archaeology is a rather recent field of academic studies that emerged in the 19th century and provides access to musical cultures of ancient civilizations. Modern research, characterized by expanding interdisciplinary methodological approaches, has its roots in the 1970s. Music archaeology explores ancient music and archaeoacoustic phenomena embedded in archaeological contexts and objects, iconographic representations, and written sources. After a long period of processing and classifying such data, cultural turns in the past two decades have increasingly influenced the interpretation of archaeological music evidence.

The sources for reconstructing the sound and musical culture produced by ancient civilizations are accessed by classical humanities disciplines, particularly archaeology, and collected, classified and interpreted from different perspectives [51.1, 2]. Conditioned by the research goals and methodologies of the humanities, archaeology investigates human sociocultural evolution and the underlying technical, economic and social innovations [51.3]. Toward this end music archaeology cooperates closely with disciplines in the natural sciences and enhances their methods and procedures. This productive collaboration yields robust, verifiable data about the living conditions of ancient societies and their culture. Ideally, music archaeology is pursued in interdisciplinary cooperation between archaeologists and musicologists, whereby the methods applied depend in each case on the particular issues and the nature of the source material. Sources associated with music and found in an archaeological context were systematically researched by individual scholars already in the 19th century. The work of the musicologist Carl Engel on *the music of the most ancient nations*, dating from 1864, is outstanding for this time [51.4]. His investigations included an analysis of archaeological relics and findings on the ancient advanced civilizations of Western Asia and Egypt. Later, lasting impulses for interdisciplinary archaeological music research relating to Western Asia and Egypt emanated from such musicologists as *C. Sachs* [51.5, 6] and *H. Hickmann* [51.7] in the early decades of the 20th century. A synthesis on prehistoric music in Europe was available in 1934 [51.8]. Also deserving of mention is an internationally acclaimed series on the iconographic history of music (*Musikgeschichte in Bildern*) edited by *Heinrich Besseler*, *Max Schneider* and *Werner Bachmann*, which also considered the *music of antiquity* [51.9] and comprised volumes on Greece, Etruria and Rome, Egypt, Mesopotamia, Central Asia, India, and America.

Continuous research on music in antiquity is, however, only discernible since the late 1970s. Since that time, an increasingly expanding, interdisciplinary field of work has been established [51.2, 10–12]. Today, the field is usually called music archaeology (Musikarchäologie, archéologie musicale) or archaeomusicology, sometimes archaeo-music (Archäomusikologie, archéo-musicolgie), depending on the disciplinary environment with which the authors or initiators of the working teams most closely associate themselves; musicology or archaeology. In several places the name of the field is controversial (see, e.g., [51.2, 12]). In this article the term *music archaeology*, which was introduced by researchers already at an early date [51.13], is understood as the designation for a specialization within archaeological research, analogous to *social archaeology*, *economic archaeology* and *industrial archaeology*. Other than several brief

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_51

surveys of developments over the past 40 years (e.g., [51.1, 2, 14]), a comprehensive, systematic history of archaeological music research worldwide is not yet available.

Numerous multidisciplinary research groups address different geographical settings and historical periods or different topics of musical culture across a spectrum ranging from the fabrication of musical instruments to aspects of musical life. In this context, basic research in the field of music archaeology has also led to the production of systematic catalogs of relevant relics and findings as well as monographs on specialized topics investigated in historical depth.

Usually embedded in an archaeological context, music archaeology is also a focus of the emerging field of archaeoacoustic research, which is also concerned with nonmusical acoustic phenomena [51.15, 16]. This is reasonable, since it cannot be determined whether many sound-generating objects, such as horns, whistles, bells and drums, were ever used to produce music, or just had a signaling function. This is also the case for metal artifacts from prehistoric European hoards, which stimulate archaeoacoustic investigation because of their sound qualities [51.17], and for many ancient American whistles that served to imitate animal sounds [51.18, 19].

A comprehensive manual of the theory and practice of music archaeology does not yet exist, although efforts in this direction are being undertaken in the international research community [51.2, 10, 20], whose members regularly interact at conferences held with increasing frequency. An overview of past international conferences and proceedings that provide information about music archaeology activities and research fields worldwide is to be found on the websites of music archaeology research teams (e.g., [51.21–24]).

51.1 Methods

Music archaeology's primary sources are cultural environments significant for their musical contexts. They are typically studied by archaeologists during stratigraphic excavations using modern methods of securing, classifying and documenting remnants of human activity. These include physical survey techniques based on geomagnetics, electrical resistivity imaging and ground-penetrating radar to locate buried structures or portable objects; excavation techniques including find-related fine-scale stratigraphic excavations to contextualize relics; documentation methods including geographic information systems and satellite-based measurement systems to determine the precise georeferenced location of relics and findings; techniques for salvaging finds, such as en-bloc recovery of fragile objects for later examination under laboratory conditions; three-dimensional (3-D) scanning technology, computer tomography and x-ray imaging to visualize objects still in an en-bloc recovery state and to determine the constructive features of artifacts; 3-D printing techniques to reproduce artifacts; restoration techniques to stabilize fragile objects; chemical investigation of material remnants in order to reconstruct surface treatments and the formation of patina; microscopy to detect traces of the fabrication and use of objects; technologies from the natural sciences to determine the age of relics and findings, including optically stimulated luminescence, radiocarbon analysis, dendrochronology and x-ray fluorescence spectroscopy; archaeobotanical, archaeozoological and archaeometallurgic methods for identifying materials; the study of isotopes suitable as markers for tracing provenance; and finally, anthropology, pathology and genetic technology to gain insights about the living conditions of individuals and the demographic characteristics of a society.

Also of importance are written records that permit conclusions about past musical life as well as iconographic representations of music scenes, musicians and musical instruments. The significance of this kind of source material depends on the philological, historical and semiotic assessment of the particular text or image evidence. Everyday knowledge is seldom adequate for interpreting texts and images in terms of music archaeology. As a rule, knowledge of ancient languages is essential for studying ancient text passages and existing translations, particularly if the texts of ancient authors have not been translated or annotated by philologists trained in musicology or music archaeology. The case is similar for the image repertoire of the past, which makes use of iconographic codes that seldom correspond to those of today. The iconographic features of an ancient civilization can only be reliably interpreted against the background of their cultural context. This requires an application of analytic archaeological methodologies to art that presuppose a firm knowledge of the artistic handicraft output and stylistics of a community. It must also be recognized that documented source materials always represent only a very small fraction of a past culture. For ancient Egyptian culture it can be asserted, as *Alexandra von Lieven* [51.25, p. 99], emphasizes,

> *that most of our material comes from tombs, ... material from younger epochs is much more abundant*

than from older periods (this is enhanced by the fact that older material is stratigraphically lower and thus more vulnerable to a high ground water level), that the continued use of traditional material can distort our view of later epochs, that texts and depictions contain only parts of the reality, and that possible oral traditions are completely lost to us.

Computer-based analyses of characteristics are used to establish typologies that can clarify technological, chronological and chorological issues. *G. Kolltveit* elaborated a paradigmatic typology of European Jew's harps, which can be identified since the 13th century [51.26, pp. 65–153]. Iconographic sources are also suitable for studying musical instruments in large geographical areas, although the meaning of images sometimes remains vague because of stylistic differences, one example being the lyres that emerged in ancient Western Asia starting from the fourth millennium BCE [51.27].

The question of the extent to which archaeological music research can take into account the insights of ethnomusicology has been and continues to be discussed [51.1, 2, 28, 29]. In this context, methodological and concrete cultural aspects that have an influence on archaeological music research have to be distinguished. From an ethnographic standpoint they primarily include terminology, classification [51.30], forms of presentation, playing techniques, and music theory. From an ethnological perspective they comprise theoretical reflections about the sociocultural relevance of the music and how analogies and symbols are handled [51.31, p. 177]. According to the latter orientation, musical phenomena are considered to be products of social and cognitive processes, just like other cultural features of a society, and perhaps only meaningful within very narrowly limited spheres, not to be regarded as the result of some kind of purposeful evolution [51.3], [51.2, p. 5], [51.31]. The extent to which analogies arising from an ethnographic perception can be legitimately used for music archaeological interpretations depends on how the ethnoarchaeological research approaches are assessed [51.2, pp. 6–7] and in any case requires verifiable justification.

Ethnomusicological analogies can be regarded as a chance to better understand the use of sound in specific cultures but it can be risky to use ethnomusicological analogies without having studied the proper archaeological context. An intensive ethnographic survey of analogies can make the reconstruction of ancient instruments more plausible. [51.20, p. XIII]

In comparison to ethnomusicology, which is primarily concerned with relatively brief periods of time (*short-term perspective*), the research field of music archaeology extends back over several millennia (*long-term perspective*). This is advantageous for archaeological music research because it allows gradual changes to be studied over long periods of time. It also discourages an ethnocentric view of music in favor of an independent appreciation of the most varied sound cultures [51.20, p. XIII]. Whether and to what extent universally valid musical absolutes gained from ethnomusicological perspective can be regarded as a prerequisite for broader music archaeological interpretations is a matter of debate [51.32]. This issue has research potential.

The methods and procedures employed by archaeologists are also used to investigate sources relevant for music history from more recent contexts, e.g., when details of written or oral transmission are to be verified with other approaches, or are not available [51.33]. Archaeological music concepts have been employed in modern history, whereby the idea of *excavation* should be understood more in a metaphorical sense and as referring to research on ancient texts [51.34].

As is the case for modern archaeology, today music archaeology can only obtain verifiable, fruitful results in multidisciplinary and interdisciplinary research partnerships. Besides the classical humanities (philology, history, archaeology, art history), these need to draw on musicology (organology, music theory), ethnology (historical ethnomusicology, oral traditions, ethnography) and the natural sciences (physics, survey methods, acoustics, chemistry, materials science, patina studies) [51.2, p. 4, Fig. 1].

51.2 Research Topics

In practice, music archaeology is dominated by research topics related to the excavation, identification and organological study of musical instruments and their sociocultural context. One of the strengths of archaeo-organological research is the macroscopic and microscopic analysis of surface traces related to the production, use, damage or ground deposition (taphonomy) of a musical instrument. To this can be added the reconstruction of the successive stages of instrument construction (*chaîne opératoire*), starting with the supply of materials and tools, extending to the various stages of crafting, and ending with a ready-to-play instrument. This makes it possible to draw conclusions about the complexity and cognitive preconditions for

the production process [51.35], to the benefit of numerous artifact studies. Examples include the interpretation of Paleolithic aerophones [51.36, 37] and the tone reservoir and function of an Egyptian necked bowl lute, which was produced, as well as subsequently repaired, in late antiquity [51.38]. As with other empirical cultural sciences, music archaeology is thus in a position to access the knowledge embedded in artifacts and to interpret it against the conceptual background of a revived *material turn* [51.39]. The possibility of reading artifacts or contexts like a text has increased dramatically due to modern natural science methodologies and procedures, and allows the reconstruction of the life history of an individual musical instrument [51.38]. Linking such material studies with spatial contexts creates fertile archaeoacoustic studies [51.40]:

> *From a material culture perspective there are at least three key areas to which archaeology can contribute: the instrument and other accoutrements on which the music is made; the place the music is made, performed or remembered; and the place that inspired that music to be made or which is recalled or described in song.*

For example, the resonant characteristics of Paleolithic caves containing wall paintings are being examined from this perspective [51.16].

Musical instruments are reconstructed in the context of experimental archaeology [51.41–44]. The insights gained in the process about the production and handling of the instruments can be used to interpret organological details and playing techniques. For example, in the case of wooden objects the design of a workpiece can be influenced by the particular tools that are available for chopping, sawing, carving, and finishing, by the properties of the wood (hardness, grain), and finally by the skills of the craftsperson. In practice, different goals may prevail that influence how the copy of an ancient musical instrument is made [51.45]. For example, there are copies produced for museums that look like the original in all details, but cannot necessarily be played. There are also archaeological music reconstructions, ideally based on reactivated ancient design and construction techniques, that can be used for experimental music making. There are also instruments produced with modern tools simply for the purpose of putting the operating principles to the test, and reconstructions primarily based on an interpretation of ancient images and the subjective aesthetic sensibilities of their makers [51.46]. The European Music Archaeology Project (2013–2018) intended to present in an exhibition reconstructions of musical instrument from European and neighboring regions [51.23].

51.3 Musical Practice

In contrast to ethnomusicology, which is concerned with the live music of recent societies and documented with the help of recording equipment, music archaeology has at best only isolated sounds with which to work, generated by either well-preserved or reconstructed musical instruments. The oldest unmistakable and complex musical instruments are over 40 000 years old and were found during systematic excavations in the Swabian Jura [51.47]. They are aerophones with up to five finger holes and made of bird bones (swan, vulture) and mammoth tusk. The latter material especially requires great technical skill to form. The discovery site of these instruments testifies to an early Upper Paleolithic context (Aurignacien) undoubtedly connected with modern humans (*Homo sapiens sapiens*). Artifacts found in a Neanderthal context that could have been musical instruments are ambiguous [51.48].

Taking into account paleoanthropological, neurophysiological and ethnological insights about Upper Paleolithic humans and hunter-gatherer societies, it becomes evident that early aerophones were components of a well-developed cultural communication system and served to strengthen the social cohesion of those societies. Images of hand-in-hand human figures, in some cases stylistically abstract and reaching back to earliest Neolithic times, can be interpreted as round dancers [51.49]. Round dances are likewise effective cultural techniques for increasing group cohesion and alliance formation [51.50].

Besides aerophones, several other instruments had been developed all over the world at the time, such as rattles, drums, bullroarers, pipes, trumpets and perhaps lithophones. However, lasting enrichment of the musical instrument inventory took place in the Old World with the development of complex stringed instruments (harps, lyres, lutes), which can be traced back to the second half of the fourth millennium BCE. It is striking that the so far earliest stringed instruments (bowed harps) arose at a time characterized by the emergence of early city-states in Mesopotamia. Harps and lyres were used on official occasions and at banquets or in the context of cultic rituals. Already in antiquity, they were a subject of music-theoretical discourse (e.g., tuning instructions). There is later evidence for spike bowl lutes

from the late third millennium BCE that frequently also occur in everyday scenes. They were first played by the singers of epic poetry in a socially elite environment, and in the second and first millennia BCE appear more frequently in the hands of socially less privileged people, such as warriors and entertainers, and in rare cases in the hands of a copulating couple [51.51].

An analysis of iconographic sources permits gender-relevant studies according to which ancient Western Asian lutes were depicted exclusively in male hands up until Hellenistic times. Along with other instruments like the box lyre, this instrument was brought to Egypt and Asia Minor in the 17th and 16th centuries BCE, where it was not exclusively played by men, but primarily by women (frequently lightly dressed dancers and women engaged in sex) [51.52–54]. Burial goods also supply evidence for this practice. It is noteworthy that lutes were not depicted in pre-Hellenistic Greece, suggesting that they were not highly valued or used. Following the line of these observations, the cultural transition characterized by Hellenistic culture could have led to a change in musical practice. Only in the extensively Hellenized world ranging from North Africa to the Middle East does the lute seem to have overcome the social barriers of prior times and neighboring regions. The question, *If the culture changed did the music change as well?* [51.28, p. 121], has not yet been systematically addressed from an archaeological music perspective. Another example related to this problem comes from Chinese music archaeology. According to Bo Lawergren, *the sliding playing technique so characteristic for modern* qin *playing was unavailable before 150 BCE*. At that time *only open strings could have been played*, which provided steady pitches [51.55, p. 297].

> *Both playing techniques (open strings and sliding technique) can be regarded as the expression of different musical styles at least: The old style may have forced the musician to a strict musical performance, while the later style may have allowed more freedom in the reproduction of the repertoire. If we follow Lawergren, the change of playing techniques took place in the early Han dynasty (206 BCE–220 CE), which is characterised by political conceptions different from those of their predecessors.* [51.20, p 11]

The elites of advanced ancient civilizations went to immense effort to produce sounds. There are examples from Mesopotamia (Ur), where already in the third millennium BCE female musicians and their instruments, including a lyre with a bull's head application of pure gold, were interred as *burial objects* to join a royal woman in her tomb. In second and first millennia BCE China, large carillon arrays composed of bronze bells in various dimensions were used to furnish royal graves. During the same period in Scandinavia, cast bronze lurs, typically played in pairs and used ritually, were produced of a quality unachieved today [51.56]. Huge numbers of resources and great expertise were invested in the creation of objects that produced sounds.

In the ancient Near East music was used to communicate with the gods, from whom one expected a good future. King Hammurabi (18th century BCE) accordingly employed musicians as part of successful political management in the sense of influencing the future for the better [51.57]. Music in ancient Greece was associated with cultic practices, similar to the situation in the ancient Near East and Egypt. Musical harmony was valued as the acoustic expression of an ideal state (Plato, *Politeia*). There was a similar understanding in ancient China, where the success of a state was associated with musical traditions (Lü Buwei, Spring and Autumn, third century BCE). By contrast, the eastern *barbarians* were unfamiliar with music, according to the Romans. The sounds they produced recalled something more like noise or a din. At that time a lack of music was a sign of inferiority [51.58]. Today, it is self-evident that this depends on the cultural point of view.

51.4 Music Theory

In the early written records of Western Asia and Egypt, especially from the third to first millennia BCE, there are numerous documents that provide very precise information about the use of musical instruments [51.59], the training of professional musicians, their musical repertoire and their social standing [51.57, 60–63]. Descriptions of rituals make it possible to draw conclusions about musical performance in practice and the role of musicians in cultic ceremonies [51.64]. Comparable sources from the 16th century CE report on the musical practices of indigenous populations of the Americas [51.18, 65].

In the ancient Near East archaeological music information sheds light on the fundamentals of music theory and tonal structures, which permits reconstruction of a heptatonic diatonic tonal system.

> *Konrad Volk wrote that Mesopotamians probably anticipated the ancient Greek heptatonic diatonic modal system. It is conjectural, however, to*

> *say how precisely these scales and modes were built. According to Stefan Hagel, the fine tuning of scales was based on a just intonation (not on a Pythagorean intonation or on tempered tuning). He does not agree with a major influence of music theory from the Near-East to Greece:* A comparison with ancient Greek music suggests a largely independent development of musical form from at least as early as the first half of the second millennium. *Leon Crickmore, however, does not exclude a possible connection:* The evidence cited from archaeology, musicology and the history of mathematics indicates the likelihood of the existence of a musical and mathematical tradition [...] lasting at least from nineteenth century Mesopotamia until fourth century Greece. Recent interpretations of the cuneiform tablets encouraged by the International Conference of Near Eastern Archaeomusicology (ICONEA) have led to alternative explanations of ancient Mesopotamian heptatonic scales and their fine tuning. [51.66, pp. 32], [51.67–72]

Although no such detailed written information on music theory exists from pre-Roman Egypt [51.25], excavations have brought to light numerous musical instruments, some of them in excellent condition [51.5, 7, 73, 74]. Instruments that convey an idea of the intervals that can be produced using the tone reservoir are of particular interest. This is the case for the *Coptic lutes* (a kind of *pandura*) of late antiquity, which were carved out from a single block of wood and originally equipped with wooden semifrets that were either glued on or fitted into a groove [51.38]. The instruments had three strings, whereby two strings formed a chord (probably tuned in unison), so only two string units were available for playing. Each of these string units had its own fret scale, variously divided by the frets. Depending on how the bridge position is reconstructed, precise intervals can be determined. The instruments were clearly designed for a limited range of modes. Impressions caused by string-wrapped full frets have been preserved on spike bowl lutes from Pharaonic times dating from the mid-second millennium BCE.

Studies of the fret series for these lutes and of the tone reservoir for end-blown flutes from the same cultural context permits reconstruction of heptatonic scales without semitones that build on a pentatonic scale. Three-quarter tones (circa 150 cents) and *neutral* thirds (circa 350 cents) are a characteristic of these scales, clearly distinguishing them from those of ancient Western Asia represented by Mesopotamian cuneiform sources of the second and first millennium BCE [51.66, 75–77]. However, traces of corrections made to the fret position between *neutral* thirds and minor thirds confirm that it was possible to alternate between different scale types in Egyptian musical performance. Such findings on musical instruments have not yet been systematically and exhaustively analyzed from a musicological perspective.

Whereas surviving records about ancient Mesopotamian music represent a theoretical foundation not yet confirmed by preserved musical instruments, ancient Egyptian musical instruments do reflect what is known of musical practice [51.77, p. 60]. This does not necessarily mean that the two advanced civilizations favored different types of scales, since many musicians were deported from Western Asia to Egypt in the second millennium BCE. If they not only brought with them Western Asian musical instruments, which first occurred in Egypt in the 17th and 16th centuries BCE, but also their own Western Asian musical repertoire, then it is possible that the fundamentals of music theory in both areas were quite similar. Further research and new discoveries of musical instruments from Western Asia are needed to clarify the matter.

Other studies on the tone reservoirs of different musical instruments concern the music cultures of other regions of the world, especially China and Central America (see, e.g., [51.78] (lithophones, gongs), [51.79] (ocarinas), [51.80] (aulos), [51.81] (end-blown flutes), and [51.82] (panpipes)). Using end-blown flutes, ocarinas, panpipes, lithophones and gongs, it was possible to ascertain interval sizes, scales, standardized tunings and tuning fluctuations that depend on how the instrument is played. Flutes from Neolithic cemeteries in Jiahu (China) allow inferences to be made, for example, about an increase in the tone reservoir in the course of settlement history (seventh and sixth millennia BCE) and an evolution from pentatonic to heptatonic scales [51.81].

51.5 Ancient Sounds

The music once produced with instruments found in an archaeological context cannot be recreated. Instructions for performing musical compositions (lyrics and instrumental accompaniment) seem to have appeared for the first time in the second half of the second millennium BCE in the locally limited region of Ugarit (Syria) [51.59, 83–85]. Some 60 notation fragments from the Greek/Roman cultural area have been dated to

the period between the third century BCE and the third and fourth centuries CE. They comprise information about instrumental music, lyrics and rhythm [51.86]. Although such records convey an idea of the melodic lines, other musical characteristics like pace, accent and dynamics are unknown. Because of the nature of its source material music archaeology can hardly deal with the structure of the music forms of ancient societies. The point of departure for research is therefore in most cases related to the tone reservoir, scale types and tonal character of the musical instruments, as well as the sociocultural function of music and musicians, whereby the actors and social relevance of musical performance are of primary interest.

One field of music archaeology involves working closely with instrument makers to reconstruct instruments and their tone reservoir in order to play them experimentally [51.87, 88]. In such cases the main goal is not related to an attempt to produce ancient music, which would be an impossible task. It is rather to demonstrate the sound potentials of musical instruments and to present new compositions and improvisations that make use of the ancient tone reservoir and the original conception of how an instrument should sound. To do this, a wide-based research approach is required that thoroughly investigates the acoustic, organological and technical framework. In the case of aerophones, both different blowing techniques and different fingering techniques have to be considered. Accordingly, the function of aerophones reclaimed from Upper Paleolithic contexts is currently a matter of controversy. It has not yet been clarified whether, to use modern terminology, we are dealing with flutes, oboes, clarinets or trumpets [51.48, 89, 90]. It is also not known whether Irish bronze horns and southern Scandinavian lurs were played with the help of circular breathing. There is currently no reliable basis for reconstructing playing techniques [51.56]. In the case of string instruments, what can be produced as a sound reconstruction depends on the tuning and characteristics of the strings, and these have, with rare exceptions, not been preserved. In general, it can be said that the sound volume of ancient string instruments is noticeably lower compared with modern acoustic instruments. Such instruments were probably not primarily used for instrumental performance but rather to accompany vocal music. This is undoubtedly a fruitful realm for future archaeoacoustic research. These few examples illustrate that any conclusions drawn in the field of experimental music archaeology require verifiable justification and documentation.

Reconstructing instruments and recording experimental music with the assistance of music archaeologists are not only suitable didactic methods for teaching and for educational programs in museums; they also have a place in living-history scenes in the entertainment media [51.87, pp. 295–296]. This is obviously an extremely speculative pursuit, but on the other hand, involvement with instruments and notation fragments from the distant past can spur the creativity of everyone participating in the process.

51.6 Conclusion

To take stock of the current situation, music archaeology is today an increasingly multidisciplinary and interdisciplinary field of research, so far primarily concerned with processing archaeological relics related to music and typological classification, and with reconstructing and explaining how sound-generating objects function. Archaeological music studies that pay more attention to the cultural context have become more common in the past two decades, thanks to different cultural turns (*spatial and material turn*). Nevertheless, there continue to be studies that extract music-related sources from their cultural context and look at them in isolation. This can lead to clarification of numerous detail problems, but frequently leaves untouched significant sociocultural changes in ancient music history. There is great potential in this area for future music archaeological research.

Acknowledgments. The comments of Adje Both and Lars-Christian Koch helped to improve previous German versions of this Chapter. Susan Giegerich translated the final version into English. Philip V. Bohlman reviewed the final English version for musicological terminology. However, all responsibility remains with the author.

52. The Complex Dynamics of Improvisation

David Borgo

This essay provides some general observations about the field of improvisation studies and surveys important theoretical and empirical work on the subject. It makes a distinction between referent-based and referent-free musical improvisation, placing particular emphasis on the specific issues that surround the latter, and highlighting recent research that has arisen to address them. Whether referent-based or referent-free, improvisation appears to involve a continual tension between stabilization through communication and past experience and instability through fluctuations and surprise. While many issues persist about how to frame and explore musical improvisation, there is broad agreement that improvisation involves novel output (for the individual, but only optionally for society) created in nondeterministic, real-time situations by individuals and collectives involving certain affordances and constraints. The critical questions involve how we chose to frame these improvisatory dynamics: either as information processing struggling to keep pace with the cognitive demands of the moment, or as an ecologically sensitive engagement with one's sonic and social world.

52.1 The Study of Improvisation

The study of improvisation, paraphrasing *Howard Gardner*'s view of cognitive science, has a relatively short history but a very long past [52.1]. All instances of human music making, from the most ancient to the most avant-garde, arguably involve at least some degree of improvisation, if by this we mean making musical decisions in the course of performance. Until the advent of sound recording, however, musical improvisation was extremely difficult to document, and therefore to study systematically.

Oral teachings, and to a lesser extent written treatises on the subject, can be found in a variety of musical traditions: from Western classical music (at least until the time of Beethoven), to folk and art music traditions of the non-Western world (especially in south, west and southeast Asia, but also throughout much of Africa and Latin America), to more contemporary popular music styles, with jazz serving as an important locus of activity. The thrust of these treatments, however, tends to be either prescriptive or anecdotal. General comparisons between various improvising traditions were sometimes made, but relatively little scholarship attempted to offer a more systematic or synthetic view of improvisation, with [52.2] being an important exception.

Audio recording provided researchers with the ability to capture and rehear a performance, allowing for microanalysis of sonic details and for comparative studies, often either involving a single musician improvising on different occasions [52.3] or different individuals improvising on the same underlying musical structure [52.4]. This methodology allowed for more nuanced descriptions of musical improvisation, but the inherent complexities of the transcription and analysis process, whether done by a human or by a machine, are nontrivial. *Peter Winkler* in [52.5] highlights many of the insurmountable challenges inherent to any attempt to reduce music as sound to music as notation. He likens a transcription to a blueprint drawn after the building is built, and cautions us not to mistake the blueprint for the building.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_52

Beginning around the 1960s, the growth of both jazz studies and ethnomusicology as academic fields precipitated an increase in research on musical improvisation, with some of the most influential texts also emerging from nonmusic-related fields [52.6–8]. At roughly the same time, a musical practice specifically described as *improvised music* or *free improvisation* emerged that borrows from a panoply of musical approaches and at times seems unencumbered by any overt idiomatic constraints. This practice was originally championed by an eclectic group of primarily American and European artists with backgrounds in modern jazz and contemporary classical music. It now involves musicians emanating from around the world and draws on an even wider spectrum of influences, including electronic, experimental, and intermedia arts. This essay will provide some general observations about the field of improvisation studies and survey important theoretical and empirical work on the subject. It makes a distinction between referent-based and referent-free musical improvisation, placing particular emphasis on the specific issues that surround the latter, and highlights recent research that has arisen to address them. The scope of the research being surveyed is primarily limited to work published in English.

52.2 The Field of Improvisation Studies

In [52.9], *Bruno Nettl* argues that improvisation is *an art neglected in scholarship*. In [52.10] *Derek Bailey* observes that improvisation is both the most widely practiced of all musical activities and the least acknowledged and understood. Despite this apparent neglect, the academic field of improvisation studies has grown considerably in recent decades, with the publication of numerous scholarly books and articles on the subject, and with the emergence of academic journals, conferences, and graduate programs with improvisation as a central focus. The appearance of the journal *Critical Studies in Improvisation/Études critiques en improvisation* in 2004, the formation of the International Society for Improvised Music in 2006, and the forthcoming publication of the two-volume *Oxford Handbook of Critical Improvisation Studies* are all watershed marks for the field's increasing prominence.

While improvisation has often been studied in discipline-specific ways (e.g., in music, theater, dance, or visual arts), only recently have researchers embarked on more multi- and interdisciplinary work, at times spurred on by developments in the cognitive and neurological sciences, or by an interest in understanding improvisation across experience. Improvisation studies as an academic field tends to draw on many of the same theories that influence other scholarly work in the arts and humanities, such as critical theory, cultural studies, and science and technology studies. Researchers in the field have become more politically and socially engaged on the whole. Work on improvisation now extends well beyond the arts into fields such as education, philosophy, sociology, anthropology, literature, law, postcolonial studies, gender studies, human-computer relations, sports, and medicine, to name only a few.

Improvisation has also become a hot topic in management studies and organizational design, along with other business-related fields. Two special journal issues dedicated to this topic are [52.11, 12]. The former offers primarily a favorable assessment of employing the *jazz metaphor* to understand and generate creativity in the business realm, while the latter provides a more critical view of the underlying ethics and profit-driven motivations of attempting to *aestheticize* neoliberal economics.

What exactly is meant by the term *improvisation* across this variety of work can be remarkably diverse, and at times frustratingly vague. Certainly improvisation involves numerous different types of creativity (another term that defies easy definition). In the arts alone, whether it is theater, dance, comedy, painting or music, improvisation undoubtedly draws on different sets of abilities and experiences, and it offers different demands and rewards. Therefore, the metaphorical comparisons frequently made to improvising music from within other fields and pursuits can illuminate, but also obfuscate.

52.3 Challenges in Defining Improvisation

Definitions of musical improvisation tend to be vague, overgeneralized, or beholden to conventional notions of musical practice. For example, improvisation is often described as composing music on the spur of the moment, or as performing music spontaneously without the aid of manuscript, sketches, or memory. These

types of definitions tend to downplay the extensive practice and experience that seasoned improvisers bring to performance, and the ways in which memory (both declarative and procedural) and often some form of notation (perhaps functioning as an *aide memoire*) are still involved when one learns how to improvise.

Improvisation, according to *Bruce Benson* [52.13], does not fit the binary opposition of composition and performance that underpins how we tend to think about music making. He insists that we view improvisation along a continuum of musical practices running through various gradations of interpretive performance towards a type of stream-of-consciousness playing. Improvisation, however, can also be understood as qualitatively different from conventional notions of composition and performance, involving very different cognitive processes and reflecting different aesthetics, even a different ontology. Might improvisation challenge traditional notions that music necessarily involves a linear process leading from *compositional* activity to *performance* activity? Might it even get us to rethink conventional ideas about cognition that subscribe to a linear progression from sensation to thinking to action?

Jeff Pressing, whose work on the cognitive modeling of musical improvisation was some of the earliest and most influential on the subject, defines improvisation as *the simultaneous design and execution of musical ideas* [52.14], a formulation that seems both to call on and exceed the conventions of composition and performance. Writing in philosophy and aesthetics about musical improvisation is limited, but often argues that improvisation and composition are driven by unique mechanisms and expressive goals and therefore should not be assessed uniformly. In general, these treatments highlight the cumulative conception and irreversible temporality of improvisation; one can make reference to what has already occurred, but any *editing* must happen retrospectively.

Ed Sarath, for instance, asserts in [52.15] that improvisers experience time in an inner-directed manner in which the present is heightened and the past and future are perceptually subordinated. These observations underscore his conviction that improvisation demands a distinct *aesthetics of spontaneity*. *Ted Gioia* in [52.16] formulates an *aesthetics of imperfection* that cautions against making judgments about musical improvisation using the same formalist criteria that we use to judge notated composition. *Philip Alperson* in [52.17] frames his arguments through an *aesthetics of action*, insisting that, while improvisation affords access to the *composer's mind at the moment of creation*, it should not be viewed as a performative token of a compositional *megatype* or model.

In general, these different aesthetics may be explainable through differences between online and offline cognition, especially when viewed from both the vantage point of the individual and from a social cognitive perspective. Online cognition is concerned with *immediate input* from our local environment and is often used to describe an interactor's point of view, whereas offline cognition involves more *careful considerations*, such as lengthy editorial decisions or future planning, and it frequently describes an observer's – rather than an interactor's – point of view. Improvisation has certainly been disparaged in settings that place a greater value on offline cognition and/or that view an activity's intrinsic value from a *universalizing* perspective of observation over interaction.

My personal favorite illustration of the oft-noted differences between composition and improvisation comes from a chance meeting between Frederic Rzewski and Steve Lacy. In this frequently recounted tale, Rzewski asked Lacy to describe in 15 s the difference between composition and improvisation. Lacy replied [52.10, p. 141]:

> *In fifteen seconds, the difference between composition and improvisation is that in composition you have all the time you want to decide what to say in fifteen seconds, while in improvisation you have fifteen seconds.*

Lacy's formulation of the answer, according to the story, lasted exactly 15 s.

The pithiness of this statement and the timeliness of its delivery belies its profundity. On the one hand, Lacy improvised his verbal response to a question about improvisation given the constraints of time and context. If he had been provided a full minute, or 10 min, or 2 h for his response, or if he was speaking to a different audience, or perhaps in French, he would, undoubtedly, have improvised a different answer. In this way, his particular response is both in-the-moment and context-dependent; it is spontaneous, yet also made to conform to the expectations and demands of the moment.

Moreover, Lacy had likely given some previous thought to the general issue, and perhaps he had even offered similar albeit differently phrased responses on the subject in the past. So, in what ways was his statement improvised, worked out, or some combination of these? Would his remark have been less effective if he had not delivered it within the provided 15 s window of time? Should we view his response as *spontaneous*, or is it better viewed as *fluent*, in the same way that fluent speakers do not necessarily intend the construction of their sentences ahead of time? What if his response had been musical rather than linguistic? How would we judge its spontaneity or fluency then?

A priori definitions of creativity are certainly ill advised, but a posteriori definitions are likely unavoidable. *P.N. Johnson-Laird* [52.18] provides a helpful acronym for exploring creative activity, NONCE, according to which the outcome of a creative process is novel (N) for the person producing the result but only optionally novel (O) for society at large, and it is the result of a nondeterministic process (N) that is guided by constraints (C) and is based on existing elements (E).

52.4 Some Contemporary Research Directions

On the whole, researchers in the fields of music psychology and music cognition have focused the majority of their attention on how listeners perceive and process music. These approaches tend to use recorded or computer-generated music examples for their consistency. When researchers have explored the complexities of music performance, they most often do so by looking at the performance of notated music, again for the experimental control it provides. Studying in vivo improvisation from the perspective of the performer or listener remains a challenging proposition, and most writing on the subject remains theoretical, with much of it emanating from practicing musicians or from academics who also improvise.

The most widely accepted approaches to the study of improvisation in cognitive psychology theorize that improvisers deal with the *cognitive constraints* of the moment by drawing on a *model* [52.19], a *blueprint* or *skeleton* [52.20], or a *referent* [52.14] stored in long-term memory. Depending on the specific musical tradition, the relationship between a given improvisation and its model or referent may be more or less fixed, with free improvisation perhaps providing something of a boundary case for this approach, since many of its practitioners disavow the idea that the music is based on a model.

While it is undoubtedly true that real-time creative processes such as improvisation place great demands on cognitive resources, the brain is only one node in a complex nonlinear feedback system. Notably fewer authors, however, have approached the topic from the vantage point of social or ecological psychology [52.21, 22]. In other words, the question of *how does one improvise?* tends to elicit cognitivist or computational models concerned with individual *information processing* and *signal generation* instead of ecological inquiries that explore how one's perception, action, and sonic and social worlds may be intertwined or entangled. I will have more to say about this topic at the end of the essay.

Work on musical improvisation from within the field of ethnomusicology has corrected some of this imbalance. For instance, *Paul Berliner*'s [52.23] and *Ingrid Monson*'s [52.24] influential work on jazz improvisation highlights its dialogical nature and the culturally contingent ways that it is learned and conceptualized. *Vijay Iyer*'s work [52.25], as well as my own [52.26], also demonstrates how contemporary views of cognition as inherently embodied, situated, and distributed can shed further light on how and why musicians improvise together.

Theoretical writing on improvisation still outpaces empirical work on the subject, although this balance is beginning to shift, as more researchers analyze data drawn from, for example, video and other performance capture methods [52.27] or galvanic skin response [52.28]. By using brain imaging techniques [52.29–31] we are also beginning to identify specific neural regions that may be involved in heightened moments of improvisational creativity – sometimes referred to as a *flow* state [52.32, 33] – but this research is still in its earliest stages and questions abound with regards to how to structure experiments and how to interpret the data meaningfully.

Other recent approaches have used a variety of interview tactics [52.34] or grouping tasks [52.35] to understand the kinds of choices that improvisers either made in performance or might likely make given certain stimuli. Here again, challenges remain regarding how to frame tasks for participants and to employ measuring and recording technologies in ecologically sensitive ways that do not unduly impede or prefigure improvisational activities, as well as how to assess and account for differences in improvisational skill level.

Some recent work has shifted focus from primarily investigating performer note choice within harmonic contexts, akin to how jazz is often taught using chord-scale relationships, towards studies of intensity and timing as key factors in how musicians improvise together, and of how listeners hear and interpret improvised performances [52.36, 37]. The importance of timbre and nonlinear organizing principles in contemporary improvised music remains understudied in the literature, although fractal dimensional analysis of recorded improvisations has produced compelling results [52.26, Chap. 5 with Rolf Bader]. Another avenue of contemporary research involves developing automatic improvising systems with the intention of creating competent or even expert performances as judged by knowledge-

able human listeners [52.38]. Some of these approaches have turned to robotics as well in order to explore the important role that physical gestures often play in facilitating group interaction and in engaging listeners [52.39].

While many issues persist about how to frame and explore musical improvisation, there is broad agreement that improvisation involves novel output (again, for the individual, but only optionally for society) created in nondeterministic, real-time situations by individuals and collectives involving certain affordances and constraints. The following two sections will attempt to clarify these ideas within the domain of referent-based and referent-free musical improvisation.

52.5 Referent-Based Improvisation

Jeff Pressing, an improvising pianist himself, was one of the first psychologists to put forward a convincing cognitive model of improvisation, and he continued to refine his work on the subject until his untimely death. In brief, his model in [52.40] characterizes improvisation as a heterarchical process involving motor, psychological, and cultural aspects (which differentiates it from other models that emphasize only rule-based procedures, such as *Johnson-Laird*'s [52.18]; see [52.41] for an analysis of these competing theories).

It is first important to make a distinction between the various timescales involved in improvisation. For the purposes of this discussion, I will divide them into *short-term*, *intermediate*, and *long-term*. On the short-term scale of a second or less, Pressing argued that embodied patterns and learned gestures of procedural memory constitute the bulk of the grist for the improviser's mill. Improvising at this timescale, according to him, involves a nonlinear cycle of motoric function and cognitive feedback and feedforward. In reviewing the physiological and neurological literature, Pressing concluded that improvisers have the biological capacity to react to unexpected changes, and hence to one's own or one another's new ideas, about twice a second. He argued that the performance of experienced improvisers on short-term timescales can be quite nuanced and flexible, but it is also largely automatized.

On an intermediate timescale, lasting from a few seconds to the length of a full performance, Pressing argued that most improvised music utilizes an underlying scheme or formal image to facilitate the generation and editing of improvised behavior. Pressing called this a referent. His most succinct description of a referent was [52.40, p. 52]:

> *a set of cognitive, perceptual, or emotional structures (constraints) that guide and aid in the production of musical material.*

In other words, having a referent allows improvisers the possibility to prepare before the performance and a means during the performance to anticipate future developments. It provides *material* for variation or development, and since a referent can be shared, it reduces the need for detailed attention to all of the component parts of a given performance.

In mainstream jazz, for instance, a *standard* song form can provide a shared template of melodic, rhythmic, and harmonic information, and a means by which performers can synchronize or orient their performances with respect to those of the other musicians. But Pressing's notion of a referent was quite open-ended. It could be abstract or sublime, such as [52.14, p. 346]:

> *a mood, a picture, an emotion, a physical process, a story ... virtually any coherent image which allows the improviser a sense of engagement and continuity.*

A referent, in other words, is essentially anything that can provide shared musical *seeds* from which an improvisation can grow.

At the longest timescale, Pressing theorized about one's *knowledge base*, which includes the *passive expertise* an individual has about a music style and music culture, as well as the more personal history of one's own compositional choices and predilections. Pressing acknowledged that some improvisation could be referent-free on the intermediate timescale, but he insisted that all improvisation involves certain constraints at the short-term and long-term timescales, since embodied patterns and enculturated knowledge are always present in improvised performance.

Pressing's model is representational and reductionist by nature, but it offers considerable complexity in proposing that improvisers are constantly representing musical structure in parallel, via motor, musical, acoustic, and other ways. His model draws distinctions between improvisational features (e.g., loudness), objects (e.g., a motif), and processes (e.g., sequencing a motif), but it is primarily centered on the level of the musical event. A musical event, for Pressing, might involve an isolated feature, object, or process, but more often it will include all of them.

According to Pressing's model, improvisers first produce a set of musical events (E1). Then each subsequent set of events (E2, E3, E4) – at whatever time grain – takes into account the referent (R) that an improviser has stored in long-term memory (LTM), as well as each previous E – with increased weight given to E instances immediately prior. In ensemble settings, improvisers are also constantly taking account of and representing what the other musicians may have just done. All of this information makes arriving at an optimum solution likely too time consuming and resource intensive, but improvisers, according to Pressing, need only find a good solution, not the best. Pressing views these compounding and constraining factors as providing the potential for unique outputs and novel interactions between musicians. Experienced improvisers, according to him, tend to have a richer knowledge of the referent, an improved motor control and flexibility with their instruments, and an improved cognitive representation with more detail at a smaller grain size about the musical events produced by themselves and others, all of which allows for a mentally nimbler and more responsive performance.

52.6 Referent-Free Improvisation

What, then, of performances that do not, by their own admission, involve a referent? A variety of descriptive terms have circulated at various times and in various locales to describe post-1960 musical improvisation, each with its own group of adherents and each with its own semantic shortcomings. The preferred terms tend to highlight the creative or progressive stance of the performers and the cutting-edge or inclusive nature of the music itself: for example, free or free-form, avant-garde, creative, experimental, contemporary or new, collective, spontaneous, and so on. Stylistic references (e.g., jazz, classical, rock, world, or electronic) are variously included or excluded, as are cultural or national identity markers (e.g., Great Black Music, British Free Improvisation, or Japan Noise). In certain cases in which these specifying linguistic markers are not included, terms may still be indelibly associated with specific individuals or locations: for instance, conduction (Butch Morris), sound painting (Walter Thompson), chance or aleatoric music (John Cage), harmolodics (Ornette Coleman), intuitive music (Stockhausen), reductionism (Berlin), and onkyokei (Tokyo), etc.

The scholarly literature on improvisation also varies considerably on the question of how to interpret the notion of *freedom* in this music. Some authors explain freedom in purely musical terms, as varying degrees of liberation from functional harmony, metered time, and traditionally accepted performance roles and playing techniques [52.42, 43]. For others, defining free improvisation in strictly musical terms misses its most remarkable characteristic – the ability to explore and negotiate disparate perspectives and worldviews [52.44].

Many authors have interpreted free improvisation, and free jazz in particular, as a sociopolitical response to the appropriation and exploitation of African-American music styles [52.45–47]. They focus considerable attention on the birth of the practice during the Civil Rights Movement in the United States and on the music's place within the context of an emerging postcolonial world. Other authors have allied themselves with Marxist or neo-Marxist critiques of hegemonic culture and have focused on free improvisation's implied critique of capitalism and its related market- and property-based economy. For instance, *Eddie Prévost*, a pioneering English improvising percussionist, argues in [52.48] that free improvisation is least susceptible to commodification and that it is, therefore, primarily the domain of those who have felt stifled or excluded. Still others view collective improvisation as a fruitful site for generating social bonds, often across cultural and class divides, or argue for its promising therapeutic uses [52.49].

Given this range of opinion and approaches, how is it that musicians attempting to leave all compositional aspects undecided until the very moment of performance can produce coherent music together in real time? Opinions about free improvisation vary widely, according to *Derek Bailey* in [52.10, p. 85]:

> *They range from the view that free playing is the simplest thing in the world requiring no explanation, to the view that it is complicated beyond discussion. There are those for whom it is an activity requiring no instrumental skill, no musical ability and no musical knowledge of any kind,* he asserts*, and others who believe it can only be reached by employing a highly sophisticated, personal technique of virtuosic proportions.*

If there is a shared bond between these diverse performers, it may be a fascination with both the surprising musical occurrences and interpersonal possibilities inherent to an improvisatory method in which the content

and form of the music at the intermediate timescale are radically underdetermined. In other words, improvised music of this kind explores matters from the microscopic level of expressive detail to the macroscopic level of collective coordination and emergent form, all without an explicit reliance on a shared model or referent. Self-imposed and shared stylistic constraints do often play a generative role in the development of the music, but in referent-free improvisation there is no explicit precommitment to what will happen once the performance begins.

Even with these ideals in mind, it is clear that artists bring to any given performance a lifetime of musical engagement, experimentation, and expectation that is evident at both short-term and long-term timescales. Free improvisation is not a *pure* form of improvisation, or a type of ex nihilo creation, as some of its adherents occasionally suggest. Embodied patterns and learned gestures provide the foundations of this approach on short-term timescales, and across longer timescales free improvisation involves the development of a personal experiential knowledge base (and, some argue, necessitates developing an identifiable *voice* or style) as much as any other practice. Calling the music *nonidiomatic*, as *Bailey* does in [52.10], runs the risk of denying culturally shared sensibilities and understandings, which certainly come into play when the musical backgrounds of the performers and listeners are similar.

It should be noted that a considerable amount of music that is grouped under the broad heading *free improvisation* is not referent-free in the way that I am using the term here, perhaps highlighting that this binary between referent-based and referent-free improvisation is ultimately untenable. For instance, in settings in which musicians have played together before or those in which they are simply aware ahead of time of the body of recorded work that the other musicians have produced (which is to say almost every professional improvised music encounter), these previous experiences often serve as a type of pseudoreferent for the current situation.

Mike Heffley [52.50] highlights three kinds of freedom in improvised music: freedom-from-form, freedom-to-form, and freedom-in-form. Freedom-from-form describes the reactive process of stretching, challenging, and breaking rules and conventions that were once embraced as laws. Freedom-to-form is a proactive step in which rules, patterns, and conventions from other musical traditions, and those of idiosyncratic origin, are embraced as temporary and mutable structures or designs. Freedom-in-form, for *Heffley* [52.50, pp. 279–80], signifies the consummate stage as well as the point at which the process has gone full circle:

> *One path is chosen from among all possible, and its route, uncharted from without, has nonetheless imprinted its own order on the improvising body as a law unto itself . . . that will come in its turn to be so challenged and changed.*

Somewhat analogously, many improvisers confront at various points in their musical careers the seeming paradox that one's instrument can be a means, a subject, and a barrier to expression. In other words, does one choose to use one's instrument to express something musical beyond the instrumental (e.g., singing a song with a saxophone)? Does one follow the more instrumental impulse to explore the sonic possibilities inherent to one's instrument (e.g., keyclicks, slap tonguing, and multiphonics on a saxophone)? Or does one's instrument potentially dictate too much of the content of what one improvises (e.g., can one play the saxophone without thinking saxophonically?).

The dynamics in ensemble situations are even more complex. Clément Canonne argues that collective free improvisation offers a paradigmatic case of the coordination problems which are present, to some degree, in every form of group improvisation. He devises a mathematical model in [52.51] using dynamical systems theory that extends, rather than contradicts, the important work of Pressing on referent-based improvisation. Briefly, on short timescales Canonne agrees with Pressing that clusters of musical events are primarily determined by previous training and embodied patterns. Cognitive limitations play a role (one can't decide too much at the same time), but so does a desire to remain flexible (one does not want to decide too much at the same time). At the intermediate timescale, which may range from many seconds to many minutes, referent-free improvisers must work to create sonic *identities* in the absence of material provided by a shared referent. Sonic identities include processes or features that are developed or explored for a short time, only to give way to new emergent *identities* via some process of gradual or abrupt transition [52.52]. How these transitions arrive and are effected by the ensemble provides some of the more fascinating moments in referent-free improvised performance (see [52.53] for a taxonomy of transition types and [52.26] for a detailed performance analysis using this taxonomy).

In [52.54], *Canonne* adopts the notion of a *focal point* from game theory to explore how potential transitional moments in the music exert various forms of salience on the performance and for the musicians. At these moments, musicians are collectively trying to single out one of many possible trajectories, or to arrive at a convergence of expectations (although, admittedly, wonderful music can also happen, from the listeners

perspective, when the expectations of the performers remain divergent). In empirical studies involving musicians with different musical backgrounds and levels of experience with referent-free improvisation, Canonne found that experienced improvisers most often take advantage of sonic disruptions to signal transitional moments or to singularize musical ideas, turning them into focal points that ensure the vivacity of the musicians' coordination. His data show that seasoned free improvisers were also more skilled than their counterparts in jazz and classical music not only at determining the salience of the sonic environment for themselves, but also in anticipating the salience that sonic events will have for others, often taking into account particular instrumental constraints and affordances, or, when relevant, their shared history of improvising together.

Team reasoning strategies and skills are likely of particular importance to referent-free improvisation settings, since without a shared referent there is little musical *scaffolding* with which to solve group coordination problems. Canonne's dynamical systems model also demonstrates that referent-free improvisation can be self organizing, particularly in situations with a small number of musicians (< 5) who can sufficiently take advantage of their virtuosity, their leadership qualities, and their team reasoning.

Whether improvising in a referent-based or referent-free setting, one's *knowledge base* appears to encompass the embodied (overlearned motoric practices), personal (conceptual, aesthetic, ideological), and culturally shared (tacit understandings) elements that allow for the coherent unfolding of a musical performance. *Canonne*'s most recent empirical work [52.35] highlights how experienced improvisers come to share an implicit mental model of the practice of referent-free improvisation; a type of higher-level knowledge or metastructure that is task-specific instead of piece-specific. He and coauthor Aucoutourier asked experienced improvisers to sort short audio examples of free improvisation into groupings based on their *pragmatic similarity*; in other words, how they would react to the sounds in a performance setting. The authors analyzed these responses and found that the degree of similarity with which participants grouped sounds predicted with better-than-random accuracy their degree of musical familiarity.

In other words, musicians who played together tended to think about improvised music in the same way. The authors conclude that shared mental metamodels such as these may play a key role in the success of referent-free improvisation by allowing more confident *mind reading* of the intentions of fellow improvisers, more frequent cognitive consensus in the course of a performance, and swifter repair of *communication errors* when there is cognitive divergence among the improvisers. They note, however, that the normalizing force of familiarity is not always desired and is therefore frequently countered when musicians opt to play in unfamiliar situations with unfamiliar collaborators (e.g., Derek Bailey's Music Improvisation Company was founded on the idea of having musicians improvise together who had never shared the stage before).

Theorizing about improvisational processes always runs the risk of reifying the result, or of remaining centered on the individual, whether the focus is on skill acquisition, mental representations, rule-based procedures, or on a more integrated view of cognitive schema involving the parallel processing of motor memory, auditory imagery, and audio-motor integration. Much of the early modeling of referent-based improvisation by Pressing and others remained firmly ensconced in an individualistic information-processing paradigm. Berliner's and Monson's influential work on jazz highlighted the complexity and centrality of interactional dynamics in jazz performance, but our understandings of the social dimensions of improvisational performance have often lagged. Interestingly, *Pressing*'s final writing on the subject [52.55] took a more ecological turn, highlighting how the mind, body and environment are all part of an interacting dynamical system.

52.7 Final Thoughts

A distinction has been made here between referent-based and referent-free improvisation primarily dependent on the presence or absence of shared mental models at the intermediate timescale of performance. Referent-based improvisation tends to have well-established (though not necessarily unified) traditions of aesthetic evaluation, and the cognitive schemas used tend to be overlearned so that they can be rapidly accessed and adapted to the needs of the moment. Referent-free improvisation, by contrast, may involve less-well established schemas and less shared conventions, but motor patterns still play a prominent role, and shared metamodels can evolve when musicians play together over time. In the absence of an agreed-upon referent, implicit strategies for group coordination emerge to compensate.

However, we may be best served by considering these as constructed-capabilities-in-action instead of as stored artifact, referent, or model. Improvising without a referent does not discount the importance of culture and experience, nor does it downplay one's embodied and skilled relationship with the available musical resources. Rather, it frames the process of improvising as enactive instead of representational. Knowledge does not emerge from passive perception, or from the analytical study of an agreed-upon referent; it emerges from the need to act in an environment. In this way, referent-free improvisation may offer an exciting window into exploring cognition from an ecological vantage point.

When viewed ecologically, cognition is best understood as a process coconstituted by the cognizing agent, the environment in which cognition occurs, and the activity in which the agent is participating: action, perception, and world are dynamically coupled. In this light, improvisation may be seen as a cyclical and dynamic process, with no nonarbitrary start, finish, or discrete steps (i. e., it is not a token of a compositional megatype). The improviser and the environment coevolve; they are nonlinearly coupled and together they constitute a nondecomposable system.

Improvisers engage with the world and with one another in ways that can not be fully captured by an individual- or brain-centric understanding of cognition. The brain of an improviser is, ecologically speaking, always-and-already in a body and in a niche of musical activity. Instead of having to represent a musical model or shared referent, improvisers *bring forth* a musical world from recurrent sensorimotor patterns and actions. The burden of improvised performance, in this way, shifts from storing and recalling information to detecting it, in the form of ecological invariants and affordances. In place of a computational model of mind – one that stresses the constraints of our cognitive abilities – an ecological one only requires that individuals follow the need to act in their environment, that they orient their actions so as to make the world appear – or sound – a certain way now. Cognitively speaking, this solution is efficient and cheap, and it produces reliable results under a wide variety of conditions.

Whether referent-based or referent-free, improvisation appears to involve a continual tension between stabilization through communication and past experience and instability through fluctuations and surprise [52.56]. This is likely a dynamic of all creativity in the arts and in life, but improvisation draws attention to itself *as* performance: to how it defamiliarizes the familiar. *Gary Peters* offers two related allusions in [52.57]: the improviser as a contestant in a scrapyard reality TV show in which she must fabricate something original out of the discarded materials readily at hand; and the improviser as the subject of Paul Klee's *Angelus Novus*, with her face always turned toward the wreckage of the past as she is propelled into the future by the storm of progress. In both cases, improvisation has more to do with a way of being in the world than with the content or *value* of a fixed work. The critical questions, in the end, involve how we chose to frame these improvisatory dynamics: either as information processing that struggles to keep pace with the cognitive demands of the moment, producing a type of *imperfect* art; or, as an ecologically sensitive engagement with one's sonic and social world.

53. Music of Struggle and Protest in the 20th Century

Anthony Seeger

This is a description of a sound, a poetics, and a political stance in the United States of America during a turbulent century and a half written by someone who grew up in the social milieu described. It endeavors to trace some of the historical and literary roots of 20th-century protest music and discusses the political and musical impact of certain musician-activists on the styles of protest music popular in the second half of the 20th century. These included Charles Seeger, John and Alan Lomax, and Pete Seeger, among others. The tradition of using song to express political ideas flourished in the first four decades of the century, declined due to political repression in the fifth decade, flourished again during the 1960–1980s, and moved to spoken poetry and rap toward the end of the century. For a brief period of time the 20th century forms and performances of music of struggle and protest in the United States had a major impact on music and how music was used in other struggles around the world.

Ethnographies are typically detailed accounts written about a group of people with whom an ethnographer belonging to a different group has had personal experience. That is what the word means – writing about (other) groups. This is an ethnography of a subgroup, a sound, a poetics, and a political stance in a place – the United States – during a turbulent century and a half written by someone who grew up in the social milieu described. Now that the poetry of struggle has largely moved to rap, it is a good moment to reflect on the history of the singer-songwriter of protest music in the 20th-century USA. Research for this essay has involved consulting primary sources such as sheet music, (among the songbooks [53.1–3]); audio recordings (particularly important historical anthologies of recordings include [53.4–8]). A flood of excellent, thoughtful books since 1990 on the US folk music revivals and biographies of some of their major figures, such as [53.9] on Handcox, [53.10, 11] on Woody Guthrie, [53.12] on John Lomax, [53.13] on Alan Lomax; and the publication of original documents of Alan Lomax [53.14, 15] and Pete Seeger [53.16], added to earlier ones on Charles Seeger [53.17] and Ruth Crawford Seeger [53.18], have also made it easier to reflect on the topic today than ever before. Recent books specifically addressing music and musicians in social change were also very useful [53.19–23] as were some older publications [53.24–29]. The author's first-hand experiences as a young member of the Seeger family backstage and in the audiences at Carnegie Hall, in the artists' seating at the Newport Folk Festival, attending numerous concerts and family gatherings, and his experiences as a musician participating in (a few) marches to end nuclear armaments or wars, were an additional resource for this essay. This essay endeavors to trace the historical and literary roots as well as the political and musical impact of certain musician/activists for the particular styles of

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5_53

protest music popular in the second half of the 20th century.

Communities and individuals around the world use music to express their struggles or to protest their situations in many different ways. Mass choirs, workers choruses, and popular music styles have been used in the Baltic states, Europe, and Korea. In other parts of the world protest music may not be a local tradition but one adopted from that of another country, as in the performance of heavy metal in the Middle East or Indonesia. Some communities do not use music to express struggle and protest at all, but demonstrate dissatisfaction by refusing to make music and remaining still while others dance. For example, the Suyá/Kĩsêdjê Indians of Brazil considered melodies and texts to be revealed by powerful entities, not made up by individuals. Songs were all parts of ceremonies and could neither be altered nor used for other purposes [53.30]. They wrote no protest songs and had no lullabies. When they were unhappy their protest was expressed through silence – ceasing to interact with others or remaining silent and motionless while others sang and danced. The tradition of using song to express political ideas has flourished, declined, and flourished again in the United States during the past one hundred years. The socially conscious songs of such songwriters and performers as Joe Hill, John Handcox, Aunt Molly Jackson, Woody Guthrie, Pete Seeger, Malvina Reynolds, Phil Ochs, Tom Paxton, Gil Turner, Jim Collier, Joan Baez, Bob Dylan, Holly Near, Bruce Springsteen, and many others have had a powerful impact on those who listened to them, as have the rhythmic speech, beats, and sampling of rappers today. Union leader John L. Lewis is quoted as saying in 1939: *A singing army is a winning army and a singing labor movement cannot be defeated* [53.5, p. 13]. If music were not perceived to be a powerful resource in social and political struggles it would not be so widely censored, controlled, and surrounded with restrictions by governments and religious organizations in different parts of the world. The United States in the 20th century was no exception – politicized music was met with government repression and commercial ostracism.

During much of the 20th century a singer with an instrument performing alone or leading a trio or quartet group was the most characteristic voice of protest music in the US. Their vocal style was often untrained and their instrumentation usually avoided the virtuosic. They often conveyed the hard times and struggles of people other than themselves, though they may have written or arranged the song texts about them. Most of these performers had large repertories and sang many kinds of songs; only a few might be classified as songs of protest. Different performance venues and different political conjunctures elicited different repertories. Many of their topical songs set new words to familiar melodies in a style sometimes referred to as *zipper songs* – you *zip the old song open*, replace the old words with new ones but keep the melody, and *zip it closed* for an instantly recognizable song. Why were these figures so representative of the music of struggle and protest? Where did this model come from? Why was their vocal style purposefully untrained? Why did they write their own songs or song lyrics? How did *folk music* become defined in the United States as someone playing the guitar and singing his or her own songs? Why were certain stylistic features and compositional techniques chosen over others? Those are among the questions this short essay will try to address.

Several kinds of analysis are required to answer such questions. Analyzing the musical sounds of specific pieces is not sufficient, nor is describing the biographies of individual performers. While historical sources can point to some of the literary and scholarly antecedents for the figure of the singer-songwriter aligned with working people on the one hand and groups of people singing together on the other, history alone is not sufficient. It is essential also to consider the specific political contexts of the 20th century within which the music was performed and to recognize the powerful impact of the activities of a few key individuals in the 20th century whose influence on the music was particularly influential.

53.1 Historical Antecedents of Music of Protest and Struggle in the United States

This essay addresses two somewhat different kinds of music, that of struggle and that of protest. Struggle, defined as a *continued effort to resist force or free oneself from constraint* [53.31, p. 3104] is different from protest, which means to make a public declaration against something [53.31, p. 2335]. Descriptions of how times are hard and how it is a struggle to survive are *songs of struggle*. I use the word protest song to mean songs that call the audience to take a specific kind of action. The boundary isn't absolute, as a song of struggle can be used to make a protest and the most important factor in defining a protest song is how the audience

perceives its performance and acts upon it. Instrumental music can also be used to express both struggle and protest through sonic parody, through its tone quality and performance style, by changing the place and time of its performance, and how it relates to a specific social context.

Music of protest and struggle had a long history in Europe and probably also in Africa before it was employed in the United States. Many songs were passed through the oral tradition and most of them were forgotten after the events passed. Broadside ballads – cheaply published poetry about current events printed on single sheets of paper and sung to standard melodies published in England beginning in the early 16th century – often described disasters and political affairs (within limits set by the censors or publishers), and many of them have survived the centuries since their initial publication. Benjamin Franklin wrote ballads about current events for his father's Massachusetts newspaper in the 1700s; an important principle in the freedom of the press was established through a legal case over published ballads in New York City in 1733 [53.32, pp. 373–374]; and songs have been written about every war in US history (from *Yankee Doodle* to *The Star Spangled Banner*, *Waist Deep in the Big Muddy*, *Born in the USA* and hundreds of others). Elections were another perennial subject of songs that would praise one candidate and often ridicule or excoriate his opponent. From 1800 to the 1940s songs were written to support every presidential candidate and in the 19th century political parties regularly published songbooks about their candidates [53.33, 34]. Songs and the social movements that performed them have advocated the elimination of slavery, abstinence from liquor, farmers' rights, the right of workers to form unions, women's right to vote, access to equal civil rights for ethnic groups and for gay, lesbian, bisexual, or transgendered individuals and other causes over the centuries. A long tradition of African-American song has addressed hard life, oppression, resistance, anger, and hope. This centuries-long history of using of music, and especially song, to express struggle and political protest nourished the nation's protest music of the 20th century and advanced the struggle of African Americans for civil rights. Almost every community in the United States has music describing their hard times, and some perceived by community members as protest. But in addition to the existence of protest songs we must explain their specific form, performance style, and the figure of the singer-songwriter.

53.2 The Poet Walt Whitman's Influence on the Image of the of the Protest Singer–Songwriter

In addition to building on an earlier tradition of songs of protest, the United States also developed a tradition of small groups (often trios or quartets) and single creators who identify with worker's struggles and write influential poetry. Singer/poets who identified with the *people* had their roles established in American literature in the mid-19th century by the very influential poet Walt Whitman (1819–1892). Bryan Garman traces what he terms *a race of singers* (specifically male singer-songwriters) back to Whitman (and some of Whitman's ideas can in turn be traced to Herder [53.24]). Whitman has sometimes been called the *father of free verse*, which eschews regular meter patterns and rhyme and tends to follow the rhythm of natural speech – an important feature a good deal of US protest music. Whitman was an admirer of the popular Hutchinson Family Singers, who toured parts of the United States and England singing antislavery songs in the mid-19th century. They filled large concert halls in New York and Boston for high fees and were probably the first commercially successful popular singers of political songs in US history [53.9, 35].

Whitman promoted the idea of a working-class poet-hero whose poetry could have a political impact. He believed that literature could change politics because art and politics were inextricably interrelated [53.36, p. 81]. Writing about music, Whitman suggested that a simple unadorned music should supplant the *stale second-hand foreign method* and replace it with an an aesthetic that subordinated style to substance in the form of *heart singing* [53.36, p. 81]. These sentiments were echoed by musicologist Charles Seeger and Alan Lomax many years later in their calls for an American music based on vernacular or folk music and can be seen in the instructions Ruth Crawford Seeger laid down for singers of folk songs.

If the influence of a 19th-century poet on 20th-century protest music seems unlikely, consider the following: Woody Guthrie read Whitman's influential book of poetry *Leaves of Grass*; Alan Lomax acknowledged the importance of Whitman on his father's and his collections of traditional music and their view of Woody Guthrie. (Alan Lomax wrote *Woody really fulfilled ideal for a poet who would walk the roads of the country and sing the American story in the language*

of the people [53.36, p. 89].) Whitman also certainly influenced the way their supporters perceived singer-songwriters like Guthrie, Seeger, and Springsteen: as poet-heroes of the people singing music that is at once political and artistic and whose verses naturally follow patterns of vernacular speech.

53.3 Ballad Collectors, Songs of Struggle, and Versions of the American Identity

In the 1930s Charles Seeger, John Lomax, and his son Alan Lomax called for a shift from Eurocentric music to an American music based on its folk music that resembled Whitman's preferences for a simpler sound. The search for *folk* or vernacular (local) music had various objectives in the United States, and books of collected songs had been published since the 1840s. The American scholar *Francis Child* published his landmark study of English ballads in the 1880s [53.37], and much of the early collecting of folk songs in the United States focused on narrative ballads performed in the southern Appalachian region in the Eastern United States. African-American music was rarely included in the ballad studies or in the educational programs proposed to teach children their cultural heritage [53.38, p. 27]:

> *The most significant effect of the myth of the white ballad singer was to help block African-American folk song from gaining a central place in the canon of America's musical heritage.*

Returning African-American music and local musical styles to their place in America's musical heritage was one of the goals of John A. Lomax and his son Alan Lomax, whose enthusiasm for recording the music of a wide diversity of Americans led to the establishment of a very different canon of 20th century music and musicians than that of the ballad scholars. Their methods were different from those of the earlier ballad collectors who wrote down the songs from dictation. They went to prisons and sharecroppers' houses and made audio recordings not for publication but for documentation – most of them were deposited in the Library of Congress. The field recordings they made, the songbooks they prepared from them, their symbolically prominent positions at the Library of Congress Archive of Folk Culture, and Alan Lomax's activities in radio, theater, and record productions all had a huge impact on the music of the 20th century. Alan wrote this about how going to people's homes to record them gave the documenter a very different perspective on the music than scholars who studied only the song texts in manuscripts [53.39, p. 365]:

> *The literary scholars, who seldom went into the field and collected their songs in the homes of the singers, have failed generally to perceive the undercurrent of tragedy and of protest that underlay the songs they footnoted and published.*

A number of important figures in the future of the folk music revival and songs of struggle and protest would meet in the 1930s and their intertwined lives would have a powerful effect on subsequent decades. These were Charles Seeger, his son Pete, and children of his second wife, Ruth Crawford; John Lomax, his son Alan, his daughter Bess, and other members of his family; Woody Guthrie; Lead Belly; and other artists. The following paragraph briefly summarizes their biographies because they appear repeatedly in this essay.

Charles Seeger (1886–1979) merits the longest description not only because he was – among other things – a systematic musicologist but also because his career took many intricate turns and three of his children became influential musicians. Born in Mexico City to an American businessman with a successful career in imports, C. Seeger studied music at Harvard (where he hated music history) and then studied in Cologne, Germany, and did some conducting at the Cologne Opera. This is not a place to summarize his career, but suffice it to say that he was a theorist-composer with great self-assurance, unusually extensive international experience by virtue of his early years in Mexico and his studies in Germany, and an organizer. His political radicalization in 1913 or so led to his dismissal from Berkeley and was followed by the end of his marriage to Constance. He was an active member and one of the theorists of the Communist Party-funded Pierre Degueyter club and taught composition in New York City for a few years. He married a young composer Ruth Crawford and moved to Washington DC to work on government programs for the arts in 1936 and later was head of music and arts programs at the Pan American Union (precursor to the Organization of American States). He was very active in national and international professional organizations. He was a founding member of the New York Musicological Society, the American Musicological Society, The Society for Comparative Musicology (founded as a way to give continuity to the work of the nearly defunct Gesellschaft für Ver-

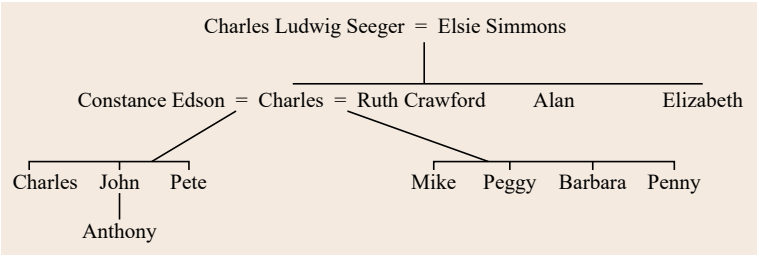

Fig. 53.1 Simplified diagram showing Charles Seeger, his parents, siblings, seven children, and the author

gleichende Musikwissenschaft in Germany because so many of its members left Germany), and the Society for Ethnomusicology. He was active in UNESCO NGO, including the International Music Council and the International Council for Traditional Music. He saw music as embedded in social life and this influenced his musicological work, his practical work in US government programs, and his theoretical writings about music and social transformation. He was also an advocate of what would later be called *applied musicology* [53.40, pp. 227–228]. Charles could look at disparate phenomena and theorize about them with an assurance that often convinced others, though much of his later writing was hampered by a very dense prose style that is difficult to read. Charles had three sons with his first wife, Constance, a concert violinist. The youngest was Pete. Their marriage eventually ended in divorce. Several years later Charles married one of his composition students, Ruth Crawford, and started another family that eventually included four children, two of which – Mike Seeger and Peggy Seeger – were active and influential professional musicians. Figure 53.1 is a very simplified family tree showing Charles and his children, and only one of his many grandchildren (the author).

John Avery Lomax (1867–1948) was raised on a central Texas farm, put himself through college and business courses, and worked for many years in college teaching and administration. Long interested in cowboy poems and songs, at Harvard he was encouraged to pursue the study of Texas traditions and published the influential book *Cowboy Songs and Other Frontier Ballads* [53.41] in 1910 with an introduction by President Theodore Roosevelt. He became a popular lecturer on folklore and often gave lecture-demonstrations in which he talked about and then performed the songs. Hard hit by the Great Depression and the death of his first wife, Lomax moved to Washington DC where he was appointed honorary consultant and curator of the Archive of Folk Song at the Library of Congress and, like Charles Seeger, worked for agencies of the US government. With his son Alan he collected thousands of recordings for the archive and published several songbooks. He had four children, Shirley, John A. Jr., Alan, and Bess. Like the Seeger family, several of his children and grandchildren were influential in American music. Alan was a brilliant recordist, a master of media production, and an intrepid traveler and researcher whose impact on American music was tremendous, and whose work was also influential in the popularization of music of struggle and protest.

The encounter of the Lomaxes in Washington DC with musicologist Charles Seeger, his son Pete Seeger, and Charles' second wife Ruth Crawford Seeger and their children was an important stimulant of the musical ferment and the performance style of singers of folk and protest music in the 1930s and 1940s and into the 21st century. Ruth Crawford's avant-garde sensibilities led her to recognize the musical subtleties of the musicians the Lomaxes recorded, which she carefully transcribed for some of their publications. Alan Lomax, Pete, Mike, and Peggy Seeger's lives were intricately intertwined in many ways over the decades.

53.4 The Vocal Style and Performance Practice of US Protest Music

Peggy Seeger has suggested that a key to understanding the stylistic continuity in American protest song is the use of vernacular speech patterns in the songs. The rhythms and melodies of the songs often follow those of spoken English (Peggy Seeger personal communication). In the late 1930s Peggy Seeger's mother, the composer Ruth Crawford Seeger, transcribed dozens of field recordings made by the Lomaxes of American vernacular music for the songbook *Our Singing Country* [53.39]. Although vastly shortened by the Lomaxes for their book, her introductory essay includes an important discussion of folk performance style as discerned from the recordings. The whole introduction, without edits, was only published in 2001 [53.42]). The sixteen instructions she gives to readers of the book who might want to sing the songs from her transcriptions are

a good characterization of the vocal style and performance practice of a lot of music of struggle and protest during the 20th century (adapted from [53.43, p. xxxi–xxxiii]):

1. Do not hesitate to sing because you think your voice is not good. The songs are better sung in a natural voice than a bel canto voice.
2. Do not sing *with expression* – maintain a level of more or less the same degree of loudness or softness from the beginning to the end of the song.
3. Do not slow down at ends of phrases, stanzas, or songs.
4. Do not hesitate to keep time with your foot [and] unless otherwise indicated sing with a fairly strong accent.
5. Do not *punch* or typewrite out each tone, when two or more tones are to be sung to one syllable of text.
6. Do not make too much difference between major and minor degrees in songs containing both.
7. Do not feel, in group songs, that these songs require harmonizing.
8. Do not hesitate to sing without accompaniment.
9. When doing so do not make noticeable pauses between. stanzas. When accompaniment is required a guitar or banjo is to be preferred.
10. Remember that most songs begin with the chorus and end with the chorus.
11. *Do not sing down* to these songs. Theirs are old traditions, dignified by hundreds of thousands of singers over long periods of time.
12. Her last injunction was *listen to phonograph recordings of these songs and others like them.*

Although recordings were available during the 20th century, radio and television rarely featured political and topical songs for most of the first half of the 20th century. Other kinds of mass media were important for the transmission of music of protest and struggle. The labor songs of the 19th century were transmitted through newspapers and in songbooks. Quite a few political movements generated their own songs in the late 19th century, but the Industrial Workers of the World (IWW) used songs quite extensively for entertaining members and for drowning out competing musical messages from other groups on public street corners. One of the IWW's best remembered singer-organizers was a man known as Joe Hill ([53.44], also known as Joseph Hillström). Hill wrote *zipper* songs of struggle set to popular melodies of the time, which made them easy to learn and to sing. Hill wrote from jail in 1914 that (cited in [53.45, p. 1]):

> *A pamphlet, no matter how good, is never read more than once, but a song is learned by heart and repeated over and over. There is one thing that is necessary in order to hold the old members and to get the would-be members interested in the class struggle and that is entertainment.*

Hill was probably framed for murder and executed in 1915. (Joe Hill is best remembered by many through the song written after his death, *I Dreamed I Saw Joe Hill*, written by Alfred Hayes in 1930 and memorably performed by Paul Robeson and later by Joan Baez.) The Industrial Workers of the World published a song book entitled *Industrial Workers of the World Songs to Fan the Flames of Discontent*, which became known as *The Little Red Songbook* [53.1, first edition 1909]. Although IWW membership diminished in the 1920s, the music and the organization continued and the idea that a good song is sung a thousand times and that workers need entertainment was influential to generations of songwriters and performers. Song books and songsheets continued to be published throughout the 20th century in order to introduce dispersed readers to new songs. Among them was a quarterly bulletin of people's songs from 1946–1950 [53.21, pp. 179–220], *Sing Out!* magazine from 1950–present, *Broadside* magazine from 1963–1988 [53.6] and *Fast Folk Magazine* (1982–1996) [53.7]. *Fast Folk Magazine* did not focus on songs of struggle and protest and used compilation LPs and CDs to supplement the printed page, but like the earlier magazines the work was collective, the song was thought to be more important than the singers, and the objective was to make the songs available for others to sing [53.46].

Audio recordings, both commercial and *field* recordings, reveal that before Charles Seeger and the Lomaxes called for a vernacular American sound a lot of Americans were already singing that way at home and in public. There is no space here to review the history of recorded sound in the United States, but both early commercial 78 rpm records and field recordings reveal a common singing style in the southern Appalachians that was also employed by local performers, textile workers and coal miners, and by Woody Guthrie, often by Pete Seeger and the Almanac Singers, and from them to other performers. Commercial audio recordings and private field recordings provided important models for generations of singer-songwriters in the 20th century. Eloquent songs of struggle are found among the large number of commercial recordings made of local southern musicians and released by major labels to sell back to members of the communities in which they were recorded in the 1920s through the mid-1930s. The recordings of rural musicians included songs of hard times, of tragic events, armed conflict, and of protests. They were often sung by solo

singers or family groups and the accompaniment was often on instruments of a string band (banjo, guitar, and or fiddle). Both the recording process and many of the artists on them ceased recording during the economic depression of the 1930s and after World War II most large record labels dropped the strategy of recording local artists for regional markets in favor of producing national hits. Preserved by collectors, the original 78 rpm records provided an inspiration to many urban performers in the 1950s and 1960s. Woody Guthrie, for example, is said to have listened to and imitated the guitar style of the Carter family (as well as using some of their melodies for his songs). In 1952 Harry Smith, an artist and record collector, assembled a long play record anthology from out-of-print 78 rpm records published between 1926 and 1934. His *Anthology of American Folk Music* was released on Folkways Records and became an important reference for the folk music revival. Among the songs of industrial transformation and rural or domestic struggle on that anthology that were subsequently played by folk revival artists were *Peg and Awl* by the Tar Heel Boys, *Down on Penny's Farm* by the Bently Boys, *Single Girl Married Girl* by the Carter family and *How Can a Poor Man Stand Such Times and Live?* by Blind Alfred Reed.

There were strong differences of opinion even within the Seeger family itself about the right way to perform these vernacular songs from an earlier era. Mike Seeger tended to take a curatorial approach, playing and singing in a way similar to the originals. Pete Seeger took a much freer approach, and often altered the melody, changed the accompaniment, and sometimes shortened or adapted the lyrics. Peggy Seeger seems to have done some of each. Both Pete and Peggy composed new songs in a variety of styles. Arguments about authenticity and representation surfaced throughout the folk revival of the 1950–1970s. Having the actual sounds from an earlier era available for consultation was thus both a boon and a point of contention. But the early commercial and field certainly influenced the endurance of a characteristic performance style.

53.5 20th Century Politics and Protest Music

The style and content of protest music does not simply derive from 19th-century poets, individuals, songbooks, and audio recordings. The policies of the Communist Party USA (CPUSA) played an important role in shaping a national culture of protest song in the US, as is ably described by *Reuss* [53.21, p. 1971] and *Dennisoff* [53.47]. Reuss traces the move to politicize music and all artistic expression to a speech by Bukharin at the 1928 World Congress of the Communist International [53.21, p. 40]:

> *The third period ideology that Bukharin promulgated had stern implications for American Communists' attitudes toward culture. All artistic expression was to be politicized.*

In 1931 the Workers Music League was formed and in 1932 the New York City section of the league founded the Pierre Degueyter Club (Pierre Degueyter had composed the *International* and had died in 1932). One of its divisions was the Composers Collective, which *developed the most important theoretical statements on music in the American Communist movement* [53.21, p. 44]. Among its active members were Charles Seeger, Mark Blitzstein, Henry Cowell, George Antheil and Elie Siegmeister. Writing under the pseudonym Carl Sands, Charles Seeger wrote in the *Daily Worker* 1934, (cited in [53.21, p. 45]):

> *Music is propaganda – always propaganda – and of the most powerful sort and: The special task of the Workers Music League is the development of music as a weapon in the class struggle.*

By the late 1930s the CPUSA was more enthusiastic about using local folk traditions to further the struggle. In the 1950s, declared an illegal organization and its members persecuted, the CPUSA lost many of its members when Stalin's atrocities were verified and the tanks rolled into Poland in 1956. But the impact of its involvement in the arts was felt by many protest musicians in the 1950s during the Cold War. After the Composer's Collective invited southern union organizer and singer Aunt Molly Jackson to attend their meetings, Charles Seeger realized that her vernacular style would be more successful in communicating radical ideas to the masses than the avant-garde compositions of his fellow members of the Composers Collective. He reportedly said to her *Molly, they didn't understand you. But I know some young people who will want to learn your songs*. One of them was his son, Pete Seeger [53.21, p. 53] whose political positions, organizational skills, writing, musicality, songwriting and commitment to getting audiences to sing with him had a very powerful impact on performances of music of protest and struggle in the second half of the 20th century.

Like his father, Pete Seeger founded and led a number of different organizations, was at the center of topical song activities and was a member of two influential musical groups. He was a founding member of a songwriting and performing collective that called itself the Almanac Singers. (Most histories of American topical song and the folk music revival of the 1960s highlight the Almanac Singers, two of whose members became important in the popular group The Weavers after World War II [53.21, pp. 147–148]. Although short-lived, the group and its songs had a strong impact on later developments.) The group was based in a shared apartment in New York City, wrote songs collectively, and recorded several albums of protest music and two albums of folk music standards in the early 1940s. The group recorded an album of antiwar songs shortly before Germany invaded Russia, after which it began to record anti-Hitler songs and virtually disbanded as its members entered the war effort. Pete Seeger volunteered in the Army and served in the Pacific as a musician; Woody Guthrie joined the Merchant Marine; Bess Lomax joined the defense effort as well. After returning to civilian life Pete Seeger became an organizing figure behind a postwar organization called People's Songs (1945–1950) and its associated booking agency, People's Artists. When those failed he was instrumental in starting *Sing Out!* magazine (1952–the present), where he wrote a regular column for decades. He also financially supported the establishment of *Broadside* magazine (1962–1988), which published new topical songs [53.6]. *Broadside* was published by Agnes 'Sis' Cunningham and Gorden Friesan, whose careers had been ruined by the anti-Communist persecution of suspected Communist Party members. There were many contributors to *Broadside* whose songs were first published in this magazine, among them Bob Dylan, Sis Cunningham, Phil Ochs, Tom Paxton, Peter LaFarge, The Fugs, Nina Simone, The Freedom Singers, Janis Ian, Luis Valdez, Jim Collier, and many others.

53.6 African-American Musical Traditions and Social Protest

African-American composers, musicians, and scholars have contributed in myriad ways to musical life in the United States and it is impossible to do them justice here. While their contributions to ragtime, jazz, and rap were original, well documented, and powerful, so too was their use of music to describe their struggles and hopes in blues forms, in church music, and in music of struggle and protest. There were many African-American union organizers in the 1930s and some of them composed powerful songs. One of these was John Handcox [53.9] who authored *Roll the Union On* and *Mean Things Happening in this Land* among other enduring songs. Another was Lucille Simmons, who arranged a composed religious song *If my Jesus Wills* by Louise Shropshire into what, after some further arrangement, became known as *We Shall Overcome*. Simmons was renowned for her very slow renditions of well-known songs on the picket line [53.3, pp. 32–35]. African-American artists' use of community singing in the political movements for unionization in the 1930s and for equal rights in the mid-20th century proved to be a powerful organizing tool and the use of music in demonstrations became a model for using music in other political struggles, especially the anti-Apartheid protests in South Africa.

The Civil Rights movement of the 1950s and early 1960s was one of the most musical social movements of the 20th century. Some of its music came out of earlier African-American community organizing and some of it was invented on the streets and in jail by young demonstrators who took popular songs of the moment and *zipped* into them new words for the occasion. Just as a great deal of the organizational strength of the movement came from African-American churches, some of the best-known movement songs come from well-known religious songs. An influential a capella group called The Freedom Singers performed at many demonstrations and other public events. Bernice Johnson Reagon, one of its members, said that singing together kept them united and also kept them from feeling afraid. Protesters sang on the streets, in the jails, and in concerts in the North to gain support outside the South. This musical movement drew some of its strength from group singing – community singing like that found in many African-American churches. This was quite different from the tradition of the singer-songwriter, and its use and successes were very different. The Civil Rights movement was marked by tragedy and only partially successful in obtaining equal rights for African Americans in the United States, but through it some important gains were made. The assassination of Dr. Martin Luther King, the continued institutionalized racism, and the shooting and imprisonment of young African-American men made the tone of *We Shall Overcome* too optimistic and has led to a variety of other musical expressions of protest including rock and rhymed poetry.

53.7 The Conservative Reaction

If the changing policies of the Communist Party in the first half of the 20th century influenced the shape and development of protest music, the subsequent government investigations, trial by innuendo, and repression of political singer-songwriters also shaped its virtual demise in the 1950s. The repression was also shaped by larger institutions, collusion between government agencies and civic organizations, and a resulting climate of fear and accusation that tore apart long-standing allies, shattered friendships, and ruined many careers.

The United States does not have an official government office of censorship. Freedom of speech has protection in the US Constitution. Social movements, especially union organizing and establishing equal rights for African Americans, however, were violently repressed throughout the early 20th century by local police, private protection agencies hired by companies, State-controlled national guards, discriminatory laws, and businesses. These were sometimes unofficially aided by the Federal Bureau of Investigation. Musicians and other performers were rarely imprisoned or executed because of their music. But they were investigated and their careers ended because of who they performed for. There was a period from the late 1940s into the 1950s when many songwriters and performers of music of protest and struggle were accused of being Communists. Many people not only lost their jobs, they were *blacklisted*, or marked as people who should not be hired by any other organization. Anyone hiring them or defending them would also be suspect. The US Congress established the House Un-American Activities Committee (HUAC), whose objective was to investigate subversive activities on the part of civilians, government employees, and organizations with suspected Communist associations. In 1950 a pamphlet called *Red Channels* appeared with a long list of alleged Communists, and many of those whose names were on the list soon found themselves unemployable in their fields, avoided by their former friends, and the subjects of harassment and government investigation. Those were terrible times. If a person under investigation confessed to his or her errors and agreed to denounce other people who were supposedly active in Communist activities, that person was sometimes taken off the blacklist (but even those who collaborated by *naming names* often found they were still unemployable). When I was about seven I was playing a 78 rpm record of the Almanac Singers singing union songs on a hot spring evening in our apartment in New York City. My father, John Seeger (Pete Seeger's older brother) stormed angrily into the room, shut the window with a crash, and said *don't you ever play those records again with the window open*. He feared that neighbors might denounce us for the music we played. This childhood moment, which I remember vividly, was probably the origin of my certainty that music is deeply intertwined with society and culture and the beginning of my becoming an anthropologist and ethnomusicologist. This was the insidious and terrible thing about the blacklist – it created fear and suspicion and caused musicians who had once been best of friends to turn upon one another. My parents, teaching at a private progressive elementary school, did not suffer much from blacklisting but most of the rest my extended family did. Charles Seeger had his passport confiscated and resigned from his job at the Pan-American Union; his oldest son, radio astronomer Charles Seeger Jr., found that no one would hire him in the US and emigrated to the Netherlands for a position at Leiden University; Pete Seeger was investigated by HUAC and found in contempt of Congress for refusing to answer their questions on the basis of the constitutional rights to free assembly and speech. His career was shattered, he was forced to mount an extended legal defense, and he did not appear on television for 15 years. Even those family members who were not overtly political themselves suffered from the other family members' blacklisting. Mike Seeger was paid through a friend because a concert organizer did not want to list his name on the roster of paid performers. Peggy Seeger moved to England, as did Alan Lomax. Even I may have been a target. At age 16 a friend and I entered and won a small-town talent contest in 1960 whose first prize was $ 25 and an appearance on local television. The television appearance never occurred, and I never found out why – but other Seegers were banned from television and my last name probably led to dropping us from the show. The 1950s is stereotyped as a bland moment in history between World War II and the turbulent 1960s – but this was partly the result of the active silencing of many voices whose songs (and films, and journalism, and other arts) could not reach a wider audience.

53.8 The Folk Music Revival and The Commercialization of Folk Music

The beginning of the American folk revival is given different dates by different authors. Some trace it back to the folk dance movement of the 1930s and 1940s; others start it with the popularity of the Kingston Trio singing *Tom Dooley* in 1958 [53.48]; yet others divide it into different parts. If *revival* means *the emergence of the commercial successful performers of traditional songs and new compositions in a similar style*, which I shall use here, I would consider the debut of the group The Weavers to be the key event. Their performance of Lead Belly's *Goodnight Irene* was on the top of the music charts for 13 weeks in 1950 and their song *Tzena, Tzena, Tzena* was a hit the following year. Comprised of two former members of the Almanac Singers, Pete Seeger and Lee Hays, and two new additions, Ronnie Gilbert and Fred Hellerman, their first manager suggested they downplay the political songs of their past. Their first album featured rich orchestral arrangements by bandleader/arranger Gordon Jenkins. Yet they did perform songs by Woody Guthrie, Lead Belly, and from the Lomax books, as well as an array of international songs, including an Indonesian lullaby, an Indian song favored by Gandhi, and the South African *Wemoweh* (Mbube). For a short time they were in high demand and sold many recordings, but Pete Seeger and Lee Hays were identified by an informer (who later recanted) as members of the Communist Party. They were called to testify before congress and The Weavers were blacklisted – their record contract canceled, denied radio play and television appearances, and most of their bookings canceled as well. The investigation of The Weavers and a number of other musicians drove the musicians and their songs *underground*. But The Weavers had established the possibility of folk music having a large popular audience and many future musicians were inspired by The Weavers and by Pete Seeger's solo concerts in colleges.

Folk music going *underground* in the 1950s meant little media exposure and playing live at small venues such as coffee houses, college auditoriums, children's schools and summer camps, which were not as influenced by the blacklist. Pete Seeger once reflected that a good result of the blacklist was that he could influence a new generation of musicians who were at the colleges and schools where he was forced to perform to make a living. Many future folk singers were influenced by his concerts. Dave Guard of the Kingston Trio heard Pete Seeger at a concert where Joan Baez was also in the audience [53.48, p. 5]. Pete's college concerts had a powerful impact on a generation coming of age in the late 1950s and 1960s. (Several recordings of live concerts given by Pete Seeger during that period are available. One is a complete 1960s concert at Bowdoin College [53.49] and his liner notes to P. Seeger 1993 discuss his approach to college concerts in some detail.) Students learned to play guitars, banjos, and other instruments and used the increasing number of LP records and music magazines and books to study technique and to learn words. This new enthusiasm for traditional music had several distinct venues.

Washington Square Park, in Manhattan, New York City was a meeting place for budding musicians in the 1960s. *The Village*, a neighborhood in New York City surrounding Washington Square Park, had long been associated with creative bohemians. It was a neighborhood of small coffee houses and nightclubs. It had stores featuring folk song books and instruments such as Izzy Young's Folklore Center. Washington Square itself became known as a gathering place for musicians who would jam together for hours on end on Sundays and go on to the clubs in the evening.

Music festivals were another important venue. Short gatherings of musicians performing for audiences have a long history in the United States [53.50], but they became an especially important venue for the folk revival in the 1960s. The most important of the folk festivals in the 1960s was the Newport Folk Festival. Conceived by George Wein and a board including Theodore Bikel, Oscar Brand, Pete Seeger and Albert Grossman, the festival drew large crowds by inviting popular folk revival musicians and then enriching the crowd's experience by also bringing more *traditional* or local artists and introducing their music to new audiences. The Festival also featured workshops and opportunities to talk with and learn from the participants. One of its most important policies was to treat all the artists alike: they all received the same performance fees for their participation, whether they were selling thousands of recordings or had sold a few hundred thirty years earlier and were coming out of retirement to showcase their skills at the Festival. The festivals also gave artists a chance to get to know one another and to play together – an important feature of most festivals. Representatives of record labels were there as well. Newport was famous for its role in the careers of Joan Baez and Bob Dylan, who went on to great commercial success and also for Cajun musician Dewey Balfa who found that his popularity at Newport changed the image of Cajun music in Louisiana and could build on that opportunity for cultural projects of his own.

Summer camps are often overlooked, but have been an important venue for introducing children to group singing. On the east coast of the United States there has been a long tradition of sending children away from the

cities to spend one or more weeks in the countryside playing sports, hiking, and (almost everywhere) singing songs. In 2014 there were nearly twelve thousand summer camps of all kinds that were attended by nearly eleven million children and adults [53.51]. The music at these camps varies, but almost everywhere children learn a distinctive camp-specific repertoire they remember most of their lives. In the 1940s some camps were run by unions, and their songs include socialist anthems. In the 1950s and 1960s, college students who were learning folk music took jobs teaching music at many summer camps where they introduced younger children to their favorite musicians and songs [53.52]. Summer camps have had a large impact on the music that children sing, and also on the training of song leaders and musicians [53.40].

In spite of these alternative, fairly noncommercial venues for performers, the blacklist ruined the careers of many fine people and created a toxic environment for the performance of protest songs. This slowly changed in the 1960s, partly because a younger generation of songwriters who had never been affiliated in any way with the Communist Party began to write their own songs – among them Phil Ochs, Tom Paxton, Bob Dylan, Jim Collier – and other groups began to sing protest songs again, like The Kingston trio (*Where Have All the Flowers Gone*), Peter, Paul, and Mary (*If I had a Hammer*), Joan Baez, and others. Although vocal quality changed, most of these musicians sang in fairly natural voices (not bel canto and with little vibrato) and played guitar or banjo either solo or in a group. Many of them continued to perform for decades, but other musicians innovated new styles to express their protest and opposition to the status quo – among them electrified bands playing rock, punk, and other genres. (The term *folk music* in the United States today usually refers to acoustic music performed by a singer-songwriter accompanied by a stringed instrument. The phrase has less to do with an affiliation with vernacular styles than with identifying it as distinct from rock, jazz, heavy metal, and other genres.)

Two of the most famous, and most popular, musicians to emerge partly through their performances at Newport Folk Festival were Joan Baez and Bob Dylan. Joan Baez, who grew up in a pacifist Quaker household of a university professor, sang a wide repertoire of old ballads, songs composed by others, and songs of protest and struggle in a beautiful, clear voice. Although she did write some songs of her own, her most riveting performances were interpretations of songs by others. Her performances at the 1959 Newport Folk Festival and in local clubs led to a contract with Vanguard Records that year. Baez's Quaker background and political sympathies led her to oppose war and injustice throughout her career. She made a lifelong commitment to using music as part of a protest against wars and injustice. In 1964 she cofounded the Institute for the Study of Nonviolence and was arrested for protesting the induction of soldiers in California. Joan Baez has sung for many social causes – antiwar, civil rights, opposition to the death penalty, gay and lesbian rights, and poverty – and participated in many public events during her entire career, including a performance at Occupy Wall Street and another in the White House for President Obama.

Bob Dylan (born Robert Alan Zimmerman) arrived in New York City in 1963 from Minnesota, well versed in the songs from Harry Smith's *Anthology of American Folk Music* as well as contemporary performers, as is evident from the eloquent first volume of his *Chronicles* [53.53]. He admired Woody Guthrie, visited him in the hospital, and became a *Woody Guthrie Jukebox* and, like Guthrie, became a brilliant and prolific songwriter. Dylan's first album was mostly covers of earlier songs but included two original compositions. After this Dylan mostly performed his own songs, driven by his poetic gifts and dedication to personal discovery. Dylan wrote some of the most iconic and popular songs of the movements of protest and struggle, among them *Blowing in the Wind*, *Hard Rain's Gonna Fall* and *The Times They Are a-Changing*. His restless creativity led him to move beyond folk music in the mid-1960s and to explore the musical potentials of rock, blues, country, and other genres. There is a very large literature about Bob Dylan, and this is not the place to enter the many debates that characterize it. His early protest songs endured through performances by other singers long after he stopped performing them.

The critically important thing about the folk music revival of the 1960s was that musicians could make much more money through their recordings and live performances than had previously been possible. Many musicians had some protest music in their repertoire, but few musicians of any generation sang only music of protest. Even the Almanac Singers recorded folk songs as well as Union and antiwar songs, and this was true of most later performers. Like love songs, songs that describe how hard life is can be sung almost any time; songs of protest tend to appear a specific times and aimed at specific things, such as abolishing nuclear weapons (1950s) or ending the Vietnam War (1960s). Many heated debates about *authenticity* and *selling out* to commercial interests appeared in the pages of *Broadside* and *Sing Out!* Magazine during that period and were extensively debated by fans and musicians like. Issues of copyright and attribution arose, and some of them affected the recording process. This was a very different period than

the 1940s when the Almanac Singers composed collectively and actively sought to perform for union meetings.

As the musical potential of electric instruments became apparent, some musicians used the new timbres and sensibilities for new kinds of protest music. Many rock musicians have also written and performed music of social commentary and been critical of political trends in the United States. One of the most famous and consistent of these is Bruce Springsteen, whose working-class roots and expressive song-writing at times expresses a deep empathy with and outrage about the struggles of workers, veterans, and the terrible results of economic depression. Like Guthrie's youth in dust-bowl Oklahoma, Springsteen's youth growing up in New Jersey marks some of his most powerful music. Garman writes *perhaps more than any contemporary popular artist, Springsteen has kept his eyes fixed firmly on the dirty ways of the world* [53.36, p. 251]. Springsteen has performed for quite a few different causes, and acknowledges his debt to Woody Guthrie and songwriters who came before him. Rock music is a huge field, of course, and many bands espouse racist right-wing opinions and use recordings to recruit supporters and spread their ideas own as a means of recruitment and affirmation [53.54]. (I could have written an entirely different essay that focused on the music of right-wing politics in the United States, but I know much less about it and as far as I know it has been far less researched. It was shaped by some of the same historical traditions and social processes as left-wing music, but musicians frequently used different musical genres for its expression.)

Woody Guthrie, Pete Seeger, and Bruce Springsteen all came together at a memorable moment in an outdoor concert in Washington DC on January 19th, 2009 as part of the inauguration events of the first African-American President of the United States, Barack Hussein Obama. On a cold afternoon they, along with Pete Seeger's grandson Tao Rodriguez Seeger and a school chorus, led a huge crowd in singing Guthrie's best known song, *This Land is Your Land*. They not only sang the well-known celebratory verses but also two verses Guthrie wrote that are rarely included in school books – verses about poverty and the excesses of private property. The truly political nature of Guthries' composition was highlighted by two of the best known singer-songwriters and *people's poets* who were strongly influenced by Guthrie and the way he wrote and used songs. Thousands of mobile phones documented their performance and sent it to people all over the world. In a country with a long tradition of enslaving African peoples and a recent history of discrimination, the election of President Obama was a moment when music could celebrate, commemorate, and affirm its active participation in the social processes of the United States. In the words of the last verse: *Nobody living can ever stop me as I go walking that freedom highway. Nobody living can make me turn back; this land was made for you and me*.

53.9 Conclusion

For most of the 20th century, music of protest and struggle in the United States had a particular musical and narrative style as well as a few characteristic performance practices. This can be traced to the Freedom Singers in the 1950s and the Almanac Singers in the 1940s and then further back to African-American musicians, labor organizers, and songwriters from the mines, cotton mills, and farms of the Southern US. In addition to those influences, a long history of protest music in the United States contributed to the 20th-century style. The music and the performers were shaped by Walt Whitman, by international and national political movements like the Communist Party, and by the vernacular singing styles of the southeastern US. Some of the performers were certainly exemplars of Walt Whitman's people's poet. Their singing style, their conviction that music could influence politics, their compositions, and their courage were an important part of the music of 20th century and continue to influence some strands of American music today. Twentieth-century political music was also shaped by the passion and talents of specific people at particular moments. Among these were the Lomaxes and the Seegers, who began their collaboration in the 1930s. Through their passion for vernacular music and their many different activities they had a profound influence on the music of the second half of the 20th century. But there were many other influential figures as well. The music they performed, encouraged, recorded, or studied was enriched by their work, their teaching, and by those who learned from them and contributed to music of struggle, protest, criticism, and hope that continues today in other forms.

Protest marches during the past fifteen years have been more often animated by group chants than by song. The winning unions (there aren't many – most unions are losing members) are not employing music as much as other organizing tools. Poets of protest are far more apt to use rap and rhythmic speech than melodic

verses – though there are of course many fine exceptions. Songs of protest and struggle are sung in many different languages as well, as they probably always have been. Many members of the general public move to their own soundtracks, hosted on personal electronic devices, rather than to collective music. But there is a lot to protest about in the United States and the centuries-long traditions of using music and speech to protest and to try to effect change will continue to stimulate activists in the future.

About the Authors

Jakob Abeßer

Fraunhofer IDMT
Ilmenau, Germany
jakob.abesser@idmt.fraunhofer.de

Chapter F.41

Jakob Abeßer holds a degree in Computer Engineering (Dipl.-Ing.) from Ilmenau University of Technology. He is a postdoctoral researcher in the Semantic Music Technologies Group at Fraunhofer IDMT and obtained a PhD degree (Dr.-Ing.) in Media Technology from Ilmenau University of Technology in 2014. His research fields include automatic music transcription, symbolic music analysis, machine learning, and music instrument recognition.

Judit Angster

Fraunhofer Institute of Building Physics (IBP)
Acoustics
Stuttgart, Germany
judit.angster@ibp.fraunhofer.de

Chapter A.8

Judit Angster graduated in Physics at Eötvös University, receiving her PhD in 1991. Since 1992, she has held the position of scientist at Fraunhofer IBP in Stuttgart, where she is Head of the Musical Acoustics/Photoacoustics Research Group. She is coordinator of several European pipe organ acoustics research projects and President of the Technical Committee of Musical Acoustics (Germany, since 2008).

Simha Arom

Paris, France
simha.arom@gmail.com

Chapter G.49

Simha Arom is Emeritus Research Director of the French National Scientific Research Center (CNRS). His work deals with the systematic features of music in the polyphony of Central Africa and Georgia, as well as the temporal organization, modeling, and cognitive aspects of oral tradition music. He holds the *CNRS Silver Medal* and many International awards.

Rolf Bader Chapter A.10 For biographical profile, please see the section "About the Editor".

Ana M. Barbancho

Universidad de Málaga
ATIC Research Group, Dep. Ingeniería de Comunicaciones, ETSI Telecomunicación
Malaga, Spain
abp@ic.uma.es

Chapter F.42

Ana M. Barbancho holds a Telecommunications Engineering and PhD degree from the University of Málaga (UMA; 2000 and 2006, respectively), and a degree in Solfeo Teaching from Málaga Conservatoire of Music (2001). Since 2000, she has been with the Department of Communications Engineering, UMA. Her research interests include musical acoustics, digital signal processing, new educational methods, and mobile communications.

Isabel Barbancho

Universidad de Málaga
ATIC Research Group, Dep. Ingeniería de Comunicaciones, ETSI Telecomunicación
Malaga, Spain
ibp@ic.uma.es

Chapters F.42, F.45

Isabel Barbancho received her Telecommunications Engineering and PhD degrees from the University of Malaga (UMA; 1993 and 1998, respectively), and a degree in Piano Teaching from the Malaga Conservatoire of Music (1994). She is currently a Professor at the Department of Communications Engineering, UMA. Her research interests include musical acoustics, signal processing, multimedia applications, audio content analysis, and serious games.

Juan Pablo Bello

New York University
New York, USA
jpbello@nyu.edu

Chapter F.39

Juan Pablo Bello is Associate Professor of Music Technology and Electrical & Computer Engineering at New York University. He studied Electronic Engineering in Venezuela and the UK, specializing in signal processing, machine listening, and music information retrieval, topics in which he teaches and publishes regularly. He is recipient of an NSF CAREER award and a Fulbright fellowship.

R. Bader (Ed.), *Springer Handbook of Systematic Musicology*, https://doi.org/10.1007/978-3-662-55004-5

Stefan Bilbao

University of Edinburgh
Acoustics and Audio Group
Edinburgh, UK
s.bilbao@ed.ac.uk

Chapter B.19

Stefan Bilbao (BA Physics, Harvard, 1992; MSc, PhD Electrical Engineering, Stanford, 1996 and 2001, respectively) is currently a reader in the Acoustics and Audio Group at the University of Edinburgh, and was previously a lecturer at the Sonic Arts Research Centre, at Queen's University Belfast, and a research associate at the Stanford Space Telecommunications and Radioscience Laboratories.

David Borgo

University of California San Diego
La Jolla, USA
dborgo@ucsd.edu

Chapter G.52

David Borgo is Professor of Music and Integrative Studies at the University of California San Diego. He authored a book that won the Alan P. Merriam Prize in 2006 from the Society for Ethnomusicology. As a saxophonist, David has toured internationally and has released eight CDs and one DVD of original music.

Jonas Braasch

Rensselaer Polytechnic Institute
Troy, USA
braasj@rpi.edu

Chapter B.14

Jonas Braasch received a Master's Degree in Physics from the Technical University of Dortmund (1998), and two doctoral degrees from the University of Bochum in Electrical Engineering and Information Technology (2001) and Musicology (2004). He joined Rensselaer Polytechnic Institute in 2006 and is Associate Professor in the School of Architecture and Director of the Center for Cognition, Communication, and Culture.

Elvira Brattico

Aarhus University
Department of Clinical Medicine
Aarhus, Denmark
elvira.brattico@clin.au.dk

Chapter C.22

Elvira Brattico (PhD in Psychology, University of Helsinki, 2007) is Full Professor of Neuroscience, Music, and Aesthetics at the Center for Music in the Brain (MIB), Department of Clinical Medicine, Aarhus University and Royal Academy of Music, Aarhus/Aalborg, Denmark. Her interests cover auditory neuroscience, neuroaesthetics, and brain plasticity. She has published more than 100 papers and 10 book chapters.

Estefanía Cano

Fraunhofer IDMT
Ilmenau, Germany
cano@idmt.fraunhofer.de

Chapter F.41

Estefanía Cano holds degrees in Electronic Engineering (BSc), Music-Saxophone Performance (BA), Music Engineering (MSc), and Media Technology (Dr.-Ing.). In 2009, Estefanía joined the Fraunhofer Institute for Digital Media Technology IDMT, where she currently works as a postdoctoral researcher on various music information retrieval topics such as sound source separation, audio matching, automatic music transcription, and music education.

Amin Chaachoo

Tetouan-Asmir Center
Tetuán, Morocco
chaachooamin@gmail.com

Chapter F.43

Amin Chaachoo is a musician and musicologist, founder and director of the Tetouan-Asmir Center for Musicological Research and Preservation of the Musical Heritage and the first violin soloist of the Orchestra of the Tetouan Conservatory. He has authored two books that are considered as inflection points in the development of Arab-Andalusian music.

Marshall Chasin

Musicians' Clinics of Canada
Toronto, Canada
marshall.chasin@rogers.com

Chapter F.40

Dr. Marshall Chasin is an audiologist and the Director of Auditory Research at the Musicians' Clinics of Canada, Adjunct Professor at the University of Toronto (in Linguistics), and Associate Professor in the School of Communication Disorders and Sciences at the Western University. He is the author of over 200 articles and 7 books.

Jesús Corral García

Universidad de Málaga
Departamento de Ingeniería de Comunicaciones, ETSI Telecomunicación
Malaga, Spain
jcorral@ic.uma.es

Chapter F.45

Jesús Corral García received his MSc degree in Telecommunication Engineering at Universidad de Málaga (UMA), Spain in 2014. He has been a researcher of the Application of Information and Communications Technologies (ATIC) Research Group at the Department of Ingeniería de Comunicaciones (IC) of UMA since 2015. His research is focused on interactive audio file formats and speech recognition and its applications.

Lola L. Cuddy

Queen's University
Dept. of Psychology
Kingston, Canada
lola.cuddy@queensu.ca

Chapter C.23

Lola L. Cuddy is Professor Emerita, Department of Psychology, Queen's University in Kingston, Ontario, Director of the Music Cognition Laboratory, and general editor of *Music Perception.* Research interests include representation of tonal hierarchies, implicit learning of musical structures, and musical memory and dementia. In 2015, she received the life time achievement award from the Society of Music Perception and Cognition.

Phillippe Depalle

McGill University
Schulich School of Music
Montreal, Canada
philippe.depalle@mcgill.ca

Chapter B.17

Philippe Depalle is Associate Professor of Music Technology in the Schulich School of Music, McGill University. He received MS and PhD degrees in Applied Acoustics from the Université du Mans, Le Mans, France, in 1984 and 1991, respectively. His research interests include sound synthesis, sound processing, sound analysis, simulation of musical instruments, control of sound synthesis, and spectral analysis.

José-Miguel Díaz-Báñez

Escuela Superior de Ingenieros,
Universidad de Sevilla
Departamento de Matemática Aplicada II
Sevilla, Spain
dbanez@us.es

Chapter F.43

José-Miguel Díaz-Báñez received his PhD in Mathematics in 1998 and serves as Professor of Applied Mathematics at the University of Seville. His primary research area is computational geometry and optimization, mainly applied to problems in aerial robotics and music technology. He has authored more than 200 publications, including 53 journal papers. He is the coordinator of the COFLA Project (www.cofla-project.com).

Christian Dittmar

International Audio Laboratories Erlangen
Erlangen, Germany
christian.dittmar@audiolabs-erlangen.de

Chapter F.41

Christian Dittmar studied Electrical Engineering at Jena University of Applied Sciences and after graduation (2003) joined the Fraunhofer Institute for Digital Media Technology (Ilmenau). He is CEO and co-founder of Songquito UG (since 2012), a start-up company responsible for marketing the music education game Songs2See. He has been pursuing his PhD thesis at the International Audio Laboratories Erlangen since 2014.

Peter Driessen

University of Victoria
Dept. of Electrical and Computer Engineering
Victoria, Canada
peter@ece.uvic.ca

Chapter F.46

Peter Driessen is a Professor in Engineering with cross-appointments in Music and Computer Science. His teaching and research interests include music technology, sound recording, audio signal processing, and multimedia. He has over 100 publications and 14 patents, and holds research funding from NSERC, SSHRC, and Canada Council for the Arts.

Zhiyao Duan

University of Rochester
Dept. of Electrical and Computer Engineering
Rochester, USA
zhiyao.duan@rochester.edu

Chapter B.15

Zhiyao Duan is an Assistant Professor in the Department of Electrical and Computer Engineering at the University of Rochester. He received his PhD in Computer Science from Northwestern University in 2013. His research interest is in the area of computer audition, i.e., designing computational systems that are capable of analyzing and processing sounds, including music, speech, and environmental sounds.

Tuomas Eerola

Durham University
Dept. of Music
Durham, UK
tuomas.eerola@durham.ac.uk

Chapter C.29

Tuomas Eerola received his MA and PhD degrees from the University of Jyväskylä, Finland, in 1997 and 2003. He is a Professor of Music Cognition at Durham University, UK. His research interest lies within the field of music cognition and music psychology, including musical similarity, melodic expectations, perception of rhythm and timbre, and induction and perception of emotions.

Ricardo Eichmann

Deutsches Archäologisches Institut
Orient-Abteilung
Berlin, Germany
ricardo.eichmann@dainst.de

Chapter G.51

Ricardo Eichmann, Director of the Orient Department of the German Archaeological Institute, is a Near Eastern archaeologist. He received his Dr. phil. from Ruprecht Karls University Heidelberg in 1984 and was a Professor of Near Eastern archaeology at Eberhard Karls University Tübingen in 1995/1996. Besides archaeological field work, he has been co-organizing international conferences on music archaeology since 2000.

Benoit Fabre

Sorbonne Universités, UPMC Univ Paris 06
LAM – Institut d'Alembert
Paris, France
benoit.fabre@upmc.fr

Chapter A.7

Benoît Fabre is currently a Professor at University Pierre & Marie Curie, in Paris, France. He was trained both in Music (Hochschule für Musik in Freiburg, Germany) and Acoustics (PhD at Université du Maine, France). Since 1993, he has carried out research on the physics, the making, and the playing of musical instruments at LAM (Laboratory for Musical Acoustics).

Ichiro Fujinaga

McGill University
Schulich School of Music
Montreal, Canada
ichiro.fujinaga@mcgill.ca

Chapter B.16

Ichiro Fujinaga is an Associate Professor and the Associate Dean of Research and Administration at the Schulich School of Music at McGill University. He has degrees in Mathematics (BSc, Alberta), Music/Percussion (BMus, Alberta), Music Theory (MA, McGill), and Music Technology (PhD, McGill). He is the Principal Investigator of the Single Interface for Music Score Searching and Analysis (SIMSSA) project.

Aaron Gibbings

The University of Western Ontario, Natural Sciences Centre
The Brain and Mind Institute, Department of Psychology
London, Canada
jgrahn@uwo.ca

Chapter C.27

Aaron Gibbings is a PhD student in Dr. Jessica Grahn's Music and Neuroscience Lab at the Brain and Mind Institute. Aaron completed his BA in Psychology at King's University College, and his MSc at the University of Western Ontario. His doctoral research investigates how neural oscillations and entrainment affect beat and rhythm perception.

Joël Gilbert

Université du Maine – CNRS
Laboratoire d'Acoustique
Le Mans, France
joel.gilbert@univ-lemans.fr

Chapter A.7

Joël Gilbert is directeur de recherche CNRS, Laboratoire d'Acoustique de l'Université du Maine. He holds the Agrégation of Physics (ENS Fontenay aux Roses, 1985) and a PhD in Acoustics from Université du Maine (1991). Since 1991, he has carried out research on linear and nonlinear acoustics of internal flows, and physics of dynamical systems applied to reed and brass instruments.

Nicholas Giordano

Auburn University
Dept. of Physics
Auburn, USA
njg0003@auburn.edu

Chapter A.6

Nicholas Giordano joined Auburn University in 2013, where he is a Professor in the Department of Physics and Dean of the College of Sciences and Mathematics. Prior to Auburn, he was a member of the Faculty at Purdue University where he served as Head of the Department of Physics from 2007–2013. He has been an Alfred P. Sloan Foundation Fellow.

Rolf Inge Godøy

University of Olso
Dept. of Musicology
Oslo, Norway
r.i.godoy@imv.uio.no

Chapter E.35

Rolf Inge Godøy is Professor at the Department of Musicology, University of Oslo. His main interest is in phenomenological approaches to music theory, meaning taking our subjective experiences of music as the point of departure for music theory. This work has been expanded to include research on music-related body motion in performance and listening, using various conceptual and technological tools.

Emilia Gómez

Universitat Pempeu Fabra
Music Technology Group
Barcelona, Spain
emilia.gomez@upf.edu

Chapter F.43

Emilia Gómez is an Associate Professor (Serra-Húnter Fellow) at Universitat Pompeu Fabra in Barcelona. She holds a BEng (Universidad de Sevilla), MSc in Music Technology (IRCAM), and PhD in Computer Science (UPF). Her research deals with music information retrieval (MIR): pitch, melody, tonality, similarity, and semantics. She has published a large number of publications on these topics.

Francisco Gómez

Technical University of Madrid
Dept. of Applied Mathematics
Madrid, Spain
fmartin@etsisi.upm.es

Chapter F.43

Dr. Gómez obtained an MSc in Mathematics from Universidad Autónoma de Madrid. Later he obtained a PhD in Computer Science from the Technical University of Madrid. He does research on music information retrieval and computational music theory. His main areas of research are: measures of similarity, mathematical measures of rhythm complexity and syncopation, and automatic analysis of music traditions.

Jessica Grahn

The University of Western Ontario
The Brain and Mind Institute, Dept. of Psychology
London, Canada

Chapter C.27

Jessica Grahn is an Associate Professor at the Brain and Mind Institute and Department of Psychology at the University of Western Ontario (Western). She has degrees in Neuroscience and Piano Performance from Northwestern University and a PhD from Cambridge, England, in the Neuroscience of Music. She specializes in rhythm, movement, and cognition.

Sascha Grollmisch

Fraunhofer IDMT
Ilmenau, Germany
goh@idmt.fraunhofer.de

Chapter F.41

Sascha Grollmisch holds a degree in Media Technology Engineering (Dipl.-Ing.) from Ilmenau University of Technology. He is a software developer and researcher at the Semantic Music Technologies Group at Fraunhofer IDMT and CTO and co-founder of Songquito UG. His main research field is automatic music transcription and gamification of music education.

Simon Grondin

Université Laval
École de psychologie
Québec, Canada
simon.grondin@psy.ulaval.ca

Chapter C.21

Simon Grondin is a Professor of Psychology at Université Laval (Québec). His research interests are mainly focused on timing and time perception, rhythm, psychological time, psychophysics, cognitive neurosciences, and the relative age effect in sports. He is a former editor of the Canadian Journal of Experimental Psychology (2006–2009) and a former associate editor of Attention, Perception and Psychophysics (2006–2015).

Peter Grosche

Huawei Technologies Duesseldorf GmbH
München, Germany
peter.grosche@huawei.com

Chapter F.39

Peter Grosche studied Electrical Engineering and Information Technology at the Technical University of Munich (TUM) and obtained a PhD degree in Computer Science from Saarland University for his work in the field of music signal processing and music information retrieval. Currently, he is working on various research topics in audio signal processing at Huawei European Research Center in Munich.

Brian Hamilton

University of Edinburgh
Acoustics and Audio Group
Edinburgh, UK
b.hamilton-2@sms.ed.ac.uk

Chapter B.19

Brian Hamilton received BEng (Hons) and MEng degrees in Electrical Engineering from McGill University in Montreal, QC, Canada, in 2009 and 2012, respectively. He is currently a postdoctoral research associate in the Acoustics and Audio Group at the University of Edinburgh. His focus of research is finite difference and finite volume methods for 3D room acoustics simulations.

Andrew Hankinson

University of Oxford
Bodleian Libraries
Oxford, UK
andrew.hankinson@bodleian.ox.ac.uk

Chapter B.16

Andrew Hankinson received his PhD from McGill University in 2014. He is currently a Senior Software Engineer at the Bodleian Libraries, University of Oxford. His research interests focus on tools, technologies, and best-practices for building large-scale document image recognition systems for libraries, with a particular focus on optical music recognition.

Reginald Harrison

University of Edinburgh
Acoustics and Audio Group
Edinburgh, UK
s0916351@sms.ed.ac.uk

Chapter B.19

Reginald L. Harrison (BSc Physics and Music, University of Edinburgh, 2013) is currently a PhD student in the Acoustics and Audio Group at the University of Edinburgh. His research interests include time domain modelling of brass instruments for sound synthesis.

Emi Hasuo

Tokyo Denki University
School of Information Environment
Chiba, Japan

Chapter C.21

Emi Hasuo received her Bachelor's degree from Kunitachi College of Music in 2006, and her Master's and PhD degrees from Kyushu University in 2008 and 2011, respectively. She worked at Laval University as a postdoctoral fellow and is currently a research fellow of JSPS. Her research focuses mainly on understanding the basic mechanisms of time and rhythm perception.

Avraham Hirschberg

Veldhoven, The Netherlands

Chapter A.7

Avraham Hirschberg is Emeritus Professor at Technische Universiteit Eindhoven (TU/e) and Universiteit Twente. He holds an MSc from TUDelft and a PhD from TU/e on Plasma Physics (1981). He researched the thermodynamics of asphaltenes from 1981–1985 (Shell Research). From 1985 on, research on aeroacoustics of internal flows including pulse tubes, microperforated plates, human speech production, and wind instruments among others.

Neil S. Hockley

Bernafon AG
Bern, Switzerland
neho@bernafon.com

Chapter F.40

Neil S. Hockley is a Senior Audiologist in research and development at Bernafon AG in Bern, Switzerland. Prior to joining Bernafon in 2001, he worked concurrently in clinical and academic settings in the Niagara region of Ontario (Canada) (1994–2001). One of his professional interests is to improve hearing aid technology for amateur and professional musicians.

Alexander Refsum Jensenius

University of Oslo
Dept. of Musicology
Oslo, Norway
a.r.jensenius@imv.uio.no

Chapter E.38

Alexander Refsum Jensenius (BA, MA, MSc, PhD) is a music researcher and research musician working in the fields of embodied music cognition and new interfaces for musical expression. He studied at Oslo, Chalmers, UC Berkeley and McGill, and is working as an Associate Professor of Music Technology at the Department of Musicology, University of Oslo.

Wilfried Kausel

University of Music and Performing Arts, Vienna
Dept. of Musical Acoustics
Vienna, Austria
kausel@mdw.ac.at

Chapters A.2, A.3

Wilfried Kausel has been the Head of the Department of Music Acoustics at the University of Music and Performing Arts Vienna since 2010, becoming a full Professor in 2015. He received his tenure as an Associate Professor in 2003 and his PhD in 1999. He is a Fellow of the ASA and a member of technical committees in musical acoustics.

Christian Kehling

Neways Technologies
Erfurt, Germany
christian@k-ling.de

Chapter F.41

Christian Kehling is a Media Technology Engineer and passionate musician. He graduated in 2014 at the Ilmenau University of Technology. His diploma work dealt with instrument-specific coding with a strong focus on automated music transcription, semantic audio analysis, and instrument synthesis. Currently he is working as a research and development engineer and software developer for spatial audio systems.

Peter E. Keller

Western Sydney University
MARCS Institute for Brain, Behaviour and Development
Penrith, Australia
p.keller@uws.edu.au

Chapter C.28

Professor Peter Keller holds degrees in Music and Psychology from the University of New South Wales in Australia. Peter is leader of the 'Music Cognition and Action' research program in the MARCS Institute for Brain, Behaviour and Development at Western Sydney University. He conducts research aimed at understanding the behavioral and brain bases of human interaction in musical contexts.

Stefan Koelsch

University of Bergen
Bergen, Norway
koelsch@cbs.mpg.de

Chapter C.24

Stefan Koelsch is Professor for Biological Psychology and Music Psychology at the University of Bergen (Norway). He has Masters degrees in Music, Psychology and Sociology, and did his PhD and Habilitation at the Max Planck Institute for Cognitive Neuroscience, where he also led the Independent Junior Research Group "Neurocognition of Music" after being a postdoctoral fellow at Harvard Medical School.

Nadine Kroher

Escuela Superior de Ingenieros,
Universidad de Sevilla
Departamento de Matemática Aplicada II
Sevilla, Spain
nkroher@us.es

Chapter F.43

Nadine Kroher received her Audio Engineering degree from the University of Technology and the University of Music and Dramatic Arts Graz, Austria. She obtained an MSc in Sound and Music Computing at Universitat Pompeu Fabra. Currently, she is a PhD candidate at the University of Seville, where she works on automatic transcription and computational analysis of Flamenco music.

Panos Kudumakis

Queen Mary University of London
School of Electronic Engineering and Computer Science
London, UK
panos.kudumakis@eecs.qmul.ac.uk

Chapter F.45

Panos Kudumakis holds a PhD in DSP from King's College London. His research interests include music and media standardization. He was head of DRM at EMI-Central Research Labs before appointment in 2007 as Research Manager at qMedia, Queen Mary University of London. He currently serves as Head of the UK delegation of ISO/IEC MPEG committee, which he joined in 1998.

Tsuyoshi Kuroda

Shizuoka University
Faculty of Informatics
Hamamatsu, Japan
tkuroda@inf.shizuoka.ac.jp

Chapter C.21

Tsuyoshi Kuroda received his PhD in Design from Kyushu University, Fukuoka, Japan in 2010, and is currently working as a postdoctoral fellow in the Cognitive and Brain Science Laboratory, Shizuoka University, Hamamatsu, Japan. His research interests include auditory organization and temporal processing in perception and motor action. He has authored publications in scientific journals such as JEP:HPP and AP&P.

Marc Leman

Ghent University
IPEM – Musicology, Department of Art,
Music and Theatre Sciences
Ghent, Belgium
marc.leman@ugent.be

Chapters E.34, E.37

Marc Leman is Methusalem Research Professor in Systematic Musicology and Director of IPEM at Ghent University. He works on the epistemological and methodological foundations of embodied music interactions. He is Laureate of the FWO Excellence Award "Ernest-John Solvay".

Alexander Lerch

Georgia Institute of Technology
Center for Music Technology
Atlanta, USA
alexander.lerch@gatech.edu

Chapter F.44

Alexander Lerch studied Electrical Engineering at the TU Berlin and Tonmeister at the UdK Berlin. He received his PhD from the TU Berlin. In 2001, he co-founded the company zplane.development – a research-driven technology provider for the music industry. In 2013, he joined the Georgia Tech Center for Music Technology, where he works on music information retrieval and intelligent audio software.

Micheline Lesaffre

Ghent University
IPEM – Musicology, Department of Art,
Music and Theatre Sciences
Ghent, Belgium
micheline.lesaffre@ugent.be

Chapter E.36

Dr. Micheline Lesaffre is a researcher in systematic musicology at IPEM, the music research institute of Ghent University. Her research has a focus on user-oriented analysis, the usability of music tools, user experiences, and cross-disciplinary approaches. Recently, this work has been expanded to the domain of health and wellbeing, with a focus on person-centered approaches to embodied music-based interaction.

Jukka Louhivuori

University of Jyväskylä
Department of Music, Art and Culture
Studies
Jyväskylä, Finland
jukka.louhivuori@jyu.fi

Chapter G.47

Prof. Louhivuori has held the post of President of the Finnish Society for Music Education (FiSME), the Finnish Society for Musicology, and the European Society for the Cognitive Sciences of Music (ESCOM). He is specialized in cross-cultural music cognition, ethnomusicology, and music and well-being. Recently, he has developed new musical interfaces for music pedagogical purposes.

Håkan Lundström

Lund University
Inter Arts Center
Lund, Sweden
hakan.lundstrom@kanslik.lu.se

Chapter G.50

Håkan Lundström is a Senior Professor at the Inter Arts Center, Malmö Faculty of Fine and Performing Arts, Lund University, Sweden. He is an ethnomusicologist who has worked on Kammu (Khmu) music, particularly singing traditions. He has conducted research in Japanese and Alaskan Native American music and has led a research program concerning documentation and revitalization of ethnic minority music.

Pieter-Jan Maes

Ghent University
IPEM – Musicology, Department of Art,
Music and Theatre Sciences
Ghent, Belgium
pieterjan.maes@ugent.be

Chapters E.34, E.37

Dr. Pieter-Jan Maes is working as postdoctoral researcher at IPEM, Ghent University. His research focuses on the role of body movement and auditory feedback in musical timing and entrainment. On the basis of empirical findings, he is developing the theory of embodied music cognition, as well as practical music applications.

András Miklós

Steinbeis Transfer Center Applied
Acoustics
Stuttgart, Germany
akustikoptik@t-online.de

Chapter A.8

András Miklós graduated in Physics at Eötvös University Budapest (Hungary), and received his PhD in 1990. From 1992–2005, he was a Senior Scientist at University Heidelberg. Since 2003, he has been a Director of the Steinbeis Transfer Center Applied Acoustics, and a scientific adviser at Fraunhofer IBP in Stuttgart. His main research fields are photoacoustics, photothermal phenomena, and musical acoustics.

Emilio Molina

Universidad de Málaga
Departamento de Ingeniería de Comunicaciones, ETSI Telecomunicación
Malaga, Spain
emm@ic.uma.es

Chapter F.42

Emilio Molina received his degree in Telecommunications Engineering from the University of Málaga in 2011, and his MSc in Sound and Music Computing from the Universitat Pompeu Fabra (Barcelona) in 2012. He then worked as a researcher at the ATIC Group (University of Málaga) in the field of singing voice analysis. Currently, he works as a research engineer for BMAT.

Thomas Moore

Rollins College
Dept. of Physics
Winter Park, USA
tmoore@rollins.edu

Chapter A.5

Thomas Moore is the Archibald Granville Bush Professor of Science and a Professor of Physics at Rollins College. His research interests lie in the physics of musical instruments and the application of optical methods to the study of vibrations. He is a Fellow of the Acoustical Society of America.

Joaquin Mora

Escuela Superior de Ingenieros,
Universidad de Sevilla
Departamento de Matemática Aplicada II
Sevilla, Spain
mora@us.es

Chapter F.43

Dr. Mora is a Professor at the University of Seville and in the Flamenco doctoral program. He has directed various doctoral theses, authored numerous articles, and given various talks on Flamenco and Spanish folk music. He is a member of the COFLA research group, where he works on computational analysis of Flamenco music.

Robert Mores

University of Applied Sciences
Faculty of Design, Media & Information
Hamburg, Germany
robert.mores@haw-hamburg.de

Chapter B.12

Robert Mores hold a Diploma in Electrical Engineering (1988) and a PhD in Computer Science (1994). From 1994 to 2001, he was with Philips Semiconductors. He holds some ten patents on in-vehicle communication systems. He is a Professor at the University of Applied Sciences Hamburg (since 2001), and teaches telecommunications and digital signal processing. His research focus is musical acoustics.

Andrew C. Morrison

Joliet Junior College
Dept. of Natural Sciences
Joliet, USA
amorriso@jjc.edu

Chapter A.9

Andrew Morrison is an Associate Professor of Physics at Joliet Junior College. He earned a BS in Physics from the University of Northern Iowa and a PhD in Physics from Northern Illinois University. He has taught at Illinois Wesleyan University, Northwestern University, and DePaul University. His research interests focus primarily on percussion acoustics, especially the Caribbean steelpan and related instruments.

Meinard Müller

International Audio Laboratories Erlangen
Erlangen, Germany
meinard.mueller@audiolabs-erlangen.de

Chapter F.39

Meinard Müller studied Mathematics and Computer Science at Bonn University, Germany. Since September 2012, he has held a Professorship for Semantic Audio Processing at the International Audio Laboratories Erlangen, Germany. His research interests include music processing, audio signal processing, and music information retrieval, which are also reflected in his recent textbook (Springer, www.music-processing.de).

Yoshitaka Nakajima

Kyushu University
Dept. of Human Science
Fukuoka, Japan
nakajima@design.kyushu-u.ac.jp

Chapter C.21

Yoshitaka Nakajima is a Distinguished Professor in the Faculty of Design, Kyushu University. He graduated in Psychology from the University of Tokyo in 1978, and received a PhD in Design at the Kyushu Institute of Design in 1999. His research fields include auditory perception, time perception, and language universals.

Tram Nguyen

The University of Western Ontario
The Brain and Mind Institute, Dept. of Psychology
London, Canada
tnguye95@uwo.ca

Chapter C.27

Tram Nguyen is currently a PhD student in the Music and Neuroscience Lab, directed by Dr. Jessica Grahn, at the University of Western Ontario's Brain and Mind Institute. Tram has completed BS and MSc degrees in Psychology at Western. Her doctoral research examines individual differences in beat perception and production, particularly between musicians and dancers.

Luc Nijs

Ghent University
IPEM – Musicology, Department of Art, Music and Theatre Sciences
Ghent, Belgium
luc.nijs@ugent.be

Chapters E.34, E.37

Luc Nijs is a postdoc at IPEM (Ghent University, BE), guest lecturer at the Royal Conservatory The Hague (NL), and clarinet teacher at "de Kunstbrug" (Ghent, BE). He holds a PhD in Arts Sciences and MA's in Music Performance (clarinet) and Philosophy. His research focuses on the musician–instrument relationship and on the role of movement in instrumental learning.

Giacomo Novembre

University College London
London, UK
giacomonovembre@gmail.com

Chapter C.28

Giacomo Novembre holds degrees in Cognitive Neuroscience (MSc, PhD) and Philosophy (BA). His research utilizes music as a model to explore the neurocognitive mechanisms that underpin action-perception coupling in the human brain. He has held lectureship and research associate positions at the MARCS Institute for Brain, Behaviour and Development (Western Sydney University, Australia) and at University College London.

Chiara Olcese

University of Ferrara
Dept. of Life Sciences and Biotechnology
Treviso, Italy
chiara.olcese@student.unife.it

Chapter C.22

Chiara Olcese holds a PhD in Biochemistry, Molecular Biology and Biotechnologies (2016). During her Master's studies she investigated sound waves' effects on human hormones and the mismatch negativity. Her postdoctoral research focuses on the molecular basis of Primary ciliary dyskinesia, using Next-generation sequencing and bioinformatics methods.

Bryan Pardo

Northwestern University
Ford Engineering Design Center
Evanston, USA
pardo@northwestern.edu

Chapter B.15

Bryan Pardo is an Associate Professor in the Northwestern University Department of Electrical Engineering and Computer Science. Prof. Pardo received an MMus in Jazz Studies in 2001 and a PhD in Computer Science in 2005, both from the University of Michigan. He has authored over 80 peer-reviewed publications and performs throughout the United States on saxophone and clarinet.

Marcus Pearce

Queen Mary University of London
School of Electronic Engineering and Computer Science
London, UK
marcus.pearce@qmul.ac.uk

Chapters C.25, C.26

Educated in Experimental Psychology at Oxford and Artificial Intelligence at Edinburgh, Marcus Pearce is Senior Lecturer in Sound and Music Processing at Queen Mary University of London. His research covers computational, psychological and neuroscientific aspects of music cognition, with a particular focus on dynamic, predictive processing of melodic, rhythmic and harmonic structure, and its impact on aesthetic experience of music.

Florian Pfeifle

University of Hamburg
Institute of Systematic Musicology
Hamburg, Germany
florian.pfeifle@uni-hamburg.de

Chapter B.20

Florian Pfeifle received his MA in Systematic Musicology and Electrical Engineering in 2010 and his PhD in 2014. His current research is concerned with real-time grand piano physical modeling on FPGAs. Additionally, he is interested in instrument acoustics, scientific computation, and jazz music research. Until recently, he worked as a musician/producer, being awarded gold records for two of his works.

Laurent Pugin

Swiss RISM Office
Bern, Switzerland
laurent.pugin@rism-ch.org

Chapter B.16

Laurent Pugin is trained both as a musicologist and a computer scientist. He obtained his PhD at the University of Geneva, Switzerland. He has been co-Director of the Swiss Office of the RISM (Répertoire International des Sources Musicales) since 2009. He is a member of the Board of the Music Encoding Initiative (MEI) and teaches Digital Humanities at the University of Bern.

Zafar Rafii

Gracenote
Emeryville, USA
zrafii@gracenote.com

Chapter B.15

Zafar Rafii received a PhD in Electrical Engineering and Computer Science from Northwestern University in 2014. He is currently a research engineer at Gracenote in the US. He also worked at Audionamix in France from 2007 to 2008. His research interests include source separation and audio identification for music signals.

Martin Rohrmeier

TU Dresden
Institute of Art and Music
Dresden, Germany
martin.rohrmeier@tu-dresden.de

Chapters C.25, C.26

Professor Martin Rohrmeier studied Philosophy, Musicology, and Mathematics at the University of Bonn. He continued with an MPhil and PhD in Empirical Musicology and Music Cognition at the University of Cambridge, under the supervision of Prof. Ian Cross. His main research interests are music perception and cognition, musical syntax, implicit learning, computational modelling, and cognitive links between music and language.

Carles Roig

Universidad de Málaga
ATIC Research Group, Dep. Ingeniería de Comunicaciones, ETSI Telecomunicación
Malaga, Spain
carles@ic.uma.es

Chapter F.42

Carles Roig received his degree in Telecommunication Engineering from Universidad Politécnica de Valencia in 2010, and his MSc in Sound and Music Computing from Universidad Pompeu Fabra (Barcelona) in 2011. Then, he worked as a researcher at ATIC Group (Universidad de Málaga) in the field of automatic composition of music. Currently, he is a PhD candidate at Universidad de Valladolid.

Thomas D. Rossing

Stanford University
Dept. of Music
Stanford, USA
rossing@ccrma.stanford.edu

Chapter A.9

Thomas Rossing received a BA from Luther College, and MS and PhD degrees in Physics from Iowa State University. He was Professor of Physics at St. Olaf College for 14 years. Since 1971, he has been a Professor of Physics at Northern Illinois University. He is presently a Visiting Professor of Music at Stanford University. His areas of research have included musical acoustics, psychoacoustics, speech and singing, and vibration analysis.

Mark Sandler

Queen Mary University of London
School of Electronic Engineering and Computer Science
London, UK
mark.sandler@qmul.ac.uk

Chapter F.45

Mark Sandler received his BSc and PhD degrees from the University of Essex, UK, in 1978 and 1984, respectively. He is a Professor of Signal Processing at Queen Mary University of London, London, UK, where he founded the Centre for Digital Music. He has published over 400 papers in journals and conferences and supervised over 30 PhD students.

Gary Scavone

McGill University
Music Research, Schulich School of Music
Montreal, Canada
gary@music.mcgill.ca

Chapter B.13

Dr. Gary Scavone is an Associate Professor of Music Technology at McGill University, where he directs the Computational Acoustic Modeling Laboratory (CAML). He received PhD and Master of Science degrees at the Center for Computer Research in Music and Acoustics (CCRMA) at Stanford University. His research includes acoustic modeling, analysis and synthesis of musical systems, and sound synthesis software development.

Albrecht Schneider

University of Hamburg
Institute of Systematic Musicology
Hamburg, Germany
aschneid@uni-hamburg.de

Chapters 1, D.30, D.31, D.32, D.33

Albrecht Schneider graduated from the University of Bonn. He worked as a Professor of Systematic Musicology in the Institute of Musicology, University of Hamburg (1981–2011). He also taught as Visiting Professor in the Department of Ethnomusicology and Systematic Musicology of UCLA. He is the author, co-author, editor, and co-editor of a number of books and many other works.

Katrin Schulze

Heidelberg University
Dept. of Clinical Psychology and Psychotherapy, Institute of Psychology
Heidelberg, Germany
katrin.schulze@psychologie.uni-heidelberg.de

Chapter C.24

Dr. Katrin Schulze is a research associate working at Heidelberg University, Germany. Her research interests include auditory memory and emotion regulation. She graduated in Psychology from Magdeburg University and finished her PhD at the Max Planck Institute for Human Cognitive and Brain Sciences/Leipzig University, Germany. Further stations include BIDMC/Harvard Medical School (US) and Claude Bernard University Lyon 1 (France).

Anthony Seeger

University of California Los Angeles (UCLA)
Dept. of Ethnomusicology
Annapolis, USA
aseeger@arts.ucla.edu

Chapter G.53

Anthony Seeger is an anthropologist, ethnomusicologist, audio-visual archivist, and musician. He is Distinguished Professor of Ethnomusicology, Emeritus, at UCLA and Director Emeritus of Smithsonian Folkways Recordings in Washington, DC. He is the author of three books, co-editor of three others, and has published over 120 other works. As a musician he was active during the US folk music revival.

Mohamed Sordo

University of Miami
Center for Computational Science
Coral Gables, USA
msordo@miami.edu

Chapter F.43

Mohamed Sordo is a postdoctoral researcher at the University of Miami, USA. He obtained his BEng, MSc, and PhD degrees at the Universitat Pompeu Fabra (Barcelona, Spain) in 2006, 2007, and 2012, respectively. Mohamed's research areas involve music text mining, music information retrieval, and machine learning. Mohamed has authored over 25 scientific articles in international journals and conferences.

Lorenzo J. Tardón

Universidad de Málaga
Departamento de Ingeniería de Comunicaciones, ETSI Telecomunicación
Malaga, Spain
lorenzo@ic.uma.es

Chapters F.42, F.45

Lorenzo J. Tardón holds a degree in Telecommunications Engineering (1995) and a PhD (1999). Since 1999, he has been with the Department of Communications Engineering, Universidad de Málaga. He is Head of the Application of Information and Communications Technologies (ATIC) Research Group. His research interests include serious games, audio signal processing, digital image processing, and pattern analysis and recognition.

Mari Tervaniemi

University of Helsinki
Cicero Learning and Cognitive Brain Research Unit
Helsinki, Finland
mari.tervaniemi@helsinki.fi

Chapter C.22

Research Director Mari Tervaniemi is a well-known expert in neurosciences of music. She has published over 150 empirical papers and reviews in peer-reviewed international journals. Her research topics cover auditory neurocognition, musical expertise, and music emotions. Moreover, she has been in a key position to initiate projects to determine the effectiveness of music therapy in stroke, depression, and dementia patients.

Leslie Tilley

Massachusetts Institute of Technology
Cambridge, USA
tilley@mit.edu

Chapter G.48

Leslie Tilley is an Ethnomusicologist who specializes in analytical approaches to world music, with particular focus on Bali, Indonesia. Her current research examines collaborative improvisation in the Balinese drum genre *kendang arja*, and seeks to discover the unspoken, unconscious constraints guiding improvisation. Leslie is an Assistant Professor of Music at Massachusetts Institute of Technology.

Alberto Torin

University of Edinburgh
Acoustics and Audio Group
Edinburgh, UK
s1164558@sms.ed.ac.uk

Chapter B.19

Alberto Torin (BA and MSc Physics, University of Padova, 2007 and 2011, respectively; PhD, Music, University of Edinburgh, 2016) is currently a postdoctoral research associate in the Acoustics and Audio Group at the University of Edinburgh. He is a member of the GMAAT project and his research topics include the numerical simulation of microphone components.

George Tzanetakis

University of Victoria
Dept. of Computer Science
Victoria, Canada
gtzan@cs.uvic.ca

Chapter F.46

George Tzanetakis is an Associate Professor in the Department of Computer Science with cross-listed appointments in ECE and Music at the University of Victoria. He is Canada Research Chair in Computer Analysis and Audio and Music. In 2011, he was Visiting Faculty at Google Research. His research focus is audio content analysis with a focus on music information retrieval.

Edith Van Dyck

Ghent University
IPEM – Musicology, Department of Art, Music and Theatre Sciences
Ghent, Belgium
edith.vandyck@ugent.be

Chapter E.34

Dr. Edith Van Dyck holds a PhD in Musicology from IPEM and currently works as a postdoctoral researcher at the same institute. Since 2009, she has been focusing on action-perception coupling in musical interaction and published several papers regarding the influence of music features and human emotions on music-induced movement (e.g., dance, running, and walking).

Doug Van Nort

York University
Computational Arts and Theatre & Performance Studies
Toronto, Canada
dvnt.sea@gmail.com

Chapter B.17

Doug Van Nort is Assistant Professor and Canada Research Chair in Digital Performance in the School of the Arts, Media, Performance & Design (AMPD) at York University. Van Nort holds degrees in Mathematics (MA), Electronic Arts (MFA), and Music Technology (PhD). His research integrates music, multimodal perception, improvisation, and computation. He is the founding director of DisPerSion Lab (York University).

Michael Vorländer

RWTH Aachen University
Institute of Technical Acoustics
Aachen, Germany
mvo@akustik.rwth-aachen.de

Chapter A.11

Michael Vorländer is a Professor at RWTH Aachen University, Germany. His research focus is auralization and acoustic virtual reality in its various applications in psychoacoustics, room and building acoustics, automotive and noise control. Michael Vorländer has published 1 book and 12 book chapters, 81 articles in peer-reviewed journals, more than 300 conference papers, and 17 plenary lectures at international conferences.

Chris Waltham

University of British Columbia
Dept. of Physics & Astronomy
Vancouver, Canada
cew@phas.ubc.ca

Chapter A.4

Before musical acoustics, Chris Waltham spent 20 years working on the Sudbury Neutrino Observatory project. In the last dozen years, he has worked on the acoustics of string instrument soundboxes, specializing in harps and qins. He is an amateur luthier, and has made several harps and violins, playing one of the latter in a Vancouver community orchestra.

Ron Weiss

Google Inc.
New York, USA
ronw@google.com

Chapter F.39

Ron Weiss is a software engineer at Google, where he has worked on content-based audio analysis, recommender systems for music, and noise robust speech recognition. Ron completed his PhD in Electrical Engineering at Columbia University in 2009. From 2009 to 2010, he was a postdoctoral researcher in the Music and Audio Research Laboratory at New York University.

Victoria Williamson

University of Sheffield
Sheffield, UK
v.williamson@sheffield.ac.uk

Chapter C.24

Dr. Victoria Williamson is the Vice Chancellor's Fellow for Music at the University of Sheffield, UK, and Director of the Music & Wellbeing research unit. This unit focuses on applied music psychology, the impact of music on everyday and extraordinary challenges to wellbeing. Dr. Williamson's special interest within this remit is the psychology of musical memory.

Shigeru Yoshikawa

Dazaifu, Japan
shig@lib.bbiq.jp

Chapter A.4

After graduating from the Physics Department of Nagoya University (1974), he began acoustical research on organ pipes. He worked for Technical R&D Institute of Defense Ministry in 1980 and investigated underwater organ pipes, while personally studying musical acoustics. He was a Professor of Musical Instrument Acoustics at the Graduate School of Design, Kyushu University from 1998 and retired in 2015.

Tim Ziemer

University of Hamburg
Institute of Systematic Musicology
Hamburg, Germany
tim.ziemer@uni-hamburg.de

Chapter B.18

Dr. Tim Ziemer is a musicologist working in applied psychoacoustics for wave field synthesis and music information retrieval at the University of Hamburg. His research interests include measurement, reconstruction, and perception of radiation characteristics of musical instruments. He is a freelance author for a computer magazine and has a background in music production, room and building acoustics, among other areas.
